We have suggested previously that the dihydropyridine (DHP) binding site on neuronal L-type voltage-sensitive Ca^{2+} channels (VSCC) may be a target site for i.v. anaesthetic agents[1]. It is not known if other binding sites on the L-type VSCC, such as verapamil or diltiazem sites, are also involved. However, Maze and colleagues reported that verapamil significantly augmented anaesthetic potency (see Hirota and Lambert[1 2]). As the verapamil binding site resides, together with the DHP binding site, on the α_1 subunit of the channel, we have examined if this site is a target for i.v. anaesthetic agents.

Materials and methods

Female Wistar rats (250–300 g) were stunned and then decapitated. The brain was removed rapidly, the cerebrocortex detached from its internal structures, and homogenized at 4 °C using a tissue Tearor (setting 5,5×30-s bursts) in Tris HCl 50 mmol litre^{-1}, pH 7.4. The homogenate was centrifuged at 18 000 *g* for 10 min and the pellet resuspended in Tris HCl buffer. This procedure was repeated three times. Membranes were frozen in aliquots at −40 °C.

All binding assays were performed in 1 ml volumes of Tris HCl buffer for 90 min at 20 °C using approximately 200 µg of cerebrocortical membrane protein. In order to determine if an i.v. anaesthetic agent interacts with the verapamil binding site on neuronal L-type VSCC, the binding site was labelled with [^{3}H]verapamil ([*N*-methyl-^{3}H]-verapamil hydrochloride, 60.8 Ci mmol^{-1}). Increasing concentrations of i.v. anaesthetic agents as unlabelled displacers were then added. Displacement of [^{3}H]verapamil binding by i.v. anaesthetic agents indicates that they are interacting at the same site as the radiolabel. A fixed concentration of [^{3}H]verapamil (0.2 nmol litre^{-1}) was displaced by the following unlabelled anaesthetics: thiopentone (n=6: 3×10^{-6}–10^{-3} mol litre^{-1}), pentobarbitone (n=6: 3×10^{-6}–10^{-3} mol litre^{-1}), ketamine (n=6: 10^{-4}–10^{-2} mol litre^{-1}), etomidate (n=6: 10^{-6}–3×10^{-4} mol litre^{-1}), propofol (n=6: 3×10^{-6}–10^{-3} mol litre^{-1}) and alphaxalone (n=6: 10^{-6}–3×10^{-4} mol litre^{-1}). Stock solutions were made as follows: thiopentone (100 mmol litre^{-1} stock in NaOH 0.1 mol litre^{-1}), pentobarbitone (50 mmol litre^{-1} stock in distilled water), propofol (100 mmol litre^{-1} stock in DMSO), alphaxalone (50 mmol litre^{-1} stock in DMSO), etomidate (50 mmol litre^{-1} stock in HCl 0.1 mol litre^{-1}) and ketamine (500 mmol litre^{-1} stock in distilled water). Appropriate solvent concentrations were added to control tubes. Non-specific binding was defined in the presence of excess (10^{-6} mol litre^{-1}) verapamil (25 mmol litre^{-1} stock in distilled water).

After incubation, each sample was filtered under vacuum through Whatman GF/B filters using a Brandell cell harvester to separate bound and free radioactivity. Filter retained (bound) radioactivity was extracted for at least 8 h in 4 ml of scintillation fluid and then estimated using a beta scintillation counter. The estimated radioactivity was quench corrected with an average [^{3}H] counting efficiency of 60.4%. The highest anaesthetic concentration used was usually limited by agent solubility.

The concentration of displacer producing 25% and 50% displacement of specific binding (IC_{25} and

Table 1 Effects of i.v. anaesthetic agents on $[^3H]$verapamil binding (mean (SEM), n=6. *Peak plasma concentration during anaesthesia (see Hirota and Lambert[1])

Agent	K_{25} (mmol litre^{-1})	K_{50} (mmol litre^{-1})	Plasma (μmol litre^{-1})*
Thiopentone	0.68 (0.14)	1.29 (0.19)	83
Pentobarbitone	1.22 (0.13)	4.86 (0.94)	155
Propofol	0.66 (0.10)	1.04 (0.08)	39
Etomidate	0.24 (0.03)	0.49 (0.07)	4.1
Ketamine	0.75 (0.04)	1.52 (0.13)	8.0
Alpaxalone	0.19 (0.02)	0.36 (0.06)	7.5

IC_{50}) was calculated by computer-assisted curve fitting (Graphpad-Prism) and corrected for the competing mass of $[^3H]$verapamil using a K_d of 94 nmol litre^{-1}[3], according to Cheng and Prusoff[4], to yield the affinity constants (K_{25} and K_{50}). All data are expressed as mean (SEM).

Results

All i.v. anaesthetics displaced specific $[^3H]$verapamil binding in a dose-dependent manner. K_{25} and K_{50} values are shown in table 1. These concentrations exceeded those seen during anaesthesia.

Discussion

Two studies[1,2] have suggested that L-type VSCC may be involved in the mechanism of general anaesthesia because L-type VSCC blockers enhanced anaesthetic potency. Previous work from our laboratory[1] indicated that DHP binding sites on neuronal L-type VSCC may be a target site for i.v. anaesthetic agents. We hypothesized that i.v. anaesthetic agents should interact with the verapamil binding site as we have shown previously an interaction with the DHP binding site. Both verapamil and DHP sites reside on the α_1 subunit of the channel, although at different structural motifs[5]. Our data clearly demonstrated that the verapamil binding site is not an important target for i.v. agents as the K_{25} (and K_{50}) exceeded the plasma concentration seen during anaesthesia (see Hirota and Lambert[1,2]). K_{25} values are quoted in addition to K_{50} values, as clinically relevant concentrations of many anaesthetic agents depress Ca^{2+} entry by 20–30%[2]. Collectively, our data suggest that a specific region of the L-channel may act as a target for i.v. agents.

However, verapamil has been reported to decrease the MAC for halothane in dogs and significantly augment the anaesthetic potency of dexmedetomidine or ketamine (see Hirota and Lambert[1,2]). Chikhale, Burton and Borchard[6] suggested that verapamil caused a significant increase in the permeability of the blood–brain barrier, although verapamil itself does not pass the blood–brain barrier. Therefore, this enhancement of anaesthetic potency may not be a direct interaction with the channel (consistent with our data) but may simply enhance agent delivery to the CNS target site(s).

In conclusion, these data indicate that i.v. anaesthetic agents are unable to interact with the verapamil binding site on L-type VSCC at clinically relevant concentrations.

Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils

J. HEINE, M. LEUWER, D. SCHEINICHEN, L. ARSENIEV, K. JAEGER AND S. PIEPENBROCK

Summary

Exposure of neutrophils to anaesthetic agents may alter their functional characteristics and in patients undergoing long-term sedation this may be clinically relevant. We have investigated the *in vitro* influence of propofol, thiopentone, methohexitone and midazolam on phorbol 12-myristate 13-acetate (PMA)-induced respiratory burst of neutrophils by the intracellular oxidative transformation of dihydrorhodamine-123 to the fluorescent dye rhodamine-123 via flow cytometry. We tested *in vitro* concentrations similar to sedating, anaesthetic, 10-fold sedating and 10-fold anaesthetic plasma concentrations. All drugs showed similar inhibition of respiratory burst at sedating concentrations (1–6%). At anaesthetic concentrations, propofol produced significantly higher mean inhibition (7.3%) compared with thiopentone (4.5%) and methohexitone (0.9%). At 10-fold anaesthetic concentrations inhibition of respiratory burst by propofol was almost complete (90.8%) and significantly higher than that by thiopentone (29.2%) and methohexitone (1.8%). Methohexitone and midazolam had only minimal effects at all concentrations. The effect of the solvent of propofol (10% Intralipid) was similar to that of propofol. Thus suppression of respiratory burst of neutrophils by propofol may be caused by this lipid carrier. (*Br. J. Anaesth.* 1996;**77**:387–392)

Key words

Anaesthetics I.v., propofol. Anaesthetics i.v., thiopentone. Anaesthetics i.v., methohexitone. Hypnotics benzodiazepine, midazolam. Measurement techniques, flow cytometry. Blood, neutrophils.

Blood neutrophils are one of the major cell populations acting against microbial infections. Alteration of neutrophil function by i.v. anaesthetics is currently under intensive laboratory investigation[1]. O'Donnell and colleagues found significant suppression of neutrophil polarization by propofol and thiopentone, which is a change in morphology as a response to a chemotactic stimulus[2]. Another group described a decrease in chemotaxis produced by propofol and its lipid carrier Intralipid after zymosan stimulation[3].

Another important aspect for bacterial killing is neutrophil respiratory burst. The respiratory burst enzyme in the plasma membrane of neutrophils catalyses the oxidation of NADPH which leads to the production of superoxide anion. This production of oxygen radicals is responsible for killing phagocytosed micro-organisms[4–6]. The importance of respiratory burst for defence of bacterial infections is evident in patients with chronic granulomatous disease, which is a congenital disturbance of respiratory burst enzyme activity. These young patients suffer from recurrent severe bacterial infections because their phagocytes are unable to produce superoxide anion, or at best produce only very low levels[7]. Thus it is possible that impairment of neutrophil respiratory burst by i.v. anaesthetics may be hazardous, especially for intensive care patients at risk.

Rothe, Oser and Valet have shown that oxygen radical production during respiratory burst can be quantified in real-time with multiparameter flow cytometry (MFC) using the dye dihydrorhodamine-123 (DHR) which reacts with free radical-derived oxidants to become the brightly green fluorescent rhodamine-123 (rho-123)[8]. MFC simultaneously assesses five variables per measured event: relative cell (particle) size, density (granularity) and three fluorescences, representing surface, intracellular or cell cycle characteristics. Compared with chemiluminescence, which estimates only non-specific oxygen radical generation, the methodology of this study has the advantage of assessing specific intracellular oxygen radical production by plasma membrane respiratory burst oxidase of a certain cell population such as neutrophils.

Thus we have evaluated if propofol, thiopentone, methohexitone or midazolam can modulate phorbol 12-myristate 13-acetate (PMA)-induced respiratory burst of human neutrophils. The concentrations of the drugs tested *in vitro* were adjusted to be similar to plasma concentrations reported for anaesthesia or sedation and also 10-fold higher concentrations[2 9]. As propofol is dissolved in 10% Intralipid for i.v. use and it has been reported that parenteral lipid emulsions can influence the cellular immune response[10–13], we also investigated the effect of 10% Intralipid on respiratory burst.

Subjects and methods

The study was approved by the Institution Ethics Committee. Informed consent was obtained from the blood donors.

ANAESTHETIC AGENTS

Different concentrations of propofol (Disoprivan, ICI Pharma, Plankstadt, Germany), its lipid carrier, 10% Intralipid (Pharmacia, Erlangen, Germany), thiopentone (Trapanal, Byk Gulden, Konstanz, Germany), methohexitone (Brevimytal Natrium, Eli Lilly, Bad Homburg, Germany) and midazolam (Dormicum, Hoffmann-La Roche, Grenzach-Wyhlen, Germany) on neutrophil respiratory burst were studied. As midazolam is suitable for anaesthesia only in combination with other agents, there are no anaesthetic plasma concentrations defined. Thus midazolam was analysed only at reported sedating doses. Thiopentone and methohexitone were purchased as dry material and dissolved in isotonic saline solution (0.9% NaCl). The desired concentrations of all tested drugs were standardized with phosphate-buffered saline (PBS, Dulbeco's without Ca^{2+} and $MgCl_2$, Gibco BRL, Eggenstein, Germany).

SAMPLE PREPARATION

Heparinized (10 u. ml^{-1}, Liquemin N, Hoffmann-La Roche, Grenzach-Wyhlen, Germany) venous blood samples (3 ml) were obtained from healthy blood donors (n=20). Blood was layered on equal Ficoll quantity (Ficoll-Paque: density 1.077 g dl^{-1}, Biochrom, Berlin, Germany). PBS was portioned (1 ml) and warmed to 37 °C. The nucleated blood cells of the supernatant were harvested after 1 *g* sedimentation at 22 °C for 45 min and resuspended in PBS. Then 30 µl of the leucocyte sample (containing 5×10^5 cells ml^{-1}) and DHR 15 µl (1×10^4 mol, MoBiTec, Goettingen, Germany) were added to the PBS and incubated at 37 °C for 5 min. Subsequently, the cell suspensions were incubated with the drug and concentrations tested at 37 °C for 10 min. Neutrophils from the samples were stimulated with PMA 10 µl (1×10^{-6} mol, Sigma, Deisenhofen, Germany) at 37 °C for 20 min. Stimulation was then terminated by transferring the samples onto ice. Viability discrimination was performed by addition of propidium iodide (PI) 10 µl (3×10^{-3} mol, Serva, Heidelberg, Germany) just before measurement. Internal positive (full PMA stimulation) and negative (no PMA) controls for each sample were carried out without addition of the tested substances. Full stimulation of neutrophil respiratory burst for the positive controls was titrated and considered 1×10^{-6} mol PMA (data not shown).

MULTIPARAMETER FLOW CYTOMETRY

Samples were analysed on a fluorescence-activated cell scanner (FACScan, Becton Dickinson Immunocytometry Systems- BDIS, Heidelberg, Germany). A minimum of 15 000 events per sample were acquired. The flow cytometer was equipped with an argon ion laser, adjusted to an excitation wavelength of 488 nm and 0.5 W. Rho-123 fluorescence emission was filtered and acquired from the corresponding photomultiplier (FL1) in the band spectrum 515–545 nm. The photomultiplier for FL2 and FL3 was used for acquisition of PI emission over the range 563–607 nm. Forward light scatter (FSC), sideward light scatter (SSC) and fluorescence signals were adjusted with the negative and positive control samples. SSC data were collected in linear mode whereas FSC and the fluorescences were collected in logarithmic amplification mode without compensation. A relatively high threshold level of FSC (channels $>10^2$) was set to exclude erythrocytes and cell debris. Data files were stored in list mode using FACScan software and analysed with the PC-Lysis software (BDIS). Two analytical gates were used for precise discrimination of the desired neutrophils (fig. 1A, C and D). Briefly, neutrophils were included by setting an arbitrary leucocyte right-angled gate in FSC *vs* SSC (fig. 1A). Further restriction of neutrophils was performed after zooming leucocytes (R1) in the same dot plot (fig. 1B), as shown elsewhere[14]. Additionally, dead cells were gated and excluded (R2) because of the high fluorescence in FL3 as a result of intracellular PI content (fig. 1C). Thus inhibition of neutrophil respiratory burst was estimated on approximately 5000 remaining events using the negative and positive controls, and an appropriate threshold in SSC *vs* FL1 (fig. 1D).

CALCULATION AND STATISTICS

The percentage of respiratory burst inhibition by the drugs was calculated using the formula:

$$\% \text{ inhibition}=((\text{positive control})-(\text{tested drug})/\text{total viable neutrophils})\times100$$

where positive control=number of rho-123 positive events by full stimulation with PMA; negative control=number of rho-123 positive events without stimulation with PMA and without drug; tested drug=number of rho-123 positive events by stimulation with PMA in the actual drug incubated sample; viable neutrophils=PI negative neutrophils.

As numeric data showed a Gaussian distribution, descriptive statistics, mean (SD), paired two-tailed Student's *t* test for inter-group significance ($P<0.05$, 95% confidence intervals) and Forman's regression were used for statistical analysis of the flow cytometry data (n=20 for each drug and concentration). Otherwise, the non-parametric Mann–Whitney *U* test was used (SPSS/PC V6.01 software package, SPSS, Munich, Germany).

Results

Overall inhibition of neutrophil respiratory burst by propofol, thiopentone, methohexitone and midazolam is illustrated in figures 2 and 3. The percentages of PI positive neutrophils were low for all drugs and concentrations tested (<5%).

SEDATING AND 10-FOLD SEDATING DOSES (FIG. 2)

All drugs showed identical low mean inhibition of respiratory burst at the corresponding sedating concentrations (1% and 6%). At 10-fold sedating doses, propofol 30 µg ml^{-1} produced significantly ($P<0.001$) more inhibition (68.6 (11.2)%) compared with the three other drugs. Thiopentone 200 µg ml^{-1} inhibited

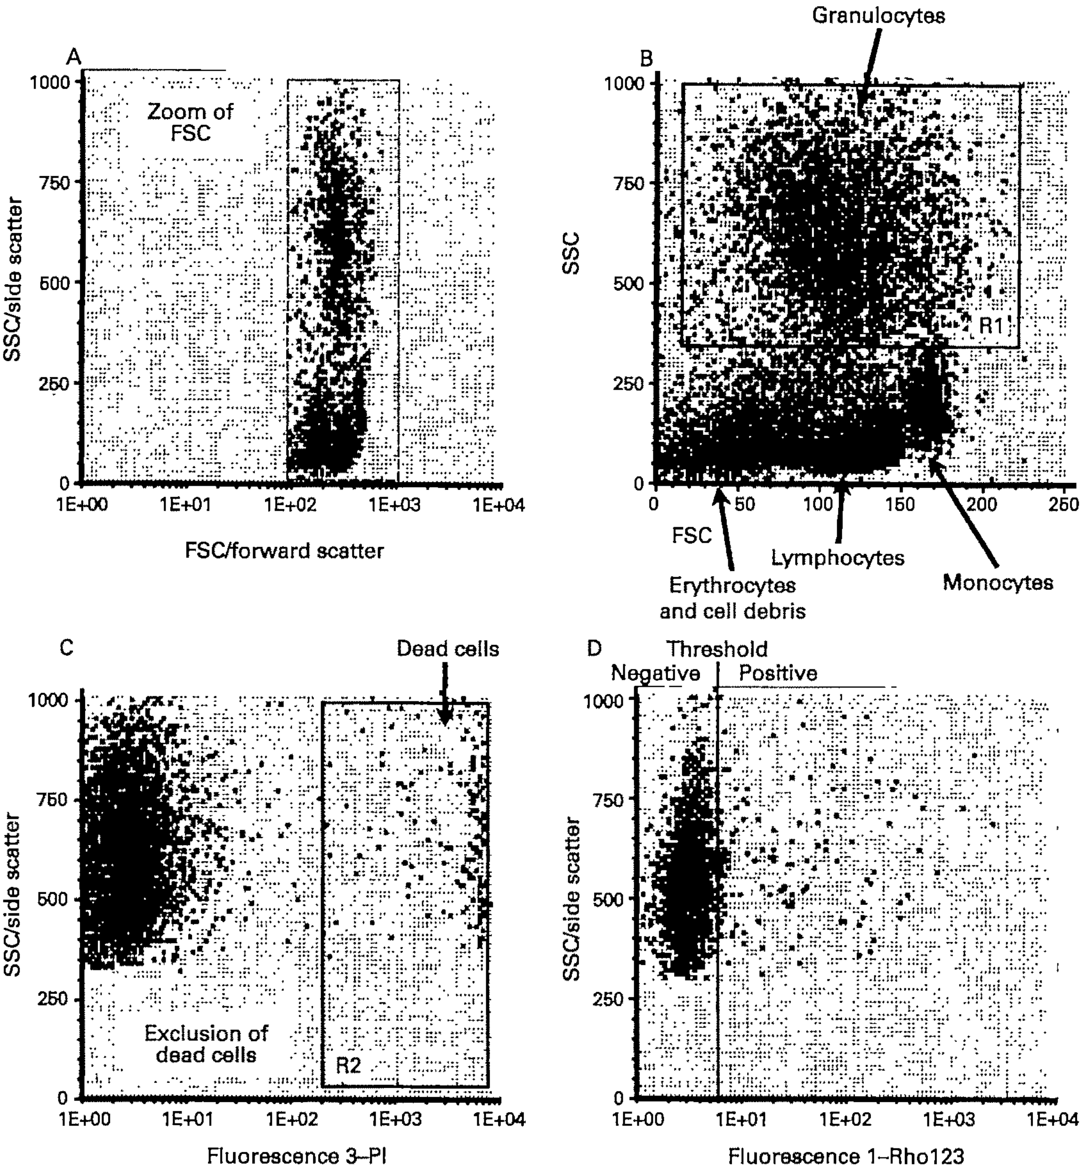

Figure 1 Adjustment of the flow cytometer for acquisition of the desired events (A, C and D) and analysis of neutrophil respiratory burst inhibition (A–D). A: FSC *vs* SSC is depicted as acquired on the flow cytometer. B: Zoomed and localized leucocyte subgroups (R1 granulocytes). C: Exclusion of PI positive cells (R2). D: Threshold setting by overlaying the internal positive and negative control, and by using the gate combination R1 and not R2.

respiratory burst more (14.6 (10.7)%) than methohexitone 50 $\mu g\ ml^{-1}$ (1.3 (1.4)%) and midazolam 6 $\mu g\ ml^{-1}$ (3.4 (3.9)%) at 10-fold sedating concentrations ($P<0.001$). The difference between methohexitone and midazolam was also significant ($P<0.05$).

ANAESTHETIC AND 10-FOLD ANAESTHETIC DOSES (FIG. 3)

At concentrations normally required for anaesthesia, the following significant differences were observed: propofol 6 $\mu g\ ml^{-1}$ and thiopentone 40 $\mu g\ ml^{-1}$ produced greater suppression (7.3 (6.0)% and 4.5 (5.3)%, respectively) ($P<0.001$) than methohexitone 10 $\mu g\ ml^{-1}$ (0.9 (1.6)%). At the highest (10-fold anaesthetic) concentrations, inhibition by propofol 60 $\mu g\ ml^{-1}$ was almost complete (90.8 (3.9)%) and greater ($P<0.001$) than that by thiopentone 400 $\mu g\ ml^{-1}$ (29.2 (15.1)%) and methohexitone 100 $\mu g\ ml^{-1}$ (1.8 (1.7)%), which had only minimal effects.

Significant correlations ($P<0.001$) for the four concentrations with inhibition of respiratory burst were observed with propofol ($r=0.93$) and thiopentone ($r=0.72$). Methohexitone did not inhibit respi-

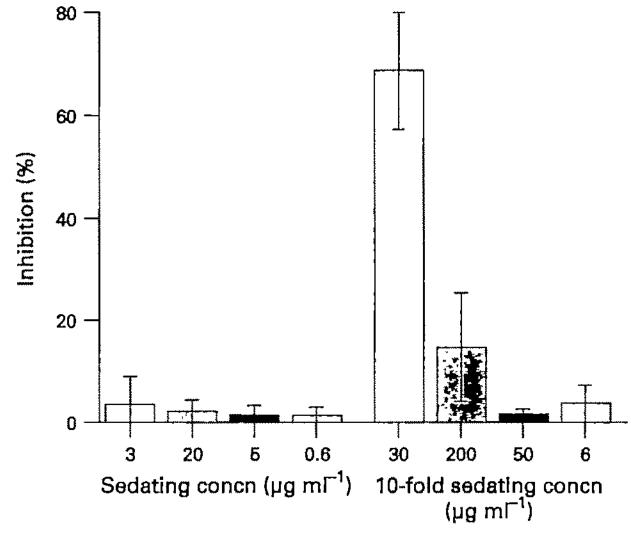

Figure 2 Percentage inhibition of neutrophil respiratory burst produced by propofol (open bars) 3 and 30 $\mu g\ ml^{-1}$, thiopentone (dark shaded bars) 20 and 200 $\mu g\ ml^{-1}$, methohexitone (solid bars) 5 and 50 $\mu g\ ml^{-1}$ and midazolam (light grey bars) 0.6 and 6 $\mu g\ ml^{-1}$ at concentrations likely to be required for sedation and 10-times these concentrations[29].

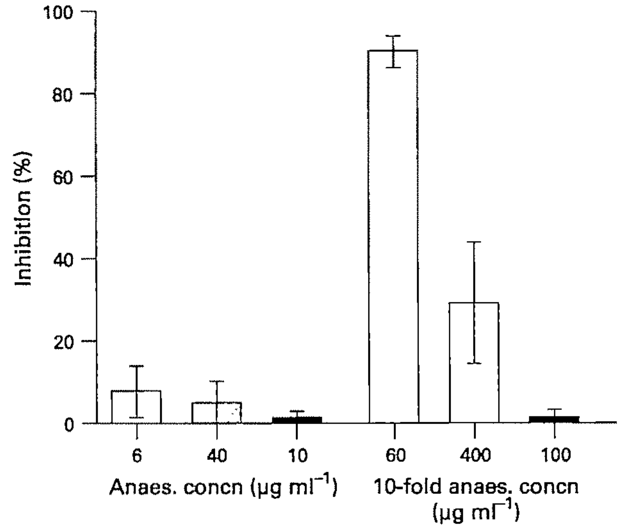

Figure 3 Percentage inhibition of neutrophil respiratory burst produced by propofol (open bars) 6 and 60 µg ml^{-1}, thiopentone (shaded bars) 40 and 400 µg ml^{-1} and methohexitone (solid bars) 10 and 100 µg ml^{-1} at concentrations likely to be required for anaesthesia and 10-times these concentrations[29].

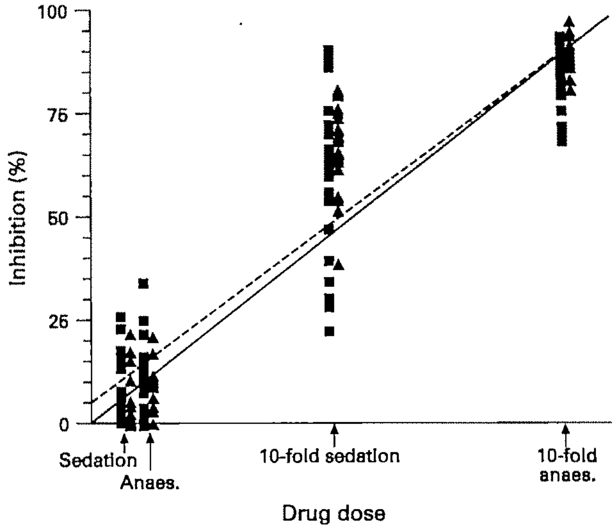

Figure 4 Regression analysis of dose–response relationship of and between propofol (■) (r=0.93, P<0.001) and its lipid carrier vehicle 10% Intralipid (▲) (r=0.9, P<0.001). *In vitro* concentrations of propofol (solid line) likely to be required in plasma during sedation, anaesthesia and 10 times these concentrations (3, 6, 30 and 60 µg ml^{-1}) and the respective volumes of 10% Intralipid (broken line) (0.3, 0.6, 3 and 6 µl ml^{-1})[29].

ratory burst in a dose-related manner. The four volumes of 10% Intralipid (0.3, 0.6, 3 and 6 µl ml^{-1}), which were carrying corresponding concentrations of propofol 3, 6, 30 and 60 µg ml^{-1}, inhibited respiratory burst to the same extent and with significant correlations between the dose inhibition relations of propofol (r=0.93) and 10% Intralipid (r=0.90). There were no significant differences between the effects of both drugs (fig. 4).

Only in samples incubated with the highest concentration (10-fold anaesthetic) of propofol (60 µg ml^{-1}, 452(75)) and with the equivalent volume of 10% Intralipid (6 µl ml^{-1}, 443(80)) was there a significant decrease in mean side scatter signal intensity compared with the negative control (mean channel numbers 550 (SD 143)) (fig. 5).

Discussion

METHODOLOGY

We have studied the *in vitro* effects of thiopentone, methohexitone, midazolam and propofol on respiratory burst of neutrophils from healthy blood donors after PMA stimulation via multiparameter flow cytometry (MFC). The discrepancy between the published data on the influence of different drugs on *in vitro* neutrophil function is probably because of the variety of techniques used and the sensitivity and fragility of neutrophils. The applied MFC technique has different advantages compared with other methodologies measuring non-specific oxygen radical production, such as chemiluminescence. With the present MFC technique it is possible to measure the direct effects on the responsible enzyme complex, the intracellular respiratory burst oxidase. Moreover, only the intracellular oxygen radical content of one selected cell population is investigated and several variables of each cell are evaluated at the same time. In this study, five variables of 15 000 cells for each sample were assessed and four variables of approximately 5000 viable neutrophils were analysed. Thus the high number of analysed events resulted in data with low coefficients of variation. The objectivity of the procedure was maintained by repeated device adjustment and the use of external and internal positive and negative controls. Cell toxicity as a possible explanation for the effects of the drugs studied was excluded by staining with fluorochrome propidium iodide (PI). PI can only attach to cellular DNA after destruction or disintegration of cell membranes, usually subsequent to cell death[14]. Only PI-negative cells (i.e. viable cells) were included in the estimation.

THIOPENTONE

The thiobarbiturate thiopentone produced dose-related suppression of respiratory burst. The highest mean suppression of up to 30% was reached with 10-fold the concentrations found in plasma during anaesthesia. The oxybarbiturate methohexitone had only minimal effects at all concentrations studied, without any dose–effect correlation. A former study showed that thiopentone suppressed *N*-formylmethionyl-leucyl-phenylalanine (FMLP)-induced neutrophil chemiluminescence and chemotaxis, even at plasma concentrations in the therapeutic range[15]. Suppression of neutrophil migration and chemiluminescence by thiobarbiturates was 10–100 stronger than that by oxybarbiturates and was attributed to the sulphur atom in the thiobarbiturate molecule[16]. Additionally, lymphocyte functions such as mitogen-induced blast transformation and cell proliferation appeared to be markedly more impaired in the presence of thiopentone than other barbiturates[17]. Eberhardt and colleagues reported an increase in pulmonary infections of up to 40% in patients with brain oedema undergoing mechanical ventilation and receiving thiopentone. Higher doses of thiopentone were associated with development of infections[18]. The reported observations and our observed suppression of intracellular oxygen radical production by thiopentone may favour the use of oxybarbiturates in

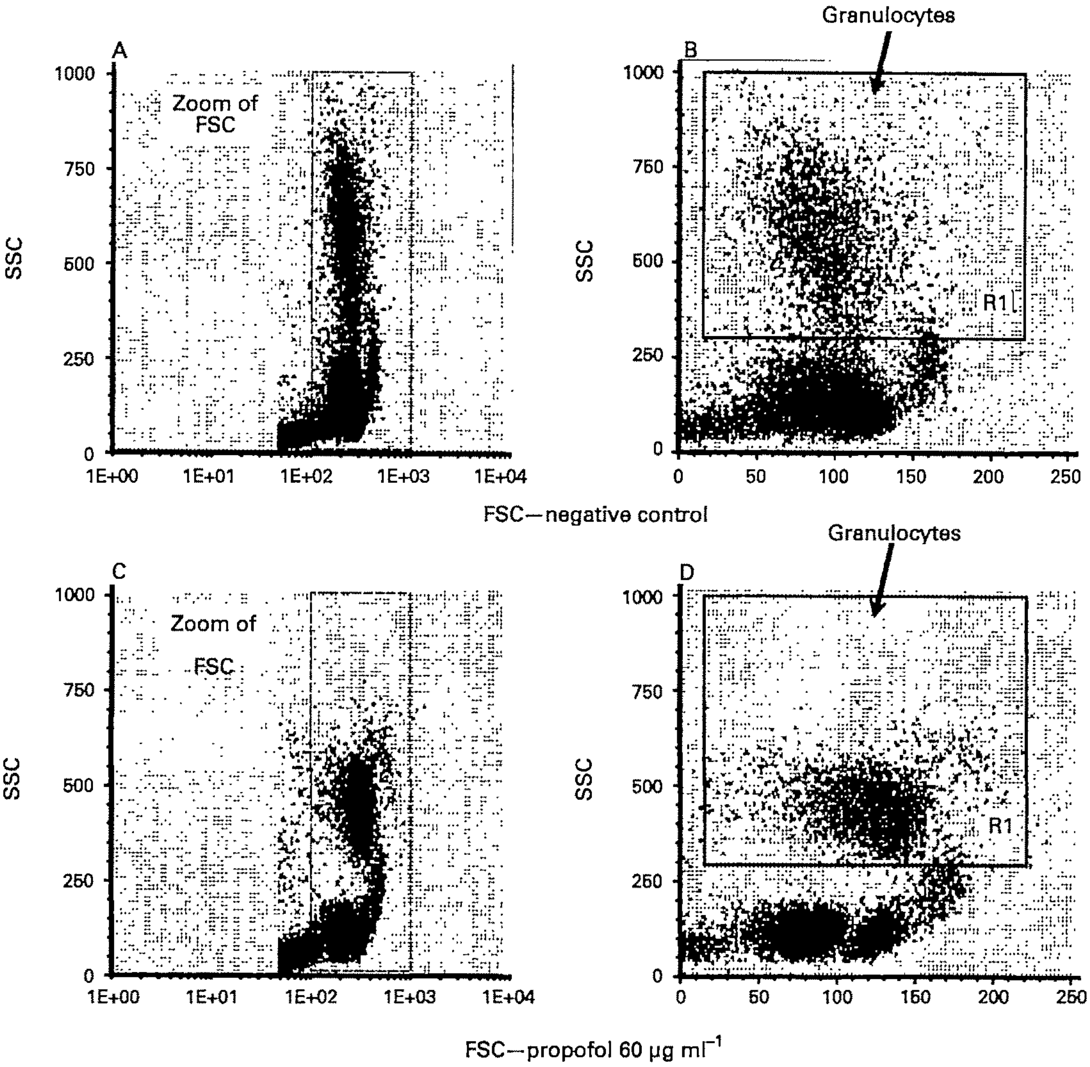

Figure 5 Decrease in SSC signals of neutrophils incubated with 10-fold anaesthetic doses of propofol (60 μg ml^{-1}) compared with the negative control. A (negative control) and C (propofol 60 μg ml^{-1}) are depicted as acquired on the flow cytometer. Changing FSC from logarithmic to linear scale and gating the neutrophils (R1) leads to figures B (negative control) and D (propofol 60 μg ml^{-1}). The SSC signals were decreased from B to C. As estimated in a SSC histogram over the gated neutrophils (R1), peak, mean (SD) and median channel numbers were as follows: 456, 452 (75) and 450 for propofol, and 553, 550 (143) and 550 for the negative control, respectively.

induced barbiturate coma during brain oedema than thiobarbiturates.

MIDAZOLAM

The influence of midazolam on respiratory burst after PMA stimulation was negligibly low. Finnerty and colleagues described stimulus-dependent inhibition of superoxide anion production by benzodiazepines measured by chemiluminescence. Benzodiazepines specifically repressed FMLP- but not PMA-stimulated neutrophil superoxide anion production[19]. Stimulation by FMLP is receptor-mediated by a formyl peptide receptor on the surface of the neutrophil granulocytes, whereas PMA activates respiratory burst oxidase through its ability to stimulate protein kinase C[6]. Suppression of neutrophil respiratory burst oxidase by benzodiazepines was found to be mediated by a specific peripheral receptor[20]. Thus stimulation with FMLP may not correlate with PMA stimulation. However, the clinical relevance of this phenomenon remains unclear.

PROPOFOL

Propofol produced the greatest inhibition of respiratory burst with tested concentrations. At 10-fold anaesthetic concentrations, suppression was almost complete (90.8%). It is not clear if the effects of propofol on leucocyte function are induced by its lipid carrier, 10% Intralipid. In a previous study, propofol was found to suppress whereas 10% Intralipid augmented neutrophil polarization[2], which is in contrast with another study, where propofol and 10% Intralipid suppressed neutrophil chemotaxis[3].

INTRALIPID

We found that propofol and equal volumes of 10% Intralipid inhibited respiratory burst to the same extent and with a significant dose–response correlation. Thus the effects of propofol on respiratory burst may be attributed to its lipid carrier. Moreover, it is well known that parenteral lipid emulsions suppress some aspects of leucocyte function. Numerous authors have described impairment of antimicrobial defence[9 10 21], chemotaxis[21 22] and T cell-mediated immunity[11 12 23]. Additionally, accumulation of particles was described in the cytoplasm of neutrophils, which correlated with reduced cell function after parenteral i.v. lipid infusions[24]. This observation correlates with the fact that polyunsaturated fatty acids can be incorporated rapidly into cell membranes[25] and increase membrane rigidity[26].

Intralipid 10% is composed of high concentrations of long chain triglycerides (LCT) containing unsaturated fatty acids. The increase in membrane rigidity in the presence of LCT may result in the observed reduction in chemotactic properties. These changes in membrane structure may also provide an explanation for the decrease in SSC signals of neutrophils found in this study, because SSC characterizes cell granularity, density or membrane folding. This decline was observed only with the highest concentrations of propofol (10-fold anaesthetic dose, 60 μg ml^{-1}) and the corresponding volume of 10% Intralipid (6 μl ml^{-1}) alone. Cell death and a coating phenomenon were excluded, because both fluorescences (FL 1 and 3) were not influenced. Many studies and the results of our study suggest that parenteral lipid emulsions can inhibit some leucocyte functions.

Atrioventricular conduction during adenosine-induced hypotension in dogs anaesthetized with sevoflurane

R. ISHII, S. AKAZAWA, R. SHIMIZU, Y. NAKAIGAWA, S. IKENO AND R. YAMATO

Summary

We have studied the effects of adenosine-induced hypotension on A-H interval (atrioventricular (AV) nodal conduction time during sinus rhythm), St-H interval (intra-atrial plus AV nodal conduction time during atrial pacing), H-V interval (His–Purkinje conduction time) and H-S interval (total ventricular conduction time) by His-bundle electrocardiography in addition to surface electrocardiogram during both sinus rhythm and atrial pacing in nine dogs anaesthetized with 1 MAC of sevoflurane. Stepwise increases in infusion rates of adenosine to 0.1, 0.3, 0.5 and 1.0 mg kg^{-1} min^{-1} produced a dose-related decrease in mean arterial pressure from 91 (6) to 38 (2) mm Hg. Adenosine significantly increased the A-H interval at infusion rates of 0.5 mg kg^{-1} min^{-1} and above, and the St-H interval at 1.0 mg kg^{-1} min^{-1}. The H-V and H-S intervals remained unchanged. Heart rate decreased significantly only at 1.0 mg kg^{-1} min^{-1} with a significant increase in the PR interval. Adenosine-induced hypotension did not have deleterious effects on AV conduction times and the surface electrocardiogram in dogs anaesthetized with 1 MAC of sevoflurane. This may indicate that the effects of adenosine on AV conduction were small and therefore are unlikely to be a contraindication to the use of adenosine for inducing hypotension in patients with initially normal conduction during sevoflurane anaesthesia. (*Br. J. Anaesth.* 1996;**77**:393–398)

Key words

Anaesthetics volatile, sevoflurane. Anaesthetic techniques, hypotensive. Heart, conduction. Monitoring, electrocardiography. Pharmacology, adenosine. Dog.

Adenosine has been used as a hypotensive agent during major surgery[1–5]. Unlike other hypotensive agents such as sodium nitroprusside and trinitroglycerin, adenosine is a naturally occurring purine nucleoside and produces rapid and stable hypotension without evidence of biochemical or haematological toxicity[1]. Tachyphylaxis and rebound hypertension have not been reported after induced hypotension with adenosine[1–5]. In addition, adenosine has an extremely short half-life (10–30 s) because of rapid uptake into cells, resulting in rapid termination of action when administration is discontinued[6].

Although adenosine has been shown to cause depression of sinus node automaticity[7 8] and atrioventricular (AV) nodal conduction *in vitro*[9], it is known to be highly effective clinically in terminating re-entrant tachycardia involving the AV node[10]. However, there has been no study on the electrophysiological effects of adenosine on the cardiac conduction system in the presence of inhalation anaesthetics.

Sevoflurane provides rapid control of arterial pressure as a result of its low blood solubility[11 12] and it has no adverse cardiac electrophysiological effects[13]. Therefore, a combination of sevoflurane and adenosine may be used to safely induce hypotension.

We have studied atrioventricular conduction and the surface electrocardiogram during adenosine-induced hypotension in dogs anaesthetized with sevoflurane.

Materials and methods

ANIMAL PREPARATION

The study was approved by the management committee of the Jichi Medical Laboratory of Experimental Medicine, based on the school's 1993 Guide for Laboratory Animals.

Anaesthesia was induced in nine mongrel dogs, weighing 13–21 kg (mean 16.6 kg), by insufflating 3–5% (1.3–2.1 MAC) sevoflurane via a funnel-shaped plastic mask fitted to the dog's face connected to a Jackson–Rees circuit. The trachea was intubated and ventilation was adjusted to maintain normocapnia with a Harvard pump respirator (R-60, Aika, Co., Ltd).

Anaesthesia for surgical preparation was maintained with 2–3% end-tidal concentrations of sevoflurane and 50% nitrous oxide in oxygen delivered into the inspiratory limb of a Harvard pump respirator. Sevoflurane was vaporized using a Sevotec vaporizer (Penlon Inst., Ltd). A micromanometer-tipped catheter (7F 45326, Toyoda Instr., Ltd) was inserted via the left femoral artery into the abdominal aorta to measure systolic (SAP), diastolic (DAP) and mean (MAP) arterial pressures.

Correspondence to R. I.

A catheter was inserted into the abdominal aorta via the right femoral artery to sample arterial blood for measurement of pH, Pa_{O_2}, Pa_{CO_2} and serum electrolyte concentrations. Lactated Ringer's solution was infused at a rate of 5–10 ml kg^{-1} h^{-1} via the left femoral vein throughout the study. Body temperature was measured with an oesophageal thermistor and maintained at 36–37 °C using an external heating blanket.

A right thoracotomy was performed at the fifth intercostal space. A quadripolar electrode catheter introduced via the right femoral vein was positioned under manual control across the tricuspid valve to obtain a stable His-bundle electrogram (HBE). The His-bundle catheter electrodes were connected to a switch box that allowed selection of any combination of two electrodes. The output of the switch box was connected to a preamplifier with bandwidth cutoff frequencies of 40–1000 Hz. The electrodes of the surface electrocardiogram (ECG: lead II and V5) were connected to another preamplifier with a filter bandwidth of 0.1–120 Hz. The output from each preamplifier was recorded on a thermal recorder (8M15, NEC San-ei, Ltd, Tokyo, Japan) at a paper speed of 100 mm s^{-1}. Heart rate was determined by counting QRS complexes over 10 s. Arterial pressures and surface ECG were recorded on a multichannel recorder (Recti-Horiz-8K, NEC San-ei, Ltd, Tokyo, Japan).

HBE was recorded at a paper speed of 500 mm s^{-1} to calculate AV conduction intervals with 1.0-ms resolution (Visigraph 5L37, NEC San-ei, Ltd, Tokyo, Japan). An electrode for atrial pacing was attached to the surface of the right atrial appendage. An R-wave coupled cardiac stimulator (3F61, NEC San-ei, Instr., Ltd) delivering rectangular monophasic pulses of 1 ms duration was used for all atrial pacing.

ELECTROCARDIOGRAPHIC AND ELECTROPHYSIOLOGICAL MEASUREMENTS

RR, PR and St-R intervals, QRS duration and QT interval were measured from ECG lead II. The PR interval during sinus rhythm was measured from the onset of the P wave to the onset of the Q wave of the QRS complex. The St-R interval during atrial pacing was measured from the beginning of the stimulus artefact (St) in the HBE to the onset of the Q wave of the QRS complex. The QT interval was corrected for heart rate by dividing the QT interval by the square root of the RR interval (s) to obtain the QTc interval[14].

AV conduction times measured were as follows: A-H interval (AV nodal conduction time during sinus rhythm); St-H interval (intra-atrial plus AV nodal conduction time during atrial pacing); H-V interval (His–Purkinje conduction time); and H-S interval (total ventricular conduction time). The A-H interval was measured from the beginning of atrial deflection to the beginning of the His-bundle spike in the HBE[15]. The St-H interval was measured from the beginning of the St to the beginning of the His-bundle spike in the HBE[16]. The H-V interval was measured from the beginning of the His-bundle spike to the beginning of the ventricular deflection in the HBE[15]. The H-S interval was measured from the beginning of the His-bundle spike to the end of the rapid ventricular deflection in the HBE[16] (fig. 1).

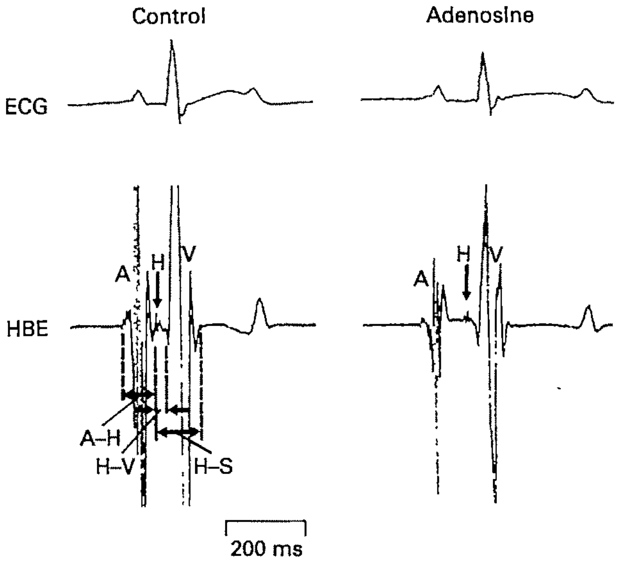

Figure 1 Surface electrocardiogram (ECG, lead II) and His-bundle electrogram (HBE) during sinus rhythm. The A-H and PR intervals were prolonged significantly with an infusion of adenosine 1.0 mg kg^{-1} min^{-1} compared with control. A=Atrial deflection; H=His-bundle spike; V=ventricular deflection; A-H (atrioventricular nodal conduction time)=interval from the beginning of atrial deflection to the beginning of the His-bundle spike in the HBE; H-V (His-Purkinje conduction time)=interval from the beginning of the His-bundle spike to the beginning of the ventricular deflection in the HBE; H-S (total ventricular conduction time)= interval from the beginning of the His-bundle spike to the end of the rapid ventricular deflection in the HBE.

EXPERIMENTAL PROCEDURE

At the end of the surgical procedure, nitrous oxide was discontinued and the end-tidal concentration of sevoflurane was adjusted to 2.4% (1 MAC) and maintained for at least 20 min. After haemodynamic stabilization, control values of the variables noted above were obtained during both sinus rhythm and subsequent atrial pacing. The right atrium was constantly paced at 100 (8) beat min^{-1}, which was slightly faster than the control sinus rate during each infusion of adenosine. Twenty beats were recorded during sinus rhythm, and then the right atrium was paced for 1 min and 20 consecutive beats were recorded. Sinus rhythm returned immediately after pacing was discontinued.

Crystal adenosine (Sigma Chemical Co., St Louis, MO, USA) was dissolved in normal saline at a concentration of 2 mg ml^{-1} and infused into the inferior vena cava. The infusion rate of adenosine was increased stepwise to 0.1, 0.3, 0.5 and 1.0 mg kg^{-1} min^{-1} every 3 min. All measurements and blood sampling were performed 2–3 min after each rate of adenosine was infused during both sinus rhythm and subsequent atrial pacing. Heart rate and arterial pressures were also measured for 5 min after discontinuation of the adenosine infusion.

DATA ANALYSIS

Data are given as mean (SEM). Statistical analysis was performed using analysis of variance (ANOVA) with repeated measures, followed by Scheffe's *F* test. $P<0.05$ was considered statistically significant.

Table 1 Effects of adenosine on arterial pressures and heart rate during sinus rhythm (mean (SEM)). SAP = Systolic arterial pressure; DAP = Diastolic arterial pressure; MAP = Mean arterial pressure. HR = Heart rate *$P < 0.05$ compared with control value; †$P < 0.05$ compared with preceding value

Results

HAEMODYNAMIC EFFECTS (TABLE 1)

Adenosine produced dose-related stable decreases in SAP, DAP and MAP. MAP decreased significantly from 91(6) to 62 (6), 45 (4), 42 (3) and 38 (2) mm Hg with adenosine infusion rates of 0.1, 0.3, 0.5 and 1.0 mg kg^{-1} min^{-1}, respectively. Heart rate remained unchanged at 0.1 mg kg^{-1} min^{-1} and tended to decrease at 0.3 and 0.5 mg kg^{-1} min^{-1}, and decreased significantly at 1.0 mg kg^{-1} min^{-1}. There were no significant differences in SAP, DAP and MAP between control values and those at 5 min after termination of adenosine infusion: rebound hypertension did not occur.

ELECTROPHYSIOLOGICAL AND ELECTROCARDIOGRAPHIC EFFECTS (TABLES 2, 3)

Adenosine significantly increased the A-H interval at infusion rates of 0.5 mg kg^{-1} min^{-1} and above, during sinus rhythm, and the St-H interval only at 1.0 mg kg^{-1} min^{-1} during atrial pacing. There were significant differences between the A-H and St-H intervals under control conditions and at each infusion rate. The H-V and H-S intervals were unchanged during both sinus rhythm and atrial pacing at all infusion rates.

The RR interval was unchanged at an infusion rate of 0.1 mg kg^{-1} min^{-1}, tended to decrease at 0.3 and 0.5 mg kg^{-1} min^{-1} and decreased significantly at 1.0 mg

kg^{-1} min^{-1}. Pacing rate was 100 (8) beat min^{-1}, which was slightly greater than the control rate at sinus rhythm (90 (7) beat min^{-1}). Adenosine significantly increased the PR interval during sinus rhythm and the St-R interval during atrial pacing, but only at an infusion rate of 1.0 mg kg^{-1} min^{-1}. However, a PR interval longer than 200 ms and AV conduction block did not appear at any infusion rate. The QT interval tended to increase during sinus rhythm, while it was unchanged during atrial pacing. QRS duration and the QTc interval were unchanged during both sinus rhythm and subsequent atrial pacing.

Discussion

We have found that infusion of adenosine produced rapid and dose-related decreases in systolic, diastolic and mean arterial pressures and significantly increased the A-H interval at infusion rates of 0.5 mg kg^{-1} min^{-1} and above during sinus rhythm, and the St-H interval at 1.0 mg kg^{-1} min^{-1} during atrial pacing under anaesthesia with 1 MAC of sevoflurane.

Decreased arterial pressures became stable within 1–1.5 min after the beginning of the infusion of adenosine at each rate. Adenosine-induced hypotension can be attributed to systemic arterial vasodilatation, as shown previously in dogs[17], pigs[18] and humans[1–3]. Rebound hypertension did not occur. This finding is in agreement with a previous report[17].

The haemodynamic and electrophysiological effects of adenosine are influenced by a complex interplay of A_1 and A_2 receptors located on the surface of cell membranes and coupled to G proteins[19]. A_2 receptors in endothelial and vascular smooth muscle cells mediate vasodilatation in almost all vascular beds, including the coronary artery, whereas A_1 receptors in cardiomyocytes mediate two types of actions: one is cyclic AMP (cAMP)-independent (direct actions), shortens the action potential in atrial cells[20], elicits sinus slowing and hyperpolarization of SA nodal cells[8 21] and causes depression of the action potential in AV nodal cells[9]; the other is cAMP-dependent (indirect actions) and antagonizes positive chronotropic, dromotropic and inotropic effects through antagonism of the increase in activity of adenylate cyclase and accumulation of cAMP caused by ß agonists and forskolin[22 23].

In general, adenosine-induced hypotension produces reflex tachycardia via activation of baroreflexes, as is the case with other hypotensive agents, in conscious dogs[24], conscious humans[25] and patients anaesthetized with phenoperidine–droperidol[1]. In this study, adenosine-induced hypotension during 1 MAC of sevoflurane anaesthesia was not accompanied by an increase in heart rate. In fact, heart rate tended to decrease with an increases in the infusion rate of adenosine and decreased significantly at an infusion rate of 1.0 mg kg^{-1} min^{-1}. This finding is in agreement with previous results in pigs anaesthetized with methomidate[17], in dogs anaesthetized with phenoperidine–droperidol[26], in rabbits anaesthetized with halothane[27] and in dogs anaesthetized with halothane–nitrous oxide[4]. These results may be attributed to a direct inhibitory effect of adenosine on the sinus node cells[7] and an indirect inhibitory effect of adenosine on cardiac sympathetic neurotransmission[28]. Our results also suggest that the direct and indirect effects of adenosine on the sinus node during sevoflurane anaesthesia may predominate over activation of baroreflexes induced by hypotension with adenosine.

Inhalation anaesthetics have been shown to depress baroreflex function; the extent of depression varies between anaesthetics, with both halothane[29 30] and enflurane[31] being more depressant than isoflurane[32]. Recently, sevoflurane has been shown to depress baroreflex function in chronically instrumented dogs[33]. In addition, we found in our earlier study that sevoflurane suppressed tachycardia associated with nicardipine-induced hypotension in dogs[34]. Therefore, the direct and indirect inhibitory effects of adenosine could be enhanced by sevoflurane anaesthesia.

Prolongation of the A-H interval with adenosine 0.5 and 1.0 mg kg^{-1} min^{-1} can be attributed to direct depression of the action potential in AV nodal cells[9]. This negative dromotropic effect of adenosine may be responsible for the significant prolongation of the PR interval at 1.0 mg kg^{-1} min^{-1} compared with the control value. Because the sensitivity of the AV node to adenosine in the dog is known to be less than that in human[35], the responses to approximately 5–10 times the clinical dose[2 3] were examined in this study. Heart block did not develop at any infusion rate of adenosine in this study, even in the presence of profound hypotension.

In this study, the right atrium was paced at a slightly higher rate than the original sinus rhythm to exclude the influence of heart rate on AV conduction times. Although the St-H interval increased significantly at 1.0 mg kg^{-1} min^{-1}, no significant differences were observed in the degree of increases between the A-H and St-H intervals at any infusion rate of adenosine. Although it is not clear why the St-H interval was 40–50 ms longer than the A-H interval during sinus rhythm, the differences between the A-H and St-H intervals probably reflected latency between the stimulus and atrial activation. Because incremental increases in atrial-paced rate were not performed, the effects of adenosine on the rate-dependence of AV nodal conduction times during sevoflurane anaesthesia is unclear.

Adenosine did not affect the H-V interval, indicating that the site of the dromotropic action of adenosine is proximal to the His bundle, that is the AV node[9]. Our results are consistent with this finding, because both the H-V and H-S intervals were unchanged during both sinus rhythm and subsequent atrial pacing. The lack of effect of adenosine on QRS duration and the QTc interval during both sinus rhythm and subsequent atrial pacing might reflect the absence of effects of adenosine on the His–Purkinje ventricular conduction system and on the average action potential duration of ventricular muscle, respectively.

Electrophysiological studies with inhalation anaesthetics demonstrated that halothane and enflurane were more depressant of A-V nodal conduction time than isoflurane[36–38]. However, the electrophysiological effects of sevoflurane have not been studied fully. We compared the effects of 1 and 2 MAC of sevoflurane, isoflurane and halothane on specialized AV conduction times in dogs anaesthetized with pentobarbitone[13] where we found that both sevoflurane and isoflurane did not affect the A-H, H-V and H-S intervals, whereas halothane significantly prolonged only the A-H interval at 2 MAC during sinus rhythm, although pentobarbitone might modify the effects of subsequently administered inhalation anaesthetics.

A battery of electrophysiological tests, including measurements of sinus node recovery time, AV nodal refractory periods and Wenckebach cycle length should be performed to provide sufficient information for measurement of the possible clinical electrophysiological risk of adenosine. Non-invasive methods using more adenosine-sensitive animals and higher concentrations of sevoflurane may also be highly desirable. Although there are several limitations, as mentioned above, our results suggest that adenosine should not exert adverse effects on AV conduction times in combination with sevoflurane anaesthesia.

In summary, adenosine-induced hypotension did not elicit reflex tachycardia and adenosine did not produce detrimental heart block during anaesthesia with 1 MAC of sevoflurane. Adenosine may therefore be used as a hypotensive agent during sevoflurane. However, the potential for coronary steal[21, 39] and renal vasoconstriction[22, 40] during adenosine administration may limit its clinical usefulness.

Effects of fentanyl, nitrous oxide, or both, on baroreceptor reflex regulation in the cat

Ö. LENNANDER, B-Å. HENRIKSSON, J. MARTNER AND B. BIBER

Summary

We have investigated the effects of fentanyl, nitrous oxide, or both, on carotid sinus baroreceptor reflexes in cats during basal chloralose anaesthesia. The bilaterally isolated carotid sinuses were perfused at prevailing systemic arterial pressure or at predetermined levels of pump-controlled pulsatile pressures of 50–200 mm Hg in steps of 25 mm Hg. Other major baroreceptor sites were denervated by bilateral vagotomy. Fentanyl decreased arterial pressure dose-dependently when the carotid sinuses were perfused at prevailing systemic arterial pressure and when the perfusion pressure was controlled artificially. High-dose fentanyl reduced significantly baroreceptor reflex responses in the sinus perfusion pressure range 50–125 mm Hg. Nitrous oxide increased arterial pressure in the carotid sinus perfusion range 75–125 mm Hg. There was no interaction between nitrous oxide and fentanyl for baroreceptor reflex responses. Our results indicated that baroreceptor reflexes, with and without nitrous oxide, were well preserved by moderate doses of fentanyl while high doses of fentanyl depressed baroreceptor reflexes. (*Br. J. Anaesth.* 1996;77:399–403)

Key words

Reflexes, baroreceptor. Model, cat. Cat. Analgesics opioid, fentanyl. Anaesthetics gases, nitrous oxide.

The baroreflex is very important for short-term cardiovascular homeostasis. Halogenated inhaled anaesthetics decrease arterial pressure in a dose-dependent manner by interaction with both central and peripheral mechanisms. There is evidence also that halogenated inhaled anaesthetics depress the baroreceptor reflex[1]. In contrast, balanced anaesthesia with nitrous oxide and fentanyl is characterized by more stable peroperative haemodynamic conditions. One reason for this might be that this type of anaesthesia blunts baroreceptor reflexes to a lesser degree.

The aim of this study was to investigate the effects of nitrous oxide alone or in combination with fentanyl on the carotid sinus baroreceptor reflex. The study was performed in an experimental model in cats allowing analysis of the carotid sinus open loop gain, that is the impact on systemic arterial pressure of changes in perfusion pressure to the bilaterally isolated carotid sinuses.

Materials and methods

The study was performed on eight cats, weighing 3.2–4.9 kg. The animals had been deprived of food for 12 h but had free access to water. The study was approved by the National Swedish Animal Experiment Ethics Committee.

Anaesthesia was induced with enflurane and 70% nitrous oxide in oxygen and continued with chloralose 50 mg kg^{-1} i.v. as basal anaesthesia. Supplementary doses of chloralose 50 mg were given when necessary during the experiment. After tracheotomy, the lungs were ventilated with air at a frequency of 20 bpm with a Harvard 661 small animal ventilator. Tidal volume was adjusted to maintain an arterial $P\mathrm{co}_2$ of 3.5–4.5 kPa, as verified by repeated arterial blood-gas analyses (ABL-2, Radiometer, Copenhagen).

Hydration and avoidance of metabolic acidosis was accomplished by a continuous infusion (10 ml kg^{-1} h^{-1} during preparation and 5 ml kg^{-1} h^{-1} during experiment) of Ringer's–glucose with the addition of 20 ml of sodium bicarbonate 0.6 mol litre^{-1} per 100 ml. Core temperature was maintained at 37–38 °C by means of a heating pad.

Cardiopulmonary and aortic baroreceptors were denervated by bilateral sectioning of the vagal nerves. The carotid sinuses were bilaterally partly isolated by ligation of the external and sometimes also the internal carotid arteries, and all other arterial branches that could be ligated without endangering the integrity of the sinus nerves by dissection. After administration of heparin 5000 IE i.v., catheters were inserted bilaterally into the common carotid arteries and femoral arteries, allowing the carotid sinuses to be perfused with blood from the femoral arteries, either at systemic arterial pressure by a direct bypass or at any desired level of pulsatile pressure using a rotor pump. To allow adjustments of carotid sinus perfusion pressure without changes in pump frequency, an arteriovenous shunt was inserted between the carotid sinuses and an external jugular vein. The carotid sinus perfusion pressure was recorded from a side branch of the tubing system. This preparation has been described in detail previously[2].

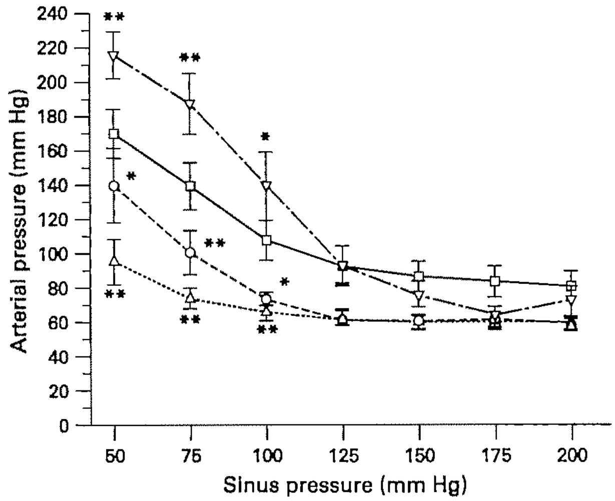

Figure 1 Baroreflex responses (systemic mean arterial pressure (MAP) *vs* carotid sinus perfusion pressure) in animals receiving air (mean, SEM). The following stages are shown: baseline (□); low-dose fentanyl (○); high-dose fentanyl (△); after naloxone (▽). $^{*}P<0.05$, $^{**}P<0.01$ compared with baseline.

The reactivity of the sinus preparation was assessed at the end of the instrumentation by recording how changes in sinus perfusion pressure influenced systemic arterial pressure. The mean maximum open loop gain[3] was 2.2 (SEM 0.3), that is systemic arterial pressure was changed inversely by 2.2 mm Hg per 1 mm Hg change in sinus perfusion pressure, calculated over a pressure interval of 25 mm Hg.

Systolic (SAP) and diastolic (DAP) arterial pressures were measured via a catheter inserted into a brachial artery and recorded on a Grass Polygraph (Grass Instruments, USA). Mean (MAP) arterial pressure was calculated using the formula: MAP=(SAP+2xDAP)/3. Heart rate (HR) was derived electronically from the arterial pressure recording.

Baroreflex activity was evaluated by changing carotid sinus perfusion pressure with arterial inflow to the bypass closed. This was accomplished by setting the pump in the bypass circuit at a steady state rate while a variable portion of the bypass flow was directed through the shunt to the external jugular vein by continuously adjusting a clamp around the shunt tubings. Sinus perfusion pressure was increased by the pump from 50 to 200 mm Hg in steps of 25 mm Hg. Recordings of arterial pressures and HR were performed at steady state after 15 min at each of the following eight stages: (1) ventilation with air; (2) ventilation with 70% nitrous oxide in oxygen; (3) ventilation with air; (4) ventilation with air. Bolus injection of fentanyl 10 μg kg^{-1} followed by an infusion of fentanyl 4 μg kg^{-1} h^{-1}; (5) ventilation with 70% nitrous oxide in oxygen. Continued infusion of fentanyl 4 μg kg^{-1} h^{-1}; (6) ventilation with air. Bolus injection of fentanyl 40 μg kg^{-1} followed by an infusion of fentanyl 16 μg kg^{-1} h^{-1}; (7) ventilation with 70% nitrous oxide in oxygen. Continued infusion of fentanyl 16 μg kg^{-1} h^{-1}; and (8) ventilation with air. At steady state, 15 min after (7), naloxone 30 μg kg^{-1} was injected i.v.

STATISTICAL ANALYSIS

Data were analysed by repeated analysis of variance and Duncan's multiple range test. $P<0.05$ was considered significant. All data are presented as mean (SEM).

Results

CAROTID SINUSES PERFUSED AT SYSTEMIC ARTERIAL PRESSURE

Fentanyl decreased arterial pressure in a dose-dependent manner during air ventilation. Although no significant changes in HR from baseline were induced by fentanyl, HR was significantly lower after the high dose than after the low dose of the drug ($P<0.01$, table 1).

Fentanyl-induced changes in DAP and HR were reversed by naloxone, while SAP and MAP were increased above baseline values ($P<0.01$ and $P<0.05$, respectively, table 1).

Administration of nitrous oxide in oxygen compared with ventilation with air did not induce any significant changes in arterial pressures or HR during basal chloralose anaesthesia with or without the addition of fentanyl (table 2).

CAROTID SINUS PERFUSION PRESSURES CONTROLLED ARTIFICIALLY

Fentanyl decreased MAP throughout the range of carotid sinus perfusion pressures (50–200 mm Hg; ANOVA main effects $P<0.001$ for both fentanyl doses). At sinus perfusion pressures of 50, 75 and 100 mm Hg, fentanyl caused a dose-related decrease in MAP (fig. 1). Baroreflex gain was not changed by low-dose fentanyl, while high-dose fentanyl reduced the gain for sinus perfusion pressure intervals of 50–75, 75–100 and 100–125 mm Hg (fig. 1). Although no significant changes in HR from baseline were induced by fentanyl, HR was significantly lower after high-dose compared with low-dose fentanyl (ANOVA main effects; $P<0.05$, table 3).

Fentanyl-induced decreases in MAP and baroreflex gain were reversed by naloxone. At carotid sinus pressures of 50, 75 and 100 mm Hg, MAP was increased significantly above baseline (fig.1).

When air was replaced by nitrous oxide in oxygen before administration of fentanyl, MAP increased at carotid sinus perfusion pressures of 75, 100 and 125

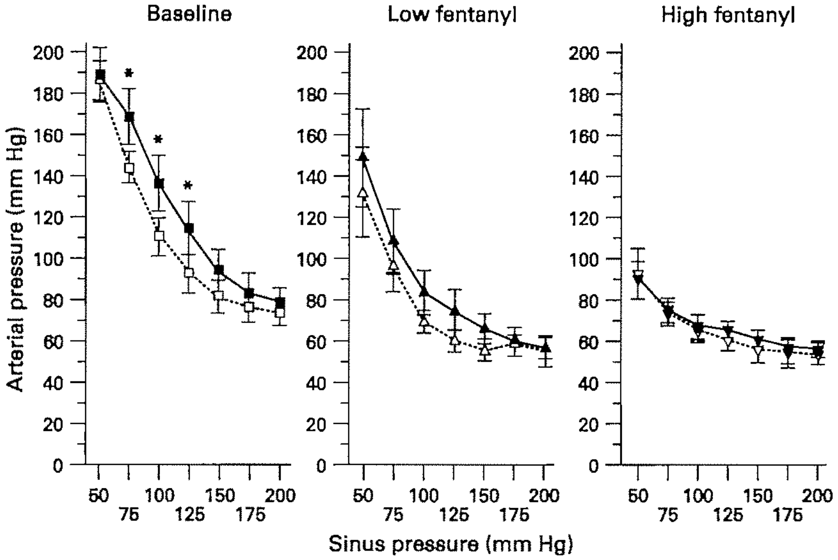

Figure 2 Baroreflex responses (systemic mean arterial pressure (MAP) *vs* carotid sinus perfusion pressure) in animals receiving either air (open symbols, interrupted lines) or nitrous oxide (filled symbols, solid lines) (mean, SEM). Panels show the following stages: baseline; low-dose fentanyl; high-dose fentanyl. $^*P<0.05$.

mm Hg (fig. 2), while baroreflex gain at 50–75 mm Hg decreased. HR responses were unchanged by nitrous oxide in oxygen (table 3).

After fentanyl, addition of nitrous oxide did not affect arterial pressures (fig. 2) or baroreflex gain. However, in the presence of fentanyl at the low and high doses, nitrous oxide in oxygen increased HR (ANOVA main effects; $P<0.05$ and $P<0.01$) (table 3).

Discussion

The aim of this study was to investigate the effect of generally used components of balanced anaesthesia, namely nitrous oxide and fentanyl, on high pressure baroreceptor reflex function. We used an animal experimental model which merits some comments on methodology.

First, we cut the vagus nerves to avoid secondary influences from cardiopulmonary low pressure reflexes[4,5]. As this procedure also denervates the baroreceptors of the aortic arch, only carotid baroreflex responses were evaluated. However, aortic baroreceptors primarily modulate high pressure responses[6,7] and thus are less likely to be significant for the overall cardiovascular reflex response to lowered arterial pressure, the object of this study. Second, the degree of baroreceptor activation depends on the carotid sinus perfusion pressure level and the velocity of the pulsatile pressure change. In our model, the profile of the pump-generated carotid sinus pressure wave differed from pressure waves normally produced by the pumping heart. This implies different baroreceptor activation compared with the intact animal at similar arterial pressure levels. However, the pulsatile characteristics of the pump-generated carotid pressure wave were essentially similar at each phase of the experiment, as pump rate was kept constant. Changes in carotid

Table 3 Heart rate (HR) at different carotid sinus perfusion pressures at baseline and after administration of fentanyl, nitous oxide (N_2O) and naloxone (mean (SEM))

sinus perfusion pressure were obtained by adjustments of the arteriovenous shunt in the extracorporeal circuit. This experimental perfusion design constitutes the basis for the comparisons in this study.

Nitrous oxide has been shown previously to increase systemic vascular resistance in combination with 1% halothane in humans[8] and in combination with pentobarbitone in dogs[9]. These findings, and other data in humans[10 11], indicate that nitrous oxide induces an increase in efferent sympathetic nervous activity (SNA). We observed circulatory effects (increased MAP) of nitrous oxide only when the carotid sinuses were perfused at pressures in the medium range (75–125 mm Hg). We suggest this reflects efficient baroreflex suppression of adrenergic nitrous oxide effects during intense baroreceptor activity (sinus perfusion pressure ≥150 mm Hg) and a background of pre-existing intense sympathetic outflow in the face of maximal baroreceptor unloading (sinus perfusion pressure <75 mm Hg). At these two extremes in sinus pressure, it is conceivable that nitrous oxide, although having sympatomimetic effects, adds only minimally to the prevailing degree of sympathetic discharge. These findings are in agreement with those of Bagshaw and Cox[12] in the dog during light halothane anaesthesia.

Fentanyl has been shown to reduce sympathetic and increase vagal neural tone[13–16]. These effects may depend on facilitation of impulse transmission at the dorsal nucleus of the vagus nerve and nucleus tractus solitarii of the baroreflex pathway[17 18]. However, the reduction in MAP produced by fentanyl throughout the sinus perfusion pressures used in our study, with vagotomized animals, indicated reduced sympathetic output or direct cardiovascular organ effects, or both. At low sinus perfusion pressures, we observed a dosedependent effect of fentanyl on MAP, probably reflecting the effects of fentanyl on the baroreflex as a dose-dependent reduction in baroreflex gain was observed at perfusion pressure increments of 50–125 mm Hg.

The effect of fentanyl on the baroreflex represents dose-dependent depression of baroreceptor arterial pressure control, as also shown in newborn infants[19]. Despite the fact that nitrous oxide attenuated the baroreceptor reflex, it did not further depress reflex control of arterial pressure when added to fentanyl at any of the infusion rates.

Data from this study support findings from other studies in humans[20] where resetting of the baroreflex has been found after fentanyl[19] and after the combination of fentanyl, diazepam and nitrous oxide[20]. Kortly and co-workers[20] also found that baroreflex control of heart rate was attenuated after lower doses of fentanyl (7.5 mg kg^{-1}). However, in their study and at higher doses of fentanyl (10 and 12.5 mg kg^{-1}) there was a discrepancy between baroreflexmediated tachycardia and bradycardia induced by lowered and increased arterial pressures compared with lower doses of fentanyl. This was postulated to be the result of enhanced vagal efferent activity mediated by fentanyl. In our study we did not find this difference in systemic arterial pressures or heart rate after low and high carotid sinus pressures, probably because we used vagotomized animals. However, species differences cannot be excluded. Furthermore, differences between human and nonerect walking animals in baroreceptor reflexes seem to apply mainly to low pressure cardiopulmonary receptors[21–24]. In our model these were excluded by vagotomy thus allowing for selective analysis of the high pressure carotid sinus part of the baroreceptor reflexes.

Naloxone was given to reverse the circulatory effects of fentanyl. After administration of naloxone, arterial pressure was not only restored but exceeded baseline arterial pressure. It is not clear from our study if this overshoot in arterial pressure reflected the central or peripheral effects of naloxone. Similar effects with naloxone have been observed in other studies. For example, in a study in conscious rabbits, naloxone increased arterial pressure both before and after sinoaortic barodenervation, but the increase was more pronounced after denervation. This indicates that the baroreceptor reflex buffers an increase in arterial pressure[25]. In other studies, naloxone has been shown to increase baroreflex sensitivity[26–29].

Effect of sevoflurane anaesthesia on plasma concentrations of glutathione S-transferase

D. C. RAY, R. BOMONT, A. MIZUSHIMA, T. KUGIMIYA, A. FORBES HOWIE AND G. J. BECKETT

Summary

To assess the effect of sevoflurane anaesthesia on hepatocellular integrity, we measured plasma concentrations of glutathione S-transferase (GST) before anaesthesia and 1, 3, 6 and 24 h after the end of anaesthesia in 41 healthy, Japanese patients undergoing elective, body surface surgery. Sevoflurane (approximately 1.0 MAC) was delivered in 50–66% nitrous oxide in oxygen via a circle system, with a fresh gas flow of 6 litre min^{-1}. Ventilation was spontaneous in all patients. Mean duration of anaesthesia was 101 min. Concentrations of GST increased significantly 1 h after the end of anaesthesia (P=0.0075), but this was not significantly different from preoperative concentrations at 3, 6 and 24 h. Three patients developed a large secondary increase in GST concentrations at 24 h. The increase observed at 1 h was probably a result of reduced total liver blood flow; the mechanism for the secondary increase at 24 h is unclear but the possibility that products of sevoflurane biotransformation are responsible cannot be excluded. (*Br. J. Anaesth.* 1996;**77**:404–407)

Key words

Anaesthetics volatile, sevoflurane. Toxicity, hepatic. Enzymes, glutathione S-transferase.

Sevoflurane is a relatively new inhalation anaesthetic agent which has recently been licensed for clinical use in the UK[1]. It undergoes more biotransformation than isoflurane and enflurane[2], although its low blood-gas solubility coefficient and rapid elimination are thought to preclude prolonged elevated concentrations of metabolites and resultant organ dysfunction[3–5]. Studies investigating hepatic function after sevoflurane anaesthesia in humans would tend to support this view[3 4 6 7], although there are at least four case reports of sevoflurane-associated hepatotoxicity in the Japanese literature[8–11]. Standard biochemical tests of liver function however, have limited use in the detection of minor degrees of anaesthetic-related liver dysfunction. In contrast, measurement of glutathione S-transferase (GST) concentration in plasma provides a highly specific test of hepatocellular damage, and GST results correlate better with histological changes than do the aminotransferases[12]. GST concentrations increase transiently after anaesthesia with halothane[13–17] and enflurane[13] but not after isoflurane[13 14 17 18] or propofol[18 19]; the frequency of abnormal GST concentrations observed after halothane, enflurane and isoflurane anaesthesia correlates directly with the extent of metabolism and incidence of reported clinical hepatic dysfunction for these agents[13]. More recently, GST concentrations have been found to increase after sevoflurane anaesthesia in children[20], although experience with the particular GST assay used is limited.

We have measured GST concentrations in adult patients undergoing anaesthesia with sevoflurane to assess its effect on hepatocellular integrity.

Patients and methods

After obtaining approval from the Ethics Committee of Juntendo University, written informed consent was obtained from 50 healthy, Japanese patients, ASA I or II, undergoing elective general anaesthesia for body surface surgery which was expected to last 1–3 h. Exclusion criteria included obesity (body weight >20% above ideal weight), excessive alcohol intake (>3 u. day^{-1}), previous liver disease or exposure to general anaesthesia in the preceding 3 months. Patients receiving medications likely to interfere with liver function were also excluded.

Premedication was not given. Anaesthesia was induced with thiopentone 3–5 mg kg^{-1} i.v. in a dose sufficient to abolish the eyelash reflex, and suxamethonium 1 mg kg^{-1} i.v. was given to facilitate tracheal intubation if necessary. Anaesthesia was maintained with approximately 1.0 MAC of sevoflurane and 50–66% nitrous oxide in oxygen (sevoflurane MAC in 65% nitrous oxide: 1.4% for patients aged 25 yr, 1.1% for patients aged 40 yr, 0.87% for patients aged 60 yr [data on file, Abbott Laboratories]). Patients breathed spontaneously from a circle system delivered with a fresh gas flow rate of 6 litre min^{-1}; the carbon dioxide absorbent used was soda lime (Dragersorb 800, Drager, Germany). End-tidal concentrations of sevoflurane and carbon dioxide (Datex Capnomac AGM-103-30-00, Helsinki, Finland) were measured continuously throughout anaesthesia. The total dose of sevoflurane administered to each patient was calculated in MAC hours. Pentazocine was used for analgesia after surgery if required.

LABORATORY ANALYSIS

Blood was sampled immediately before induction of anaesthesia (time 0), and 1, 3, 6 and 24 h after the end of anaesthesia for measurement of plasma GST B_1 concentration by specific radioimmunoassay, as described previously[21]. All samples from the same subject were measured in the same assay run. Inter- and intra-assay coefficients of variation were <10% and <5%, respectively, over the range 2–25 µg litre^{-1}. The reference range for GST concentration is 0.5–4.8 µg litre^{-1}.

STATISTICAL ANALYSIS

Data were analysed by Friedman's two-way analysis of variance for repeated measurements. The Wilcoxon signed rank test was used to examine changes in GST concentration from time 0 to 1, 3, 6 and 24 h after induction of anaesthesia. $P<0.05$ was taken as significant. Analysis was performed with Minitab for Windows (version 10.2) run on a Dell Dimension computer.

Results

Of the 50 patients studied, nine were excluded from analysis; three patients needed to be paralysed and their lungs ventilated for surgical requirements, and six were administered extradural anaesthesia in addition to general anaesthesia. Data from the remaining 41 patients (27 male; mean age 42 (range 18–67) yr) were analysed. This sample size gave the study a power of 76% for a change in GST concentration of >0.5 µg litre^{-1}.

Thirty of these patients underwent minor or intermediate eye, nose or throat surgery; the remainder underwent relatively minor orthopaedic surgery such as arthroscopy. Forty patients received suxamethonium to facilitate tracheal intubation. The mean dose of thiopentone given for induction of anaesthesia was 263 (SD 39) mg and the mean sevoflurane dose administered for maintenance was 1.73 (range 0.59–3.18) MAC h. Mean duration of anaesthesia was 101 (45–155) min. Significant temporal changes in GST concentrations occurred after anaesthesia ($P<0.001$). Plasma GST concentrations increased significantly 1 h after the end of anaesthesia from time 0 ($P=0.0075$), but these were not significantly different from preoperative concentrations at 3, 6 and 24 h (table 1, fig. 1).

Although GST concentrations were still increased at 3 h this was not statistically significant ($P=0.069$). Ten patients had GST concentrations >4.8 µg litre^{-1} in blood samples obtained before anaesthesia; the overall pattern of GST changes after anaesthesia in these patients was similar to that in patients who had GST concentrations <4.9 µg litre^{-1} before anaesthesia. Three of these 10 patients had GST concentrations >4.8 µg litre^{-1} only in the sample obtained before anaesthesia. Three patients (7%) with preoperative GST concentrations within the reference range developed a large secondary increase in GST concentrations at 24 h (table 2). Seven of the 31 patients (23%) with preoperative GST concentrations <4.8 µg litre^{-1} developed an increased GST concentrations at some time during the study. No patient developed hypotension (mean arterial pressure <70% of pre-induction level), arterial oxygen saturation <94% or end-tidal carbon dioxide concentration >8 kPa at any time during anaesthesia.

Table 1 Median (1st, 3rd quartiles) glutathione S-transferase concentrations (µg litre^{-1}) in 41 patients receiving sevoflurane anasthesia. $^*P < 0.01$ compared with concentrations before anaesthesia

Before anaesthesia	1 h	3 h	6 h	24 h
2.8	3.9*	3.5	2.8	3.3
(2.0, 5.0)	(2.6, 5.3)	(2.6, 5.2)	(2.1, 3.8)	(1.6, 4.6)

Discussion

The results of this study suggest that sevoflurane influences plasma concentrations of GST after anaesthesia, confirming previous findings in children[20]. GST concentrations increased significantly from preoperative values 1 h after the end of anaesthesia, were still increased at 3 h and had decreased to preoperative concentrations at 6 and 24 h. We have demonstrated previously that GST concentrations increase 3 and 6 h after anaesthesia with halothane[13–16] and enflurane[15] but not after isoflurane[13 14]. Other workers have confirmed that GST concentrations increase after halothane but not after isoflurane anaesthesia[17] and have also demonstrated no change after propofol anaesthesia[18 19]. Reduced liver blood flow is believed to be responsible for these increases; alternative explanations such as variation in GST concentration throughout the day or reduced clearance of GST have been discounted previously[22]. Several studies have shown that sevoflurane has little overall effect on hepatic blood flow in experimental animals[23–26], although if hepatic arterial

Table 2 Plasma concentrations of glutathione S-transferase (µg litre^{-1}) in patients who developed a large secondary increase at 24 h

Before anaesthesia	1 h	3 h	6 h	24 h
1.4	2.6	2.6	2.8	7.3
2.8	4.9	4.4	4.0	10.2
4.7	6.3	7.2	5.8	9.4

flow is compromised there may be a smaller margin of safety against hypoxia with sevoflurane compared with halothane and isoflurane[27]. There is evidence in humans to suggest that sevoflurane reduces total hepatic blood flow[28], although this has not been confirmed by other workers[29,30]. Our findings appear to support the view that sevoflurane reduces hepatic blood flow in humans.

Three patients (7%) developed a much larger secondary increase in GST concentrations at 24 h. In a previous study, 18% of patients anaesthetized with halothane and 10% of those who received enflurane developed similar increases at 24 h; this later increase did not occur in patients after isoflurane anaesthesia[13]. The mechanism for these increases at 24 h is unclear but the possibility that products of biotransformation (including those of sevoflurane) are responsible cannot be excluded. The overall extent of sevoflurane metabolism in humans is approximately 5%[23], resulting in the formation of hexafluoroisopropanol (HFIP) and fluoride ion. Neither of these products is likely to be responsible for initiating hepatic damage[5]. Sevoflurane reacts with carbon dioxide absorbents resulting in generation of breakdown products. Five degradation products have been identified *in vitro*[31], although only compound A (and to a lesser extent compound B) is produced under conditions likely to be encountered clinically. Factors which alter the concentration of compound A include fresh gas flow, temperature of the soda lime and concentration of sevoflurane in the circle system. Low fresh gas flows are associated with an increase in temperature of the soda lime and increased concentrations of compound A which increase further with prolonged anaesthesia[32,33]. In this study, a fresh gas flow of 6 litre min^{-1} was used to prevent the build up of a significant concentration of compound A. While there is debate about the potential for compound A to induce renal damage, there is no suggestion that it may initiate hepatic damage[34]. We do not believe that compound A is responsible for the observed increase in GST concentration.

The reference range for GST concentration in adult patients in the UK is 0.5–4.8 µg litre^{-1}; the range for the Japanese population is not known. As 10 patients (20%) in this study had preoperative GST concentrations >4.8 µg litre^{-1}, it could be argued that there is a different reference range for Japanese patients. However, the pattern of GST response after anaesthesia was similar if these patients were excluded from analysis, and therefore the overall conclusion from this study is unaltered. Three of these 10 patients had GST concentrations > 4.8 µg litre^{-1} in the preoperative sample only, suggesting that in these patients increased GST concentrations may have resulted from fasting, as has been described previously[22].

We conclude that sevoflurane anaesthesia is associated with a transient increase in plasma GST concentrations after anaesthesia, reflecting a minor degree of impaired hepatocellular integrity. Some patients develop increased GST concentrations 24 h after sevoflurane anaesthesia; the reasons for this secondary increase are unclear and require further investigation.

Normovolaemic haemodilution attenuates cardiac depression induced by sodium bicarbonate in canine metabolic acidosis[†]

M. TANAKA, T. NISHIKAWA AND T. MIZUTANI

Summary

This study was designed to determine if coexisting metabolic acidosis or normovolaemic haemodilution, or both, modifies the acute cardiodepressant effect of i.v. sodium bicarbonate. Thirty-one mongrel dogs were anaesthetized with halothane, and the lungs ventilated mechanically; dogs were allocated randomly to one of four groups: control group (pHa 7.39 (SD 0.03), base excess −1.0 (1.6) mmol litre^{-1}, haemoglobin 13.9 (2.5) g dl^{-1} (n=8)), metabolic acidosis group (pHa 7.21 (0.05), base excess −11.2 (2.1) mmol litre^{1}, haemoglobin 13.4 (2.6) g dl^{-1} (n=8)), anaemia group (pHa 7.40 (0.04), base excess 0.1 (2.0) mmol litre^{-1}, haemoglobin 7.2 (1.1) g dl^{-1} (n=8)) or anaemia acidosis group (pHa 7.22 (0.04), base excess −11.0 (2.2) mmol litre^{-1}, haemoglobin 7.4 (0.3) g dl^{-1} (n=7)). Metabolic acidosis was induced by continuous i.v. infusion of hydrochloric acid 2 mol litre^{-1}. Normovolaemic haemodilution was undertaken by phlebotomy and simultaneous exchange with lactated Ringer's solution at 37 °C. Mean arterial pressure (MAP), pulmonary artery pressure, right atrial pressure (RAP), maximum rate of change of pressure in the right ventricle (RV dP/dtmax) and pulmonary blood flow (PBF) were measured at 30 s, 1 and 3 min after administration of 7% sodium bicarbonate solution 1 mmol kg^{-1} given into the right atrium over 5 s. Sodium bicarbonate produced significant decreases in MAP and RV dP/dtmax at 30 s in all groups except for the anaemia acidosis group ($P<0.05$). There was a significant decrease in right ventricular stroke volume in the metabolic acidosis group from baseline values ($P<0.05$), and compared with the three other groups ($P<0.05$). These results indicate that the cardiodepressant effect of sodium bicarbonate 1 mmol kg^{-1} i.v. during metabolic acidosis was more pronounced than without acidosis, but was attenuated in the presence of normovolaemic haemodilution. (*Br. J. Anaesth.* 1996;**77**:408–412)

Key words

Acid–base equilibrium, metabolic acidosis. Acid-base equilibrium, respiratory acidosis. Complications, hypercapnia. Pharmacology, sodium bicarbonate. Dog.

Massive haemorrhage and systemic hypotension treated by replacement with crystalloid solution are frequently accompanied by metabolic acidosis and haemodilution. Although administration of sodium bicarbonate may be considered in these situations, it may reduce peripheral oxygen availability by increaseing extracellular pH[1] and produce paradoxical intracellular acidosis by free diffusion of carbon dioxide liberated from bicarbonate[2,3]. Depression of cardiac performance and peripheral vascular dilatation as a result of paradoxical intracellular acidosis have been implicated in circulatory alterations after bicarbonate administration[4]. A combination of these effects has detrimental consequences both metabolically and haemodynamically[5,6]. A recent study has demonstrated that maximum depression of cardiac performance by bicarbonate is more pronounced during metabolic acidosis than without acidosis in *in vivo* canine preparations[7].

When normovolaemia is maintained, progressive anaemia causes a modest increase in cardiac output with little change in arterial pressure and heart rate (HR) in both humans[8,9] and animals[10–12]. Systemic vascular resistance is decreased because of peripheral vascular dilatation secondary to anaemia. The pharmacologically depressed myocardium has diminished ability to increase cardiac output in response to haemodilution[10]. How augmentation of cardiac output in response to haemodilution is modified by the presence of metabolic acidosis is unknown. In addition, the effects of coexisting metabolic acidosis and normovolaemic haemodilution on myocardial depression produced by sodium bicarbonate have not been examined.

This study was designed in an *in vivo* canine preparation to assess the effects of normovolaemic haemodilution on the acute cardiovascular effects of sodium bicarbonate at physiological arterial pH (pHa) and with metabolic acidosis at a pHa value of approximately 7.2.

Materials and methods

The study was approved by our institutional Animal Care Committee. We studied 32 adult mongrel dogs of both sexes, weighing 10.5–15 kg. All dogs were

anaesthetized with thiamylal 15 mg kg^{-1} and the trachea intubated. The lungs were ventilated mechanically with room air supplemented with oxygen via a cuffed tracheal tube, using a volume-cycled animal ventilator (model R-60, Aika Co., Ltd, Tokyo, Japan). End-tidal halothane concentrations were measured continuously (Capnomac Ultima, Datex, Helsinki, Finland) and maintained at 0.65–0.75%. Suxamethonium 20 mg was given i.v. at the time of tracheal intubation followed by 10 mg h^{-1} thereafter to produce neuromuscular block. During all measurements, pulmonary arterial blood temperature was maintained at 35.8–38.0 °C. Lactated Ringer's solution was administered at a constant rate of 10 ml kg^{-1} h^{-1} during surgical preparation and equilibration period, followed by 5 ml kg^{-1} h^{-1} during haemodynamic measurements.

An i.v. cannula was inserted into a forelimb vein for administration of lactated Ringer's solution. Lead II of the electrocardiogram (model 2236A, NEC San-ei Instruments Co., Ltd, Tokyo, Japan) was monitored continuously using subcutaneous electrodes. HR was measured on a beat-to-beat basis by a cardiotachometer (model 1321, NEC San-ei Instruments Co., Ltd, Tokyo, Japan) triggered by lead II of the electrocardiogram. Measurement of arterial pressure and blood sampling for blood-gas analysis and measurement of haemoglobin concentration (288 Blood Gas System, Ciba-Corning, Medfield, MA, USA) were performed via the femoral arterial catheter. A flow-directed, balloon-tipped pulmonary artery catheter (5Fr Thermodilution Catheter, Arrow, Reading, PA, USA) was inserted via the femoral vein to permit continuous monitoring of pulmonary artery pressure. Another catheter was positioned in the right atrium from the contralateral femoral vein for monitoring right atrial pressure (RAP). A 5-French gauge catheter-tipped transducer (model MPC-500, Miller Instruments Inc., Houston, TX, USA) was inserted via the right external jugular vein and positioned in the right ventricle to obtain maximum rate of change of pressure in the right ventricle (RV d*P*/d*t*max) using a differential amplifier (model 1323, NEC San-ei Instruments Co., Ltd, Tokyo, Japan).

After the pulmonary trunk was dissected free of the surrounding tissue through a left-sided thoracotomy in the fourth intercostal space, an electromagnetic flow probe of appropriate size (model FR 12–16 mm, Nihon-Koden Co., Ltd, Tokyo, Japan) was placed around the pulmonary trunk for continuous measurement of pulmonary blood flow (PBF). The flow probe was calibrated with 0.9% saline solution *in vitro* before implantation, and PBF was measured continuously with a square-wave electromagnetic blood flowmeter (model MFV-3200, NihonKoden Co., Ltd, Tokyo, Japan). All recordings were made on an eight-channel recorder (model Recti-Horiz-8K, NEC San-ei Instruments Co., Ltd, Tokyo, Japan).

The dogs were allocated randomly to one of four groups: control (*n*=8), metabolic acidosis (*n*=8), anaemia (*n*=8) or anaemia acidosis (*n*=8). After a stabilization period of at least 2 h after the surgical procedures, in the control group (Pa_{CO_2} 4.9–5.7 kPa and base excess > −3 mmol $litre^{-1}$) 7% sodium bicarbonate solution 1 mmol kg^{-1} (1.2 ml kg^{-1}) was given into the right atrium over 5 s, and haemodynamic variables were recorded continuously for 3 min. Ventilator settings were kept constant during these measurements.

Metabolic acidosis of base deficit less than −8 mmol $litre^{-1}$ was induced and maintained in the metabolic acidosis group by continuous infusion of hydrochloric acid 2 mol $litre^{-1}$ at an approximate rate of 10–15 ml h^{-1}, while Pa_{CO_2} was maintained at 4.9–5.7 kPa. After a stabilization period of at least 2 h, after establishment of the target metabolic acidosis, 7% sodium bicarbonate solution 1 mmol kg^{-1} (1.2 ml kg^{-1}) was given into the right atrium over 5 s, and the same haemodynamic measurements made.

The anaemia and anaemia acidosis groups were treated similarly to the control and metabolic acidosis groups except that normovolaemic haemodilution was produced to obtain haemoglobin concentrations of 7–7.5 g dl^{-1}. Normovolaemia was produced by phlebotomy and simultaneous exchange with lactated Ringer's solution at 37 °C in a ratio of approximately 1:3 aided by the stability of pulmonary artery occlusion pressure (PAOP). In the anaemia acidosis group, haemodilution preceded metabolic acidosis.

All values are expressed as mean (SD). Both mean arterial pressure (MAP) and mean pulmonary artery pressure (MPAP) were obtained by electronic integration of pulse pressure. Right ventricular stroke volume (RVSV) was calculated as PBF divided by HR. Analysis of changes in haemodynamic variables from baseline (30 s, 1 and 3 min) and comparison of data between the four groups (baseline values and maximum changes from baseline) were performed using one-way and two-way ANOVA, respectively, followed by the Student's *t* test with Bonferroni's correction. $P<0.05$ was considered the minimum level of statistical significance.

Results

One dog from the anaemia acidosis group died before completing the study and only data from the remaining 31 dogs were analysed. Mean values of pHa and base excess in the metabolic acidosis and anaemia acidosis groups were significantly lower than those in the control and anaemia groups, whereas there were no differences in Pa_{CO_2} and Pa_{O_2} values between the groups (table 1). Haemoglobin concentrations in the anaemia and anaemia acidosis groups were significantly lower than those in the control and metabolic acidosis groups (table 1). There were no differences in plasma electrolyte concentrations between the groups (table 1).

There were no differences in PAOP values before and after haemodilution, immediately before administration of sodium bicarbonate in the anaemia group (6.5 (3.2) *vs* 6.7 (3.3) mm Hg, respectively) and in the anaemia acidosis group (5.4 (0.9) *vs* 5.2 (1.3) mm Hg, respectively). Before administration of sodium bicarbonate, PBF in the anaemia acidosis group was significantly greater than in the control group ($P<0.05$, table 2). Similarly, RVSV in the anaemia acidosis group was significantly greater than that in the control and metabolic acidosis groups ($P<0.05$, table 2). Compared with baseline values, administration of 7% sodium bicarbonate 1.2 ml kg^{-1} produced consistent but transient increases in RAP in all groups ($P<0.05$, table 2). Transient but signifi-

cant decreases in MAP and RV d*P*/d*t*max occurred in all groups except for the anaemia acidosis group. In the non-acidosis groups (the control and anaemia groups), PBF and RVSV increased significantly from baseline values at the end of the observation period. PBF and RVSV values in the metabolic acidosis group decreased significantly for a period of 1 min after administration of sodium bicarbonate. The percentage reduction in RVSV in the metabolic acidosis group at 30 s after administration of bicarbonate was significantly more than in the three other groups ($P<0.05$, table 2). HR was unchanged after administration of sodium bicarbonate in all groups. The mean times at which maximum changes in MAP, RV d*P*/d*t*max and PBF occurred were all within 20 s of bicarbonate administration: MAP: 18 (7), 19 (11), 17 (4), 13 (4) s; RV d*P*/d*t*max: 16 (2), 20 (4), 14 (3), 16 (4) s; PBF: 17 (3), 20 (6), 15 (6), 17 (6) s in the control, metabolic acidosis, anaemia and anaemia acidosis groups, respectively.

Discussion

We have observed cardiodepressant effects associated with rapid administration of sodium bicarbonate 1 mmol kg^{-1} in control, metabolic acidosis and anaemia groups, demonstrated by significant depression of RV d*P*/d*t*max, and this response was attenuated in the anaemia acidosis group. It is not explained simply by dilution, as depression of RV d*P*/d*t*max was also observed in the anaemia group. Maximum reductions in RV d*P*/d*t*max, PBF and MAP occurred within 20 s of administration of bicarbonate, but the changes were transient. Although the extent and duration of these changes may not be clinically important, they may be significant in patients undergoing cardiopulmonary bypass where normovolaemic haemodilution is practised, and also after massive bleeding and haemodilution complicated by metabolic acidosis.

The cardiodepressant effect of bicarbonate is considered to be caused by a rapid decrease in the intracellular pH of the myocardium caused by free diffusion of carbon dioxide liberated from bicarbonate[2], rather than a result of volume expansion[13]. The fact that such a detrimental effect of bicarbonate is more pronounced during metabolic acidosis suggests that a further reduction in intramyocardial pH occurs with pre-existing extracellular acidosis at pHa 7.2. A marginally reduced intracellular pH is not cardiodepressant in itself, as evidenced by comparable haemodynamic variables between the control and metabolic acidosis groups in our study and previous experiments[14–16].

It is not clear from our study why the haemodynamic response to sodium bicarbonate was more pronounced during metabolic acidosis but less marked when there was coexisting normovolaemic haemodilution. Clinical[8 9] and experimental[10–12] studies have observed typical responses to normovolaemic haemodilution characterized by an increase in stroke volume and cardiac index, and a decrease in systemic vascular resistance, with essentially no changes in arterial pressure and HR. One possible explanation is that these underlying haemodynamic changes induced by haemodilution may have counteracted the cardiodepressant effect of bicarbonate.

There are three possible shortcomings to our study. First, this was not a dose–response study, and interpretation of the results should be confined to the doses studied. Most importantly, bicarbonate was given over a brief period of time. A smaller dose of bicarbonate or slower speed of injection could have resulted in less depression of the myocardium[4]. The dose of bicarbonate in our study has been used in previous studies and is recommended in some circumstances during cardiopulmonary resuscitation[4 17 18]. In addition, the degree of metabolic acidosis studied would not be expected to produce significant cardiovascular depression[14–16]. With more profound acidosis where myocardial depression caused by acidosis *per se* is apparent, cardiac depression induced by bolus administration of bicarbonate may be more aggravated. Second, we did not determine circulating blood volume. In previous experiments, a ratio of 1:2.5 of bleeding and exchange crystalloid infusion resulted in a constant blood volume estimated by ^{125}I-labelled albumin in dogs[11]. In contrast, exchange transfusion with a ratio of 1:3 has been reported to produce progressive metabolic acidosis, hypovolaemia and eventually death[19]. These previous conflicting results may be attributed in part to the differences in time for equilibration. Our study has confirmed that an equilibration period of at least 2 h is required after surgical preparation, establishment of acidosis or haemodilution, during which lactated Ringer's solution was infused continuously. A significant amount of extravasation of plasma, had it occurred during this period, must have been replaced, as indicated by the unchanged PAOP before and after haemodilution, before administratin of bicarbonate in the anaemia and anaemia acidosis groups.Third, administration of hydrochloric acid effectively induced extracellular acidosis, but we did not measure intracellular pH. However, greater depression of cardiac performance with administration of bicarbonate in the metabolic acidosis group than in the control group suggests marginally disturbed intracellular environment by maintenance of extracellular pH at 7.2 for 2 h or longer. In an *in vivo* experiment using rabbits, i.v. infusion of hydrochloric acid followed by an equilibration period of 1 h produced dose-dependent linear decreases in intracellular pH of the left ventricular myocardium[20].

Inhalation of a nitric oxide synthase inhibitor to a hypoxic or collapsed lung lobe in anaesthetized pigs: effects on pulmonary blood flow distribution

F. FREDÉN, J. E. BERGLUND, A. REBER, M. HÖGMAN AND G. HEDENSTIERNA

Summary

I.v. administration of the nitric oxide synthase inhibitor, nitro-L-arginine methyl ester (L-NAME), not only reduces blood flow in a hypoxic lung region but also causes systemic vasoconstriction and a decrease in cardiac output. In this study, we delivered nebulized L-NAME 0.2–1 mg kg^{-1} to the left lower lobe of 10 anaesthetized pigs. The left lower lobe was made hypoxic by selective inhalation of 5% oxygen or collapsed by interrupted ventilation, or both. Inhalation of L-NAME reduced fractional blood flow to the left lower lobe from 5.3 (SD 3.1)% to 1.7 (1.4)% ($P<0.05$) in lobar hypoxia and from 6.0 (3.3) to 2.7 (2.7)% ($P<0.05$) in lobar collapse. These reductions were accompanied by a significant increase in Pa_{O_2}. There were no significant changes in arterial pressure, cardiac output or heart rate. We have shown that selective inhalation of L-NAME reduced blood flow to a hypoxic or collapsed lung region without systemic effects. The possible role for nitric oxide synthase inhibition in reducing shunt during one-lung ventilation, however, requires further study. (*Br. J. Anaesth.* 1996;**77**:413–418)

Key words

Pharmacology, nitric oxide. Ventilation, one-lung. Lung, blood flow. Pig.

In 1980, Furchgott and Zawadski[1] reported that vasodilatation caused by acetylcholine was endothelium-dependent and that endothelial cells, when stimulated, can release substances that cause relaxation of vascular smooth muscle. One substance has been identified as nitric oxide[2 3].

There is now evidence that nitric oxide is produced in the lung and is important in the regulation of the tone of the pulmonary vessels. Endogenous nitric oxide production has been demonstrated by Gustafsson and colleagues[4] who measured nitric oxide in the exhaled breath of rabbits and humans. When the rabbit was hypoxaemic, the exhaled nitric oxide concentration decreased. Nitric oxide synthase, constitutive and inducible, has been found in many cell types in human lung tissue[5].

Inhaled nitric oxide at concentrations of 5–80 ppm has been shown to diminish or abolish the hypoxic vasoconstrictor response and pulmonary hypertension caused by thromboxane analogues in conscious lambs[6 7] and in a porcine model of adult respiratory distress syndrome (ARDS)[8]. Inhalation of nitric oxide may reduce pulmonary hypertension in healthy volunteers breathing hypoxic gas[9] and in patients with ARDS[10].

When endogenous nitric oxide production was blocked by administration of L-arginine analogues, anaesthetized rabbits developed hypoxaemia and an increase in respiratory frequency[11]. There was also an increase in pulmonary vascular resistance, which was more marked during hypoxia than during normoxia. In regional lung hypoxia, blockage of endogenous nitric oxide production caused a shift of blood away from the hypoxic region and improved arterial oxygenation[12 13]. By inhaling nitric oxide to the non-hypoxic region, this blood shift was more accentuated and blood flow to the hypoxic region was almost abolished[13]. These findings indicate that administration of nitric oxide inhibits hypoxic pulmonary vasoconstriction and that blockage of endogenous nitric oxide production enhances it. The combination of inhaled nitric oxide and nitric oxide synthase inhibitors provides a method of altering pulmonary blood flow distribution that may be of clinical use in acute lung injury and in one-lung ventilation. However, i.v. administration of nitric oxide synthase inhibitors causes systemic effects with increased systemic arterial pressure and lowered cardiac output[13].

In this study, we have examined the hypothesis that *inhalation* of a nitric oxide synthase inhibitor, nitro-L-arginine methyl ester (L-NAME), to a hypoxic lung region would decrease blood flow to this region without causing systemic effects. The study was performed in an animal model where hypoxia was induced in the left lower lobe. To simulate one-lung ventilation we also studied the effect of inhaled L-NAME to a subsequently collapsed left lower lobe.

Materials and methods

The study was approved by the Animal Research Ethics Committee of Uppsala University. Twelve pigs of Swedish country breed, weighing 25–32 kg, were used in the study. The animals were premedicated with pentobarbitone 20 mg kg^{-1} and atropine 0.5 mg i.p. Anaesthesia was induced 30 min later with pentobarbitone 180–360 mg i.v. and maintained with a continuous infusion of chlormethiazole 800–1600 mg h^{-1} [14] and pancuronium 4–8 mg h^{-1}. Repeated

Accepted for publication: February 20, 1996.

doses of fentanyl 0.2–0.5 mg i.v. were given as necessary. After induction, the animals were placed in the supine position for the remainder of the study. Isotonic saline 10–15 ml kg^{-1} h^{-1} was given for hydration.

VENTILATION

A tracheotomy was performed after induction of anaesthesia and two cuffed tracheal tubes were inserted. One tube with an internal diameter of 6.0 mm was positioned in the trachea and the second, with an internal diameter of 4.5 mm, was placed in the bronchus of the left lower lobe. In this way, the left lower lobe could be isolated and ventilated independently, a technique described in detail in a previous report[13]. Two synchronized, volume-controlled ventilators (Siemens Servo ventilator 900 C, Siemens Elema, Lund, Sweden) were used and 30% of the total minute ventilation was administered to the left lower lobe. This volume corresponded to the weight of the left lower lobe as a percentage of the total weight of both lungs (unpublished data, Fredén and colleagues, 1993). Both ventilators were adjusted to give a positive end-expiratory pressure (PEEP) of +5 cm H_2O and the inspired oxygen fraction (F_{IO_2}) was set at 0.8. The oxygen cell of the ventilator was used to measure F_{IO_2}. Ventilatory frequency was maintained at 20 bpm and tidal volume was adjusted to obtain a Pa_{CO_2} of 5.2–6.2 kPa. To prevent atelectasis, the lungs were ventilated three times with a double tidal volume at the beginning of each measurement period (see experimental design).

PREPARATION

An ear vein was cannulated for induction and maintenance of anaesthesia. A triple-lumen, balloon-tipped catheter (Swan Ganz No. 7-French gauge) was introduced via the right external jugular vein to the pulmonary artery for blood sampling and pressure recording. A large bore catheter was inserted into the contralateral jugular vein for infusion purposes with its tip in the superior caval vein. The right carotid artery was cannulated to measure arterial pressure and sample blood.

Via a median sternotomy, the artery to the left lower lobe and the pulmonary artery were identified, ultrasonic flow probes were attached and connected to a flowmeter (probes, 6 SB and 12 SB; flowmeter, T208; Transonic, Ithaca, NY, USA).

MEASUREMENTS

Arterial, central venous and pulmonary artery catheters were attached to appropriate pressure transducers (Sorenson Transpac transducers, Abbott Critical Care Systems, IL, USA). Mean arterial pressure, mean pulmonary arterial pressure, central venous pressure and pulmonary capillary wedge pressure were recorded on a Marquette 7010 monitor (Marquette Electronics Inc., WI, USA). Pressures were averaged over the whole respiratory cycle and the mid-thorax was used as the zero reference level.

Mixed venous and arterial blood samples were collected for blood-gas analysis (ABL 3, Radiometer, Copenhagen, Denmark), oxygen saturation and haemoglobin concentration (OSM 3, Radiometer, Copenhagen, Denmark). Cardiac output and blood flow to the left lower lobe were measured continuously with the flow probes.

Mean airway pressure and expired minute volume were recorded from both ventilators.

EXPERIMENTAL DESIGN

After preparation, a rest period of 30 min was allowed before baseline measurements were obtained. Each set of measurements comprised mean arterial pressure, mean pulmonary artery pressure, heart rate, central venous pressure, pulmonary capillary wedge pressure, cardiac output, blood flow to the left lower lobe, arterial and mixed venous blood-gas tensions, saturations and airway pressures. F_{IO_2} was maintained at 0.8 in the right lung and the upper and middle lobes of the left lung. Three different settings were used for the left lower lobe: baseline and control (F_{IO_2} 0.8), lobar hypoxia (5% oxygen, 5% carbon dioxide and 90% nitrogen (AGA, Lidingo, Sweden)) and lobar collapse (with the ventilator to the left lower lobe disconnected). Thirty minutes were allowed at each setting before measurements were made.

L-NAME (Sigma Chemical Co, St Louis, MO, USA) was dissolved in isotonic saline 20 ml and delivered to the left lower lobe with an ultrasonic nebulizer (De Vilbiss, Ultraneb 99, PA, USA). Inhalation of L-NAME was always performed during lobar hypoxia as preliminary experiments had shown that inhalation during normoxia caused systemic effects, presumably because of increased absorption of L-NAME caused by larger lobar blood flow.

The different experiments used in the study are outlined in table 1. In four animals, the effect of inhaled L-NAME was tested during both lobar hypoxia and lobar collapse. To ensure that a preceding period of lobar hypoxia did not interfere with any effects of lobar collapse on blood flow or vice versa, three animals were investigated with lobar collapse only and three with lobar hypoxia only. Evaluation of these different designs showed no differences in the response to lobar hypoxia or collapse and therefore the results are given for the two groups: lobar hypoxia (n=7) and lobar collapse (n=7).

Re-opening of the left lower lobe after lobar collapse was controlled in two ways. Via the thoracotomy, the lobe was examined visually to ensure that no parts of the lobe were atelectatic and, before inhalation of L-NAME, fractional blood flow to the left lower in the control situation was compared with the baseline recording.

In three of the animals with lobar collapse, a third period of lobar collapse was induced, measurements were performed and followed by i.v. injection of L-arginine 1 g kg^{-1} (Sigma Chemical Co, St Louis, MO, USA) to reverse the effect of L-NAME, and new recordings were performed.

In two additional animals, L-NAME 0.2 mg kg^{-1} was delivered to both lungs and systemic and pulmonary haemodynamic measurements, and arterial and mixed venous blood-gas tensions were measured during normoxia and hypoxia (F_{IO_2} 0.12) before and after inhalation. Cardiac output was measured with thermodilution as no thoracotomy was performed, 10 ml of isotonic saline at room temperature were injected as a bolus and cardiac output was computed

Table 1 A survey of the three different experimental designs used in the study showing F_{IO_2} to the right lung and upper and middle lobes of the left lung (F_{IO_2} RL), and F_{IO_2} to the left lower lobe (F_{IO_2} LLL); "X" marks the different steps in each experiment. Experiment I included four animals and experiments II and III three each. Experiments I and II were used for the "lobar hypoxia" group (n=7) and experiments II and III for the "lobar collapse" group (n=7) (see tables 2 and 3)

	Baseline	Lobar collapse	Control	Lobar hypoxia	Inhalation L-NAME	Lobar hypoxia	Control	Lobar collapse	Control

Experiment III (n=3)	X	X	X		X		X	X	X

Table 2 Lobar perfusion and arterial oxygenation in the two groups given lobar inhalation of L-NAME (mean (SD)). Fractional blood flow to the left lower lobe (Q_{LLL}/Q_T) and arterial oxygenation at baseline (F_{IO_2} 0.8), during lobar hypoxia-collapse before and after L-NAME, and in the control situation (F_{IO_2} 0.8). Ten animals were used for these two groups; of these, four were studied during both lobar hypoxia and lobar collapse, hence n=7 in both groups (also see table 1). Wilcoxon signed rank test was performed to compare baseline with control ($^*P < 0.05$) and to compare conditions during lobar hypoxia–collapse before and after L-NAME ($^\dagger P < 0.05$)

	Lobar hypoxia				Lobar collapse			
	Baseline	Before L-NAME	After L-NAME	Control	Baseline	Before L-NAME	After L-NAME	Control
Q_{LLL}/Q_T (%)	23.2 (5.5)	5.3 (3.1)	1.7 (1.4)†	18.8 (4.5)*	21.2 (6.5)	6.0 (3.3)	2.7 (2.7)†	19.2 (4.0)
Pa_{O_2} (kPa)	38.9 (8.5)	23.3 (6.7)	28.8 (9.2)†	36 (4.6)	37.5 (9.9)	21.6 (4.7)	24.8 (6.0)†	33.9 (8.7)

(cardiac output computer Marquette 7010, Marquette Electronics Inc., WI, USA). Three injections were given for each measurement and the mean calculated. The injections were distributed evenly over the respiratory cycle.

When the experiment was completed the animal was killed with an i.v. injection of potassium chloride and the lungs were removed for inspection.

Fractional blood flow to the left lower lobe was calculated as blood flow to the left lower lobe divided by cardiac output. Pulmonary vascular resistance (PVR) was calculated using standard formulae.

STATISTICS

All data are given as mean (SD). Two paired comparisons were performed: between baseline data before inhalation and control data after inhalation of L-NAME; and between lobar hypoxia–collapse data before and after inhalation of L-NAME. Wilcoxon's signed rank test was used and P<0.05 was considered significant.

Results

Table 2 shows fractional blood flow to the left lower lobe and arterial oxygenation for the two groups with lobar hypoxia and lobar collapse, and table 3 shows other essential data for the two groups. The following recordings are presented: baseline, hypoxia–collapse preceding administration of L-NAME, hypoxia–

Table 3 Inhalation of L-NAME during lobar hypoxia and lobar collapse (mean (SD)). Data shown are baseline (F_{IO_2} 0.8) before lobar hypoxia–collapse, during lobar hypoxia–collapse before and after inhalation of L-NAME, and in the control situation (F_{IO_2} 0.8) after inhalation of L-NAME. Ten animals were used for these two groups; of these, four were studied during both lobar hypoxia and lobar collapse, hence n=7 in both groups (also see table 1). Cardiac output (Q_T), arterial carbon dioxide tension (Pa_{CO_2}), mean arterial pressure (MAP), heart rate (HR), mean pulmonary arterial pressure (MPAP), pulmonary capillary wedge pressure (PCWP), central venous pressure (CVP), mixed venous oxygen tension ($P\bar{v}_{O_2}$) and pulmonary vascular resistance (PVR) are shown. Wilcoxon signed rank test was performed to compare baseline with control in the two groups ($^*P < 0.5$) and to compare conditions during lobar hypoxia–collapse before and after inhalation of L-NAME ($^\dagger P < 0.05$)

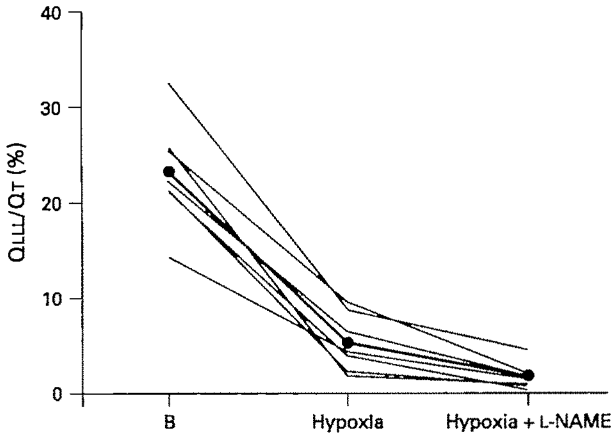

Figure 1 Relative perfusion (*QLLL/QT*) to the left lower lobe at baseline (B) and during lobar hypoxia, before (Hypoxia) and after (Hypoxia+L-NAME) inhalation of L-NAME 0.2–1 mg kg^{-1}. Individual and mean values (bold line) are shown. The marked decrease in lobar perfusion by hypoxia was enhanced significantly by inhalation of L-NAME.

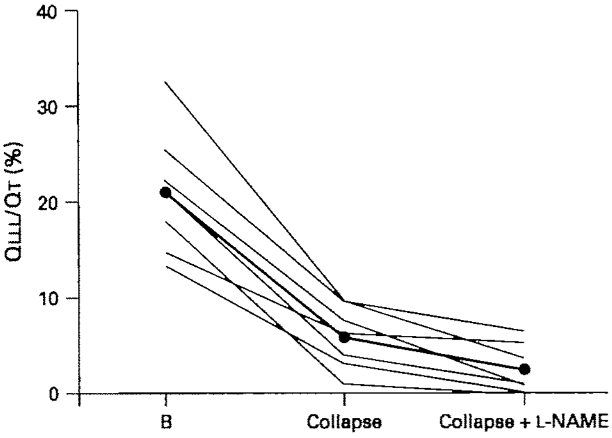

Figure 2 Relative perfusion (*QLLL/QT*) to the left lower lobe at baseline (B) and during lobar collapse, before (Collapse) and after (Collapse+L-NAME) inhalation of L-NAME 0.2–1 mg kg^{-1}. Individual and mean values (bold line) are shown. The marked decrease in lobar perfusion caused by lobar collapse was enhanced significantly by inhalation of L-NAME.

pcollapse subsequent to L-NAME and the last control recording.

BASELINE

At baseline, cardiac output, mean arterial pressure, mean pulmonary arterial pressure, central venous pressure and pulmonary capillary wedge pressure values were similar to those reported previously for pigs undergoing mechanical ventilation with healthy lungs[15]. Fractional blood flow to the left lower lobe was 23.2 (5.5)% in the hypoxic group and 21.1 (6.5)% in the lobar collapse group, which is in accordance with previous reports[13]. Arterial oxygenation was good with Pa_{O_2} values of 38.9 (8.5) kPa and 37.5 (9.9) kPa, respectively. Both groups were normocapnic. During the course of the experiment, mean airway pressure in the left lower lobe varied from 8.7 (0.5) to 9.9 (0.2) cm H_2O and, in the right lung and upper and middle lobes of the left lung, 9.9 (0.4) to 10.4 (0.2) cm H_2O; these changes were not significant (data not shown in tables).

LOBAR HYPOXIA AND L-NAME

Hypoxia of the left lower lobe caused a marked reduction in fractional blood flow to the left lower lobe to 5.3 (3.1) % and a decrease in Pa_{O2}. Mean pulmonary arterial pressure increased by a mean of 5 mm Hg. Delivery of L-NAME to the hypoxic left lower lobe caused a further reduction in fractional blood flow to the left lower lobe to 1.7 (1.4) % ($P<0.05$) (see fig. 1) and a significant increase in Pa_{O_2}. There were no significant changes in cardiac output, heart rate or mean arterial pressure. There was a further increase in mean pulmonary arterial pressure. When the left lower lobe again received hyperoxic gas (FI_{O_2} 0.8), after inhalation of L-NAME, a persistent decrease in lobar perfusion and increase in mean pulmonary arterial pressure were seen compared with baseline measurements, whereas Pa_{O_2} did not differ significantly from baseline.

LOBAR COLLAPSE AND L-NAME

Collapse of the left lower lobe caused a reduction in fractional blood flow to the left lower lobe to 6.0 (3.3) % and a decrease in Pa_{O_2}. There was also an increase in mean pulmonary arterial pressure by a mean of 3 mm Hg. Re-opening of the lobe (FI_{O_2} 0.8) before L-NAME increased fractional blood flow to the left lower lobe to 19.4 (4.0) % and Pa_{O_2} to 35.8 (6.3) kPa. These values did not differ significantly from baseline (data not shown in tables).

When the left lower lobe was collapsed a second time, after inhalation of L-NAME, fractional blood flow to the left lower lobe decreased to 2.7 (2.7) % ($P<0.05$) (fig. 2) and Pa_{O_2} increased significantly. There was a small, non-significant increase in mean pulmonary arterial pressure. There were no significant changes in cardiac output, heart rate or mean arterial pressure. When the left lower lobe at the end of the experiment was ventilated with 80% oxygen, fractional blood flow to the left lower lobe and Pa_{O_2} did not differ significantly from baseline measurements, but mean pulmonary arterial pressure remained increased.

L-ARGININE

I.v. injection of L-arginine 1 mg kg^{-1} to three animals reversed the reduction in fractional blood flow to the left lower lobe caused by inhaled L-NAME. In these pigs with lobar collapse, mean fractional blood flow to the left lower lobe was 9.1% before L-NAME and 3.9% after, while injection of L-arginine increased it to 8.7 % (fig. 3).

L-NAME TO BOTH LUNGS

After delivery of L-NAME to both lungs in two animals, there was an increase in mean arterial pressure of approximately 20 mm Hg both during normoxia and hypoxia. There was also an increase in mean pulmonary arterial pressure (3 mm Hg during normoxia and 4–5 mm Hg during hypoxia), but there was no change in cardiac output or arterial oxygenation.

Discussion

The major finding of this study was that selective inhalation of a nitric oxide synthase inhibitor to an hypoxic or subsequently collapsed lobe reduced

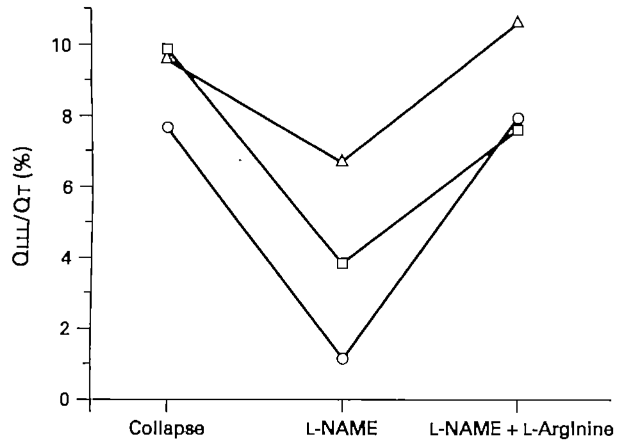

Figure 3 In three pigs with lobar collapse, L-arginine 1 g kg^{-1} was infused after inhalation of L-NAME; relative perfusion (*Q*LLL/*Q*T) of the collapsed lobe before inhalation of L-NAME (Collapse), after inhalation of L-NAME (L-NAME) and after infusion of L-arginine (L-NAME+L-Arginine). L-Arginine reversed the effect of L-NAME in all three animals.

blood flow to this lobe and improved arterial oxygenation without causing systemic effects. It has been reported previously that nitric oxide synthase inhibitors constrict pulmonary vessels and that this effect is more pronounced during hypoxic conditions[11]. In regional hypoxia, i.v. administration of nitric oxide synthase inhibitors enhances hypoxic pulmonary vasoconstriction and thus diverts blood flow away from the hypoxic region and improves arterial oxygenation[12 13]. However, i.v. administration of L-NAME causes an increase in mean arterial pressure and a decrease in cardiac output, except when used in very small doses [12 13].

Administration of L-NAME via the airways to the target organ, that is the hypoxic lobe, caused a reduction in lobar blood flow similar to that seen during i.v. infusion[13]. A much lower dose was delivered by nebulization than by infusion (0.2–1 mg kg^{-1} *vs* 30 mg kg^{-1}); however, no dose–response experiments were performed in either study. In this way, systemic effects could also be avoided and neither cardiac output nor mean arterial pressure changed. In addition, inhalation of L-NAME caused only a small increase in mean pulmonary arterial pressure by approximately 2–3 mm Hg, which can be compared with the pronounced increase seen after i.v. administration, when mean pulmonary arterial pressure increased by more than 15 mm Hg[13]. Delivery of L-NAME to both lungs in two animals, caused systemic effects with a pronounced increase in mean arterial pressure, presumably because of higher uptake of L-NAME to the systemic circulation.

Inhalation of nitric oxide synthase inhibitors, L-NAME and N^{G}-monomethyl-L-arginine (L-NMMA), has been shown previously to cause an increase in tracheal tone and also to induce airway hyper-responsiveness to histamine, carbachol and metacholine[16]. In this study, mean airway pressure did not change during or after inhalation of L-NAME but this does not preclude smaller alterations in airway tone.

In regional hypoxia, the hypoxic vasoconstrictor response has been reported to be complete after 15 min of hypoxia; prolonged hypoxia does not appear to potentiate or decrease this response[17 18] although one study reported differently[19]. Our measurements were performed after 30 min of hypoxia, at a time when the vasoconstrictor response was assumed to be stable. In atelectasis, the vascular response is of similar magnitude, but Glasser and colleagues reported it to be slower, with a maximal response after 60 min[20]. Our recordings were made after 30 min of lobar collapse, which according to Glasser and colleagues is too early, however, we found that lobar blood flow was always stable after 15–20 min of lobar collapse.

Repeated hypoxic challenges have been reported to potentiate the hypoxic vasoconstrictor response in lobar hypoxia in the dog[21] which, in our study, could be a cause of error. However, there are also reports showing no potentiation of hypoxic pulmonary vasoconstriction in dogs with unilateral hypoxia[22] or in humans[23]. To our knowledge, there are no reports of repeated regional hypoxia induced in pigs but unpublished data from our laboratory showed no enhancement of the hypoxic response after three periods of lobar hypoxia, each lasting for 30 min (Fredén and colleagues, 1995).

In the ventilated lung, alveolar oxygen is the most important determinant of hypoxic pulmonary vasoconstriction but, in atelectasis, $P\bar{v}_{O_2}$ becomes more important[24]. A reduction in $P\bar{v}_{O_2}$ could therefore decrease fractional blood flow to the left lower lobe and be a source of error; however $P\bar{v}_{O_2}$ did not alter in any of the groups in our study (see table 3).

The clinical implication of this study is one-lung ventilation in thoracic surgery. Inhalation of L-NAME to the lung that is not to be ventilated would, according to our results, decrease shunting and improve arterial oxygenation. Improvement in Pa_{O_2} in this study was not impressive but it is important to keep in mind that the pig is known to develop a very strong vascular response to hypoxia[25], and blood flow to the left lower lobe was reduced markedly during hypoxia or the collapse *per se* (see table 2). Furthermore, the effect of L-NAME may have been more marked if one entire lung had been rendered hypoxic rather than just one lobe. The use of one lobe instead of one lung in this study was because of the bronchial anatomy of the pig, which makes separation of the two lungs difficult. However, increased absorption of L-NAME to the circulation and ensuing systemic effects cannot be excluded if L-NAME is delivered to a whole lung.

In ARDS, inhalation of nitric oxide has been shown to improve oxygenation and lower pulmonary artery pressures[10]. A combination of inhaled nitric oxide and i.v. administration of a nitric oxide synthase inhibitor has been tested in animal models of ARDS[26 27]. Although the results have varied, it appears to be an interesting approach to constrict vessels in shunt areas. Obviously our model based on inhalation of L-NAME would not be feasible in ARDS; it might even be harmful, as L-NAME would only reach the ventilated areas and probably increase the degree of shunting.

In conclusion, the present study has shown that the selective delivery of nebulized L-NAME reduces blood flow to a hypoxic or collapsed lung lobe without causing any systemic effects. It may, in the future, be a way of reducing shunting during one lung ventilation; this, however, requires further study.

SHORT COMMUNICATIONS

Influence of patient position on withdrawal forces during removal of lumbar extradural catheters

G. N. MORRIS, B. B. WARREN, E. W. HANSON, F. J. MAZZEO AND D. J. DIBENEDETTO

Summary

We have investigated the force required to remove lumbar extradural catheters from 88 parturients to determine the effects of patient positioning at removal, relative to the position at insertion. Parturients were allocated randomly to one of four groups: LS (lateral insertion, sitting withdrawal), LL (lateral insertion, flexed lateral withdrawal), SL (sitting insertion, lateral withdrawal) or SS (sitting insertion, sitting withdrawal). In both positions, the lumbar spine was kept maximally flexed. The force required to remove the catheter was measured at withdrawal. We found that the withdrawal force was influenced by the relationship between the position at removal and that at insertion, and we recommend that for ease of removal, patients should be placed in the same position as they were at the time of insertion. Compared with all other groups, the withdrawal force in patients in group LS was significantly greater ($P<0.05$). (*Br. J. Anaesth.* 1996;**77**:419–420)

Key words

Equipment, catheters extradural. Anaesthesia, obstetric.

Extradural catheters are usually removed without complications. However, there are reports of catheters that are difficult to remove, catheter breakage and shearing[1 3]. Fragments of catheter may be sequestered in the extradural space. Removal of an extradural catheter also has the potential for inducing extradural haematoma formation[4]. Hence, minimizing the extraction force is desirable. Previous studies have indicated that the force at extraction of lumbar extradural catheters was significantly greater with patients sitting compared with the lateral position[5 6]. These studies did not consider the position of the patient at insertion as an influencing factor. At insertion, the catheter is passed through a firm Tuohy needle and is held in a straight line to the extradural space. We hypothesized that if patients were placed in the same position for removal as they were at insertion, the catheter would again take a straight course and be less likely to be held by adjacent structures (lumbar fascia, vertebral arches and vertebral processes).

Methods and results

We studied 88 parturients at the University Hospital requesting analgesia for labour and delivery, Caesarean section, or both, using a standardized set (Baxter Healthcare Corporation, Cat. No. 2T0023). The study was approved by the Human Investigation Committee at the University of Virginia and informed consent was obtained from all patients. Patients were allocated randomly to one of four groups, depending on the position of the patient during insertion of the extradural catheter (sitting (S) or lateral (L)) and the position during removal of the catheter: LL, SS, LS or SL. Patients were ASA I or II and the usual exclusion criteria, including chronic low back ache or previous lumbar spine surgery, were applied.

All extradural catheters were inserted via the L2–3 or L3–4 intervertebral space using a 17-gauge Tuohy needle with loss of resistance to normal saline to identify the extradural space. A 19-gauge, styletted extradural catheter, with bullet tip and three lateral eyes, was threaded to allow 2–5 cm to remain in the extradural space. The position of the patient during insertion and removal was either lying in the lateral position or sitting with the legs over the edge of the bed, according to group allocation. In both positions the lumbar spine, hips and knees were kept maximally flexed. The catheter was left *in situ* until after vaginal or Caesarean section delivery. At removal, the catheter was connected to a portable force gauge using a knot tied at the 20–30-cm catheter mark, and slow incremental traction was applied in a direction perpendicular to the skin of the back. Peak tension during withdrawal was measured by a Normark digital force gauge (Normark Corporation, Minneapolis, MN, USA) with an accuracy to within 0.56 Newtons (N). The investigator who inserted the catheter also removed the catheter in all but three cases, when they were removed by another investigator. All catheters were removed intact, without stretching or kinking. The duration that the catheter was in place (h), depth of the lumbar extradural space from the skin and length of the catheter left *in situ* just before withdrawal (SD 0.5 cm), were noted.

Patient data were comparable in the four groups (table 1). Ten unused catheters were clamped at the tip and tested for break strength using the same equipment.

Data were analysed by Kruskal–Wallis one-way analysis of variance, followed by Dunn's method for pairwise multiple comparison, using SigmaStat

(Jandel Scientific Software, San Rafael, CA, USA). $P<0.05$ was considered statistically significant. The power of the study was 0.79 (where difference in group mean to be detected was 1.0, expected SD of results=1.0, number of groups=4, group size=22 and $\alpha=0.05$). The force required to remove the catheters in group LS (lateral position at insertion, sitting position at removal) was significantly greater compared with all other groups (table 1). Comparison between the other groups revealed no significant differences. The greatest recorded force occurred in group LS (5.8 N). The mean break strength of 10 extradural catheters was 15.9 N, breakage occurring at the site of one of the three lateral eyes in all instances.

Comment

Minimizing the force at extraction of an extradural catheter may reduce the risk of breakage with sequestration. Previous studies advocated the lateral position for ease of removal[5,6] without considering the position of the patient at the time of insertion of the catheter. In this study we standardized all variables except that of position at insertion and removal.

We determined that significantly greater force was required to remove catheters in group LS compared with all other groups. Thus our findings agree with those of Boey and Carrie[4] who found that when catheters were inserted with patients in the lateral position, less force was needed if they were also removed in this position (group LL). We also identified a difference between groups LS and SS (different positions at insertion, both sitting at withdrawal) confirming the importance of the position of the patient at insertion in relation to the position at withdrawal, a fact that has not been documented previously. There was no detectable difference between groups SS and LL, implying that the sitting position at removal *per se* did not result in an elevated extraction force if the catheter was also inserted in this position. These are the groups in which the catheter was most likely to be held in a straight course at both insertion and removal. However, the significant difference between groups LS and SL (the position at removal differs from that at insertion in both groups) cannot be explained by a more tortuous course of the catheter alone, and indicates additional influencing factors.

We noted a large difference between the maximum recorded force at removal (5.8 N) and break strength of the catheters used (15.9 N). The weakest point of the catheter was at the site of the side wall perforations. However, should partial shearing occur inadvertently by manipulation of the catheter while the Tuohy needle is in place, the break strength may be reduced considerably.

In summary, the force required to remove lumbar extradural catheters was affected by the position of the patient both at insertion and removal. We agree with previous investigators that when an extradural catheter is placed with the patient in the lateral position, the withdrawal force is significantly elevated when this patient is seated at the time of removal[5,6]. However, when a catheter is placed in the sitting position, our results indicated that removal in this same position required no extra force. The position of the patient at extraction in relation to the position at insertion is an influencing factor which has not been recognized previously. Therefore, if resistance or stretching of the catheter occurs while attempting withdrawal, we recommend placing patients in the same position as they were at the time of insertion.

Effect of oral antihistamine premedication on mivacurium-induced histamine release and side effects†

A. DOENICKE, J. MOSS, W. LORENZ, M. MAYER, J. RAU, A. JEDRZEJEWSKI AND P. OSTWALD

Summary

In this randomized, double-blind, placebo-controlled study, we have examined histamine release, haemodynamic and cutaneous effects of mivacurium administered in low (0.105 mg kg^{-1}=1.5×ED_{95}) and high (0.21 mg kg^{-1}=3×ED_{95}) doses and assessed if oral pretreatment with H_1/H_2 antagonists would blunt the effects of mivacurium-induced histamine release. Patients received either ranitidine 300 mg and dimethindene 0.1 mg kg^{-1} (H_1 blocker) or placebo, orally 1 h before induction of anaesthesia. Twelve patients were allocated to each group. Although plasma concentrations of histamine increased significantly in three patients in the placebo group given low-dose mivacurium, the mean value for the group was unchanged. Plasma concentrations of histamine increased significantly in five patients in the placebo group after high-dose mivacurium and the mean value was increased. There was no consistent correlation between haemodynamic changes, cutaneous manifestations and histamine concentrations. Significant cardiovascular reactions occurred in six patients in the placebo groups and in only one patient treated with antihistamines. (*Br. J. Anaesth.* 1996;**77**:421–423)

Mivacurium is a non-depolarizing neuromuscular blocking agent with a relatively short duration of action. Increasing the dose of mivacurium may speed the onset of neuromuscular block, but may also increase histamine release and adverse haemodynamic effects[1 2]. Previous studies have shown that prophylactic use of i.v. antihistamines can attenuate many of the histamine-mediated side effects of atracurium[3]. In this randomized, double-blind, placebo-controlled study, we have investigated if oral antihistamines are effective in reducing the histamine-related side effects of mivacurium.

Methods and results

After obtaining approval from the hospital's Ethics Committee and written informed consent, we studied 48 ASA I-II patients of both sexes, aged 18–65 yr, weighing 45–100 kg, undergoing elective surgery. Subjects were allocated randomly to one of four groups. All patients received premedication with lormetazepam 2 mg orally, 1–2 h before induction of anaesthesia. One hour before induction of anaesthesia, patients received either ranitidine 300 mg and dimethindene 0.1 mg kg^{-1} or placebo orally. Anaesthesia was induced with thiopentone 5–7 mg kg^{-1} and maintained by spontaneous breathing of a mixture of 0.8–1.5% enflurane and 66% nitrous oxide in oxygen via a face mask. Six minutes after administration of thiopentone, mivacurium 0.105 mg kg^{-1} or 0.21 mg kg^{-1} was given over 30 s. Administration of drugs in our study differed from that of routine clinical practice in that there was a temporal delay of approximately 6 min between administration of thiopentone and neuromuscular block. This was done intentionally so that we might examine the individual effects of the two drugs.

Blood was obtained for measurement of plasma concentrations of histamine 1 min before administration of thiopentone, 3 and 5 min after thiopentone, and 3 and 5 min after mivacurium. Plasma concentrations of histamine were measured using the fluorometric enzymatic method[4]. Heart rate was measured continuously by ECG. Systemic arterial pressure was recorded by periodic, non-invasive measurement by an oscillation method (Dinamap, Critikon) every 1 min. Changes in arterial pressure or heart rate were considered significant if they deviated 20% from baseline values. We identified the most significant changes in arterial pressure or heart rate within the first 5 min of drug administration as peak levels. An investigator blinded to the study assessed cutaneous manifestations of histamine release on a scale described previously[5].

Data are presented as mean (SD). Data were analysed using the Mann–Whitney *U* and Wilcoxon tests. The effects of antihistamines in preventing mivacurium-induced flush were analysed by Fisher's exact test and the Mantel–Haenszel test, which permits combination of chi-square data[6].

†Presented in part at the annual meeting of the American Society of Anesthesiologists, October 1993.

There were no significant differences between the treated and placebo groups in age, weight, type of procedure or ASA classification (grades I or II).

Thiopentone alone caused similar decreases in arterial pressure and heart rate in both groups. Mean plasma concentrations of histamine did not increase after administration of thiopentone. While five patients in the placebo group and three in the antihistamine group had increased concentrations, there was no correlation between these changes and hypotension and flush (see table 1).

Comment

Plasma concentrations of histamine increased significantly in three patients in the placebo group given low-dose mivacurium, although the mean value was unchanged. After high-dose mivacurium, histamine concentrations were increased in five patients in the placebo group, and mean values increased from baseline values of 0.59 (0.56) to 5.91 (12.31) ng ml^{-1}. Antihistamines decreased mivacurium-induced histamine release. We had observed previously that pretreatment with similar regimens of i.v. antihistamines significantly reduced histamine concentrations 2 min after administration of atracurium (0.24 *vs* 0.38 ng ml^{-1}; $P<0.04$)[5]. Our results using oral antihistamines were even more dramatic. In those patients pretreated with antihistamines receiving high-dose mivacurium, however, the increase in mean plasma histamine concentrations was significantly attenuated (0.76 (1.14) *vs* 5.32 (12.22) ng ml^{-1}; $P\leq0.04$). We suggest therefore that in addition to receptor antagonism, another significant effect of antihistamines may be to inhibit drug-induced histamine release.

Heart rate and systolic arterial pressure did not differ significantly between the placebo and treatment groups after administration of mivacurium. In the treated group, only one patient (No. 21) showed significant cardiovascular changes after either low- or high-dose mivacurium, even in the presence of increased histamine concentrations. However, four patients in the placebo group exhibited significant tachycardia after high-dose mivacurium (table 1).

Table 1 Relationship between histamine concentrations (ng ml^{-1}) (before (baseline (B)) and after mivacurium (M)) and systolic arterial pressure (SAP), heart rate (HR) and cutaneous manifestations. Individual values are shown only for patients exhibiting significant cardiovascular changes or cutaneous manifestations, although mean (SD) values are shown for each treatment group. Values indicate peak concentrations or concentrations obtained after mivacurium. *Significant changes in histamine concentration compared with baseline; †significant changes (> 20%) in SAP and HR compared with baseline. In addition, two patients in the placebo group showed a marked decrease in systolic arterial pressure after high-dose mivacurium. In patient No. 4, heart rate increased (from 79 to 104 beat min^{-1}) coincident with a histamine concentration of 21.07 ng ml^{-1}, although there was no significant decrease in arterial pressure. In patient No. 44, arterial pressure decreased from 130/58 to 75/40 mm Hg after high-dose mivacurium. Six patients, all in the placebo group, showed evidence of significant histamine release without any evidence of hypotension. Neither the frequency nor extent of hypotension after administration of mivacurium were correlated significantly with histamine concentrations.

After low-dose mivacurium, a flush was seen in five patients, four of whom were in the placebo group (table 1). After high-dose mivacurium, the number of cutaneous reactions increased in both groups; nine in the placebo and four in the treated group. Although antihistamines did not influence the likelihood of flush after either low- or high-dose mivacurium (two-tailed Fisher's exact test, P=0.31 and P=0.09, respectively), when data from low- and high-dose mivacurium were combined there was convincing evidence for such protection (Fisher's exact test, P=0.03). Using the more definitive Mantzel–Haenszel test, the likelihood of flush in the antihistamine group compared with the placebo group was 0.25 and 0.44 (95% CI 0.32–1.89 and 0.18–1.05) for low- and high-dose mivacurium, respectively, and 0.38 (95% CI 0.17–0.86) when the data were combined.

Six of the seven significant cardiovascular changes observed were accompanied by flush, and four of the six exhibited concomitant increases in plasma concentrations of histamine. However, our findings, and those of our previous atracurium study[3], suggest that many patients flush without cardiovascular changes. In this study, flush occurred in 13 patients in the placebo group, although plasma histamine concentrations increased without flush or cardiovascular changes in two patients. We postulate that not all cutaneous manifestations associated with mivacurium are directly attributable to histamine release and thus may not be prevented by antihistamines.

Our results may have clinical implications. While significant hypotension occurred in three patients in the placebo group, only one of the antihistamine-treated patients sustained significant hypotension despite evidence of histamine release. In most patients, oral pretreatment with H_1 and H_2 antagonists appeared to be effective against mivacurium-induced rash or flush. It is well known that slow injection or the use of low doses of mivacurium may reduce histamine release after administration of mivacurium. Our results indicate that the use of oral H_1 and H_2 receptor antagonists represents another option for clinicians to prevent or at least reduce histamine-related side effects after administration of high-dose mivacurium.

Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block

M. NAGUIB, A. H. SAMARKANDI, H. S. BAKHAMEES, A. TURKISTANI AND S. W. ALHARBY

Summary

We have compared the reversal characteristics of mivacurium after administration of an edrophonium–plasma cholinesterase (PCHE) combination with that produced by each antagonist alone. Forty ASA I adults were given mivacurium 0.15 mg kg^{-1} during fentanyl–thiopentone–nitrous oxide–isoflurane anaesthesia. TOF stimulation was applied to the ulnar nerve every 12 s, and the force of contraction of the adductor pollicis muscle was recorded. When spontaneous recovery of first twitch height (T1) reached 10% of its initial control value, patients were allocated randomly to one of four groups (n=10 in each). Neuromuscular function in patients in group 1 (control group) was allowed to recover spontaneously. Patients in groups 2–4, respectively, received edrophonium 1 mg kg^{-1} (group ED), exogenous PCHE equivalent to activity present in 25 ml kg^{-1} of human plasma (group PCHE) or edrophonium 1 mg kg^{-1} with exogenous human PCHE equivalent to the activity present in 25 ml kg^{-1} of human plasma (combination group). The time to attain a TOF ratio of 0.75 in the combination group was 4.6 (SD 0.9) min. This was shorter (P<0.01) than that observed in patients in the control (16.8 (3.3) min), ED (8.9 (3.6) min) and PCHE (9.3 (1.6) min) groups. There was no difference in recovery indices between groups ED and PCHE. We have demonstrated that the edrophonium–PCHE combination significantly accelerated recovery of mivacurium-induced block compared with that observed with the use of individual antagonists. (*Br. J. Anaesth.* 1996;**77**:424–426)

Key words

Antagonists, enzyme, plasma cholinesterase. Antagonists, neuromuscular block, edrophonium. Monitoring, neuromuscular function. Neuromuscular block, mivacurium. Neuromuscular block, measurement of response.

Mivacurium chloride is a bis-benzylisoquinolinium non-depolarizing neuromuscular blocking agent[1]. Spontaneous recovery from 90% mivacurium block to 95% twitch height and train-of-four (TOF) of 0.75 normally occurs within 15 min[2]. We noted that these recovery times can be shortened by administration of edrophonium, neostigmine or human plasma cholinesterase (PCHE)[2 3].

Although both PCHE and edrophonium produce dose-dependent antagonism of mivacurium-induced block[2 4], each drug acts by a different mechanism. PCHE is an enzyme that enhances hydrolysis of mivacurium in plasma, whereas edrophonium (an anticholinesterase) acts mainly by increasing the concentration of acetylcholine in the end-plate region of the muscle. These differences in pharmacodynamic characteristics might confer some advantages in combining the two drugs in clinical practice. Accordingly, we have compared the reversal characteristics of mivacurium after PCHE and edrophonium in combination with that produced by each drug alone.

Methods and results

After obtaining institutional approval and informed consent, we studied 40 ASA I patients of both sexes, aged 16–51 (mean 34) yr, weighing 52–85 kg (mean 68.8 (SD 8.9) kg). All patients were undergoing elective procedures, had no neuromuscular, renal or hepatic disease, and were not receiving any drug known to interfere with neuromuscular function.

All patients received lorazepam 2 mg orally, 90 min before operation. An infusion of lactated Ringer's solution was given i.v. before induction of anaesthesia. The electrocardiogram, haemoglobin oxygen saturation by pulse oximetry and arterial pressure were monitored. Temperature was monitored by a nasopharyngeal thermistor and maintained at 36.5± 0.5 °C. Anaesthesia was induced with fentanyl 2 μg kg^{-1} and thiopentone 3–5 mg kg^{-1}, and maintained with 70% nitrous oxide and 0.5% inspired isoflurane in oxygen. Concentrations of isoflurane, nitrous oxide, oxygen and carbon dioxide were measured continuously by a multiple-gas analyser (Capnomac, Datex Instrumentarium Corporation, Helsinki, Finland). Ventilation was adjusted to maintain normocapnia (end-tidal carbon dioxide pressure 4.8–5.3 kPa).

Isoflurane was administered for 30 min before control twitch height was recorded. The ulnar nerve was stimulated supramaximally at the wrist with square pulses of 0.2-ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz every 12 s, using a Myotest peripheral nerve stimulator (Biometer International, Odense, Denmark). The resultant

contraction of the adductor pollicis muscle was recorded using a force displacement transducer and neuromuscular function analyser (Myograph 2000, Biometer International, Odense, Denmark). Preload tension on the thumb was maintained at 300 *g* throughout the study.

After a stable neuromuscular response was obtained for 10 min, the patient received mivacurium 0.15 mg kg^{-1} i.v. as a bolus dose. Tracheal intubation was performed when neuromuscular response was abolished. Additional increments of mivacurium 0.1 mg kg^{-1} were given to patients who required continued neuromuscular block whenever the first twitch recovered to 10% of the control value.

At the end of surgery, when first twitch height (T1) (the first response in the TOF) had recovered to 10% of control, patients were allocated randomly to one of four groups (n=10 in each). Neuromuscular function in patients in group 1 (control) was allowed to recover spontaneously, whereas patients in groups 2–4, respectively, received edrophonium 1 mg kg^{-1} (group ED), exogenous human PCHE equivalent to the activity present in 25 ml kg^{-1} of human plasma (group PCHE) or edrophonium 1 mg kg^{-1} with exogenous human PCHE equivalent to activity present in 25 ml kg^{-1} of human plasma (combination group). All drugs were given in 5 s into a rapidly flowing i.v. infusion. In the combination group (group 4), drugs were given simultaneously into two separate i.v. catheters inserted into one arm. Atropine 0.02 mg kg^{-1} was given to all patients who received edrophonium.

Serum cholinesterase P Behring was used in this study, which is a dry concentrate of highly purified enzyme. The contents of each vial (27–83 mg) are equivalent in activity to 500 ml of fresh normal human plasma. However, cholinesterase activity is standardized by the manufacturer. The purified human PCHE is derived from donor plasma, that is hepatitis B surfactant antigen-negative and anti-HIV-1-negative. It is pasteurized at 60 °C to inactivate DNA viruses. The risk of treatment with purified human PCHE is considered comparable with administration of human albumin.

The TOF ratio (the amplitude of the fourth evoked response as a fraction of the first evoked response: T4/T1) was recorded continuously in all patients until the TOF ratio recovered to 0.75 or more. Isoflurane was continued during this observation period. All patients were assessed in the recovery room, on admission and 10 min later, for signs of residual weakness by their ability to maintain 5-s head-lift, tongue protrusion and cough.

In all patients, two venous blood samples were obtained from an antecubital vein in the contralateral arm to that used for i.v. fluid administration for measurement of plasma cholinesterase activity. The first sample was obtained before induction of anaesthesia and the second when the TOF ratio had recovered to 0.75. Plasma cholinesterase activity was measured by the change in absorbance at 600 nm after hydrolysis of butyrylthiocholine to thiocholine, using Du Pont Dimension, Clinical Chemistry System (Wilmington, DE, USA).

Recovery times of the first twitch from 25% to 75% (recovery index) and from 10% to 95% of control, and time to a TOF ratio of 0.75 were compared using analysis of variance. Dunnett's test was used to compare the spontaneous recovery group with each of the other groups. Comparisons between groups that received different antagonists (groups 2–4) were carried out using Tukey's Studentized range method. All statistical analyses were carried out using BMDP statistical package, release 7.01 (University of California Press, Berkeley, CA, 1993). Unless otherwise specified, results are expressed as mean (SD). P<0.05 was considered statistically significant.

Baseline activity of PCHE was similar and within the normal range in all groups (reference range 7–19 iu ml^{-1}) (table 1). The activity in the second assay was greatest (P<0.01) in patients who received exogenous PCHE (groups 3 and 4) compared with those in groups 1 and 2.

Final T1 recovery was always within 10% of the initial control value. Indices of recovery are shown in table 1. The initial T1 recovery in all patients in the combination group and in two patients in group ED was >25% of control. The times taken for twitch height to recover from 25% to 75% and from 10% to 95% of control, and from 10% of control to a TOF=0.75 were significantly longer in patients in the control group compared with those in other groups (table 1). The time to attain a TOF ratio of 0.75 in the combination group was 4.6 (0.9) min. This was significantly shorter (P<0.01) than that observed in patients in groups ED and PCHE. There was no difference in recovery indices between groups ED and PCHE (table 1).

There was no indication of residual weakness in the recovery room after anaesthesia.

Comment

We have demonstrated that the time to attain a TOF ratio of 0.75 (after return to 10% first twitch height) was shorter ($P<0.01$) with a combination of edrophonium 1 mg kg^{-1} and exogenous human PCHE equivalent to activity present in 25 ml kg^{-1} of human plasma than that observed in patients in the control (16.8 (3.3) min), ED (8.9 (3.6) min) and PCHE (9.3 (1.6) min) groups. Further, both PCHE and edrophonium (in the doses used in this study and in patients with normal PCHE activity) had similar efficacy as antagonists of mivacurium-induced neuromuscular block (table 1).

The results of this study confirm our recently published data that administration of either edrophonium or exogenous PCHE equivalent to activity present in 25 ml kg^{-1} of human plasma results in reliable antagonism of mivacurium-induced neuromuscular block[2,3]. We have also demonstrated that when antagonism of mivacurium was attempted with edrophonium or PCHE alone, at 90% twitch depression, the time saved to return to TOF=0.75 compared with control was <8 min. However, with the use of the PCHE–edrophonium combination, mean time saved was >12 min.

Our data suggest that when recovery is established, residual mivacurium block is sensitive to both increases in PCHE activity and inhibition of acetylcholinesterase at the neuromuscular junction. The relative importance of both components cannot be determined from our study. Although the magnitude of recovery was similar after administration of either PCHE or edrophonium, the PCHE–edrophonium combination proved to be superior than any of the individual drugs alone. Each drug acts by a different mechanism. Increasing PCHE activity enhances hydrolysis of mivacurium in plasma. As the plasma concentration of mivacurium declines, there is net movement of mivacurium from the neuromuscular junction back into the blood. This accelerates recovery of neuromuscular function. In addition, inhibition of acetylcholinesterase at the neuromuscular junction facilitates recovery further. It should be noted, however, that the pharmacological action of edrophonium is not limited to inhibition of acetylcholinesterase. Evidence suggests that the direct influences of the acetylcholinesterase drugs on neuromuscular transmission involve at least three distinct, although possibly interacting mechanisms: (a) weak agonist action, (b) formation of desensitized receptor complex intermediates, and (c) alteration of the conductance properties of active channels[5].

The dose of PCHE equivalent in activity to 25 ml kg^{-1} of human plasma in a 65-kg patient represents, on average, the equivalent of PCHE activity of 1625 ml of adult human plasma. Serum cholinesterase P Behring concentrate is expensive, at approximately $US 300 for one vial, and the shelf-life is 2 yr. Therefore, the average cost of PCHE administered per patient in groups 3 or 4 is more than $US 1000. Nevertheless, because of the prohibitive cost of this compound, this reversal modality is unlikely to have a routine practical application at this time. A possible exception might be the individual who is homozygous for atypical butyrylcholinesterase[6].

Beneficial effects of dexmedetomidine on ischaemic myocardium of anaesthetized dogs†

P. M. H. J. ROEKAERTS, F. W. PRINZEN AND S. DE LANGE

Summary

We have studied the effect of dexmedetomidine during coronary artery stenosis (CAS) in dogs. Three periods of 15 min of CAS were induced at 40-min intervals in two groups of dogs (dexmedetomidine compared with placebo). Dexmedetomidine was administered before the second and third periods of CAS in doses of 1 and 3 µg kg^{-1}, respectively. Dexmedetomidine decreased plasma concentrations of noradrenaline by mean 71 (SEM 9) %, heart rate by 8 (4) %, cardiac output by 30 (6) % and increased mean arterial pressure by 23 (10) %. Dexmedetomidine reduced blood flow in non-ischaemic myocardium and in the ischaemic epicardial layer by 16 (8) %, but blood flow was preserved in the ischaemic mid-myocardial and subendocardial layers. Consequently, dexmedetomidine increased the ischaemic–non-ischaemic blood flow ratio. Dexmedetomidine did not change myocardial oxygen consumption but decreased myocardial oxygen demand from 4.91 (0.33) to 3.76 (0.25) µmol min^{-1} g^{-1}, thereby reducing the oxygen deficiency of the ischaemic myocardium from 1.47 (0.37) to 0.29 (0.32) µmol min^{-1} g^{-1}. (*Br. J. Anaesth.* 1996;**77**:427–429)

Preliminary studies suggest that perioperative use of dexmedetomidine may result in a decreased risk of adverse cardiac events, including myocardial ischaemia[1]. This probably depends on a centrally mediated sympatholytic effect which decreases catecholamine-mediated stress responses. In contrast with these beneficial central effects, α_2 agonists may also cause peripheral and coronary vasoconstriction by stimulation of postjunctional α_2 adrenergic receptors. The effect of this vasoconstriction during myocardial ischaemia is controversial. Heusch and Deussen presented evidence that α_2 adrenoreceptor activation can worsen ischaemia[2]. In contrast, other investigators reported that α adrenoreceptor stimulation can beneficially modulate coronary blood flow during myocardial ischaemia by preventing transmural redistribution of blood flow away from ischaemic endocardium[3].

The aim of this study was to determine if systemic dexmedetomidine has beneficial effects on ischaemic myocardium in an animal model known to be highly sensitive to the direct, peripheral vasoconstrictor effect of α_2 agonists.

Methods and results

After obtaining animal Ethics Committee approval, mongrel dogs were anaesthetized with pentobarbitone and their lungs ventilated with 1% halothane and nitrous oxide in oxygen. The dogs were instrumented, as described previously[4], to measure aortic and left ventricular pressure and cardiac output. A cuff was placed on the left descending coronary artery (LAD). Coronary pressure was measured distal to the cuff. The degree of stenosis was controlled by keeping constant mean perfusion pressure distal to the stenosis using a Servo system feeding a motor pump, which determined the degree of cuff inflation. Global myocardial oxygen demand was estimated using the pressure–work index[5]. Regional oxygen consumption was measured from blood flow (radioactive microspheres) and local arterial–coronary venous oxygen content difference. Oxygen deficiency was calculated by subtracting oxygen consumption from oxygen demand.

Five minutes before the first period of CAS, control blood samples were obtained and haemodynamic measurements were performed. Thereafter, CAS 1 was induced by reducing mean pressure in the LAD distal to the stenosis to 40% of mean arterial pressure. After 12 min of stenosis, microspheres were injected. Two minutes later, blood samples were obtained and haemodynamic measurements performed. Thereafter, the CAS was released. Twenty minutes after release of the stenosis, measurements were repeated, followed by administration of dexmedetomidine 1 µg kg^{-1} in the active drug group (n=11) and saline in the placebo group (n=9). Twenty minutes after administration of dexmedetomidine, measurements were repeated followed by a second period of stenosis. Measurements during stenosis and the subsequent recovery period were the same as during the first episode of stenosis. This procedure was repeated a third time after administration of dexmedetomidine 3 µg kg^{-1} in the drug group.

†Presented in part at the 9th Annual Meeting of the European Association of Cardiothoracic Anaesthesiologists, June 1994, Turku, Finland.

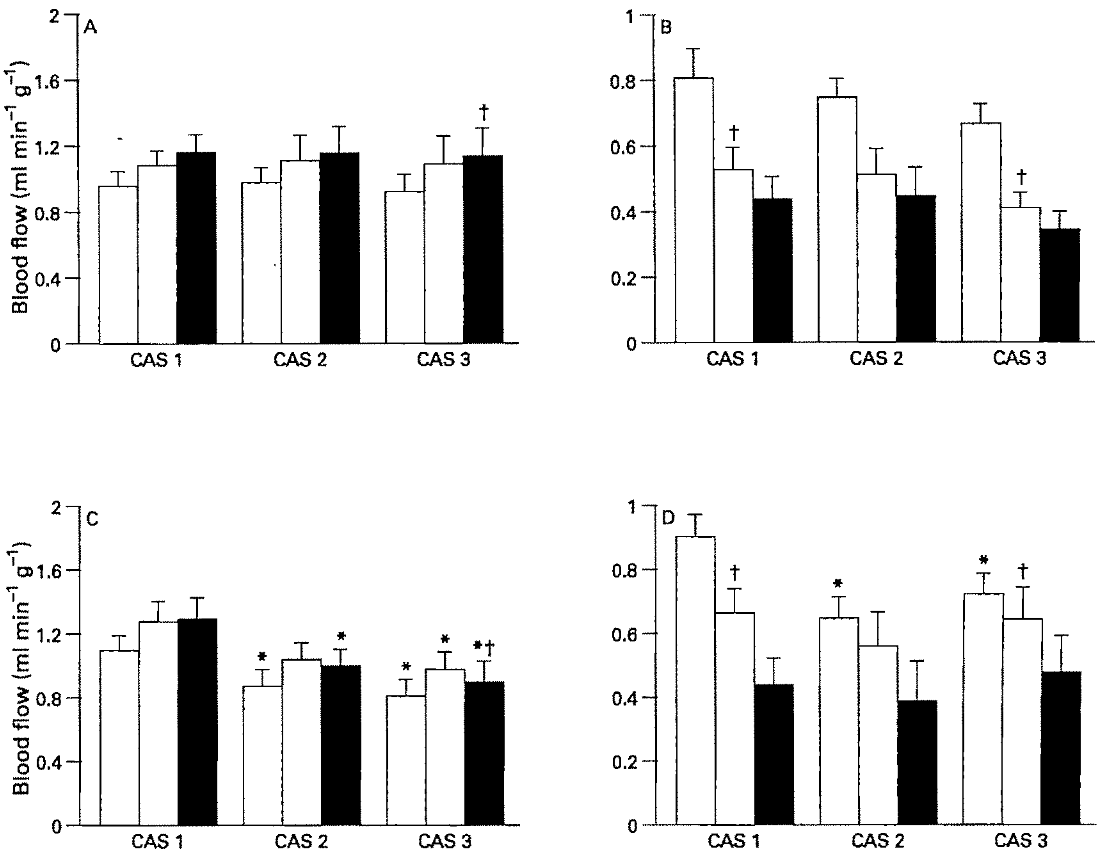

Figure 1 Regional blood flow distribution in non-ischaemic (left, A and C) and ischaemic (right, B and D) myocardium in the placebo (upper, A and B) and drug (lower, C and D) groups, measured with radioactive microspheres. Transmural samples were obtained from the perfusion area of the LAD (ischaemic myocardium) and from the posterior wall and interventricular septum (non-ischaemic myocardium). Samples were divided into subendocardial, mid-wall and subepicardial layers. In this way, coronary blood flow was measured simultaneously in non-ischaemic and ischaemic myocardium during the three stenoses. Shaded bars=epicardial flow; open bars=mid-myocardial flow; solid bars=endocardial flow. CAS=Coronary artery stenosis. Data are mean (SEM); *n*=9 in the placebo group, *n*=11 in the drug group. *Significantly different from corresponding CAS 1 value; †significantly different from corresponding value in other group.

Two-way ANOVA for repeated measures was used for inter-group comparisons. Intragroup comparisons were evaluated using one-way ANOVA for repeated measures and Fisher's protected LSD test as *post hoc* test. Baseline values between the two groups were compared using Student's *t* test. $P<0.05$ was considered significant. Results are expressed as mean (SEM).

Dexmedetomidine decreased heart rate (from 126 (6) to 114 (5) beat min^{-1}), d*P*/d*t*max (from 1371 (128) to 1177 (62) mm Hg s^{-1}) and cardiac output (from 4.2 (0.3) to 2.4 (0.4) litre min^{-1}) and increased mean arterial pressure (from 81 (4) to 98 (4) mm Hg) and systemic vascular resistance (from 1572 (131) to 3902 (563) dyn s cm^{-5}). In the placebo group, no haemodynamic changes were observed throughout the study.

Dexmedetomidine decreased plasma concentrations of noradrenaline from 121 (17) to 25 (12) pg ml^{-1}.

After dexmedetomidine 3 μg kg^{-1}, ischaemic–non-ischaemic blood flow ratios were significantly higher in the epicardial (from 0.81 (0.07) to 0.93 (0.09) and endocardial (from 0.33 (0.06) to 0.47 (0.10) layers compared with placebo (fig. 1).

Dexmedetomidine increased haemoglobin concentration from 7.2 (0.2) to 8.4 (0.3) mmol litre^{-1} and decreased myocardial oxygen demand from 4.91 (0.33) to 3.76 (0.25) μmol min^{-1} g^{-1}. Regional myocardial oxygen consumption did not change after dexmedetomidine (from 3.08 (0.39) to 3.20 (0.51) μmol min^{-1} g^{-1}). Dexmedetomidine decreased myocardial oxygen deficiency from 1.47 (0.37) to 0.29 (0.32) μmol min^{-1} g^{-1}.

Comment

In this study, dexmedetomidine decreased myocardial oxygen demand and reduced blood flow in non-ischaemic myocardium. This was related to its haemodynamic effects; reduction in heart rate and d*P*/d*t*max. Blood flow in the ischaemic inner layers was preserved. In this way, the ischaemic–non-ischaemic blood flow ratio decreased and myocardial oxygen deficiency was reduced.

The effects of dexmedetomidine on regional blood flow in ischaemic myocardium are in accordance with studies on the effects of aspecific α block or stimulation during ischaemia[5]. Preservation of blood flow in ischaemic myocardium by α_2 agonists is probably caused by more powerful local metabolic stimuli during ischaemia, which overrule adrenergic vasoconstriction. As the degree of ischaemia is most severe in the inner layers during hypoperfusion, adrenergic vasoconstriction in this region is inhibited to a greater extent than in the outer layer.

Distal to a flow-limiting stenosis, such specific epicardial vasoconstrictive effect may lead to improvement in endocardial perfusion, the "reverse steal" effect[3]. The decrease in heart rate after dexmedetomidine could be an additional explanation for this beneficial effect on blood flow, because slowing of the heart rate favours endocardial relative to epicardial perfusion. The different findings of Heusch and Deussen[2] who found that α_2 adrenergic activation can worsen myocardial ischaemia, may be explained by differences in preparation, degree of ischaemia, anaesthesia, and intensity and mode of α adrenergic stimulation.

Our preparation was expected to be highly sensitive to the direct, peripheral vasoconstrictor effects of dexmedetomidine[4]. Compared with humans, we therefore may have overestimated the coronary vasoconstrictive effects and underestimated the central sympatholytic effects of dexmedetomidine. This could also underestimate a possible anti-ischaemic effect of dexmedetomidine, because it was shown that systemic clonidine had anti-ischaemic properties, while intracoronary administration caused vasoconstriction[6]. However, these results should be extrapolated with caution to potential clinical use in humans as the results relate only to halothane-anaesthetized dogs. Halothane not only has marked haemodynamic effects, but could also have influenced the sympathetic responses.

CASE REPORT

An iatrogenic arterial foreign body

U. S. SHAH, R. DOWNING AND I. DAVIS

Summary

The creation, possible complications and retrieval of an unusual, perhaps unique, arterial foreign body are described. (*Br. J. Anaesth.* 1996;**77**:430–431)

Key words

Monitoring, arterial pressure. Arteries, cannulation. Complications, foreign body.

Case report

The patient was a right-handed, 72-yr-old woman undergoing internal fixation of a pathological fracture of the left femur by interlocking nail. Ten months before operation she had undergone a total left knee replacement under spinal and light general anaesthesia without incident. Three months before operation she had a left pneumonectomy for lung cancer: her early postoperative course was stormy as within hours of surgery she developed respiratory failure and atrial fibrillation, and required ventilation. Tracheotomy was performed and she was weaned from ventilatory support over the next 2 weeks. She was discharged with a prescription for domiciliary oxygen, and digoxin, verapamil and bumetanide. While walking at home she sustained a mid-shaft fracture of her left femur and was admitted for surgical fixation. She was in hospital for 1 week before operation during which time diclofenac and sustained-release morphine were added to her drug regimen.

At the preoperative visit she was sitting upright breathing oxygen from a face mask with her left leg in traction. She was dyspnoeic on slight exertion (moving herself in bed, eating lunch) and spoke in short sentences. She was orthopnoeic at about 45° and physically weak with a thoracolumbar kyphoscoliosis and sacral sores. Her haemoglobin concentration was 9.9 g dl^{-1} and serum albumin concentration 24 g $litre^{-1}$, but all other haematological and biochemical variables were normal.

The planned operation was estimated to take 2 h and required a supine patient. General anaesthesia was used with lumbar extradural block for intra- and postoperative pain management. The procedure took 3 h and involved transfusion of 4 u. of blood after which her lungs were ventilated electively overnight and her trachea extubated without difficulty the next morning.

A left subclavian central venous catheter and left radial arterial cannula were inserted to facilitate monitoring and management. The arterial cannula was a 20-gauge Ohmeda arterial catheter with Flo Switch (1 mm in diameter by 45 mm in length). The device is designed to be sewn to the skin by means of a fenestrated plate, with holes for two sutures, which is integral with the hub of the cannula. Insertion of a third suture to hold the cannula firmly at the junction of the hub and catheter sections led to a jet of blood from the cannula wound indicating some damage to the device. A 0.5-mm by 20-cm guidewire was inserted through the hub of the arterial cannula with the intention of withdrawing the device while maintaining vascular access, but the wire emerged from the cannula 2 mm from the hub which was then seen to have been completely severed from the catheter section (fig. 1). As a pulsatile jet of arterial blood continued to issue from the cannula wound, it seemed possible that the detached fragment might be protruding from the vessel wall. However, a cutdown showed the bleeding came from the arteriotomy wound indicating the catheter section of the cannula was wholly within the arterial lumen. Firm pressure was applied to the wound and a right radial arterial cannula was inserted. A vascular surgical opinion was sought.

While the left hand appeared pink and warm and had a good pulse oximeter signal, with saturation readings from the index finger identical to those from the right hand, it was felt that the risk of digital ischaemia from embolization by a large foreign body, and possible later infection, was unacceptable. The arteriotomy site was re-explored and the palmar arch searched using a Fogarty embolectomy catheter without result. The detached fragment of the cannula was finally delivered from the radial artery proximal to the point of its insertion by means of the Fogarty catheter. The surgical arteriotomy was closed with 6/0 Prolene sutures.

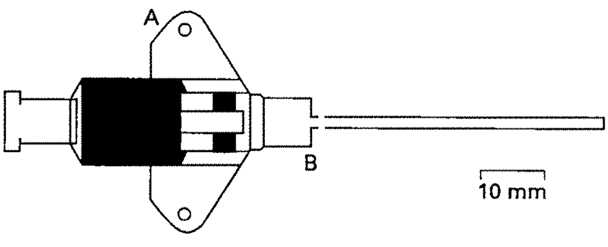

Figure 1 Ohmeda arterial cannula with Flo Switch showing fenestrated plate for suturing (A) and point of severance by cutting needle (B).

UMAKANT S. SHAH, MB, BS(BARODA), DA, RICHARD DOWNING, BSC, MB, CHB, MD, FRCS, IAN DAVIS, MB, BS, FRCA, DA, Worcester Royal Infirmary, Ronkswood Branch, Worcester WR5 1HN. Accepted for publication: May 1, 1996.

The patient made a rapid and uneventful recovery from both operations with normal hand function when assessed 2 and 5 weeks after operation.

Discussion

Continuous display of arterial pressure[1] by cannulation of an accessible artery is a valuable adjunct in the management of complex and difficult surgical cases, and during respiratory support in intensive care. It is usual to cannulate the radial artery on the non-dominant side and, although minor complications are common, ischaemic injury is almost unknown[2-4]. The procedure appears to be safe when, in the absence of peripheral vascular disease, Allen's test[5] does not demonstrate adequate collateral circulation[6] or when failed radial cannulation is followed by cannulation of the ipsilateral ulnar artery[7].

The complications of arterial cannulation have been classified and comprehensively reviewed recently[8]. Immediate local complications are extravasation and haematoma formation: delayed local complications are reduced or absent flow, sensory impairment, infection, skin necrosis and false aneurysm. Distal complications include embolization of the deep palmar arch by thrombus from the wall of a partially occluded vessel, from the external surface of the cannula or flushed from the lumen of the device. The extensive interconnections between the palmar arterial arches and their many branches appear to be highly protective of circulation to the digits: minor embolic events are not clinically obvious and their incidence is unknown. Partial or complete radial artery occlusion, which occurs in approximately 25% of cannulations and is more common in women and after haematoma formation[7], is almost invariably devoid of clinical signs.

Foreign bodies in peripheral arteries are rare and result from missile injuries[9 10], radiological interventions[11] or complications of surgery[12 13]. There has been one report of palmar arch embolization from a penetrating injury of the forearm[14] and none from arterial catheter fragments. The concern in the last case quoted, as in this, was that distal embolization might lead to digital ischaemia or later infection with the attendant risk of secondary haemorrhage or mycotic aneurysm formation.

Management of foreign body emboli which have been investigated fully and are causing no problems, or which are difficult to deliver, may be conservative[14 15] but most agree that the foreign body should be localized by radiological and angiographic studies and retrieved if possible.

Small peripheral arteries are presently beyond the reach of interventional radiology[15] and therefore retrieval implies surgery. In our case there was no immediate circulatory compromise, a limited and accessible field for exploration (even under local anaesthesia) and surgical skills and equipment were available. Somewhat surprisingly exploration of the deep palmar arch by embolectomy catheter was fruitless and the 43-mm long fragment was delivered subsequently from the arterial lumen proximal to the arteriotomy. Without radiological studies the reasons for its immobilization are conjectural: impaction in the vessel wall and local spasm[11] may have contributed, as may the length and relative rigidity of the fragment in what was probably a small and tortuous artery.

The lessons of the episode are clear: first, when fixing arterial cannulae, suture needles should be kept well clear of the devices; second, when distal exploration for an arterial foreign body is fruitless, proximal exploration may be worthwhile before resorting to imaging studies.

EQUIPMENT

An effective method of scavenging nitric oxide

S. Squire, R. Kightley and A. J. Petros

Summary

We report an effective method of scavenging nitric oxide and nitrogen dioxide. We have compared three agents, a commercially available filter, soda lime and activated charcoal, for their effectiveness and duration of action. Complete absorption of nitric oxide and nitrogen dioxide for a period of 170 h was obtained using the commercial filter. However, soda lime and charcoal were unable to successfully scavenge either gas. The resistance characteristics of this filter when dry or humidified were determined. (*Br. J. Anaesth.* 1996;**77**:432–434)

Key words

Gases non-anaesthetic, nitric oxide. Gases non-anaesthetic, nitrogen dioxide. Equipment, filters.

Inhaled nitric oxide can significantly improve oxygenation in both paediatric[1 2] and adult populations[3] and it is invaluable in the treatment of critically ill patients. Effective scavenging of this gas and its higher oxides may present an obstacle for those wishing to take advantage of this new treatment. Various groups of health care workers looking after patients receiving inhaled nitric oxide have expressed concern over long-term exposure. Many individuals can detect a bitter odour when working with nitric oxide, even at very low concentrations. However, having undertaken a risk assessment, advice from NHS Estates (personal communication, Mr L. W. M. Arrowsmith, Chief Engineer, NHS Estates, Trevelyan Square, Leeds) is that provided there is adequate ventilation, scavenging is not necessary. Despite this reassurance we have continued to search for an effective method of scavenging nitric oxide exhaust. Foubert and colleagues[4] have demonstrated convincingly the limited role of soda lime during administration of nitric oxide, and others have shown that simple activated charcoal is also ineffective[4–6]. We have found a device available from the chemical industry and have compared it with soda lime and activated charcoal.

Methods

The Evita 2 (Draeger, Hemel Hempstead) ventilator was used under normal clinical conditions with a peak inspiratory flow of 60 litre min^{-1}, frequency of 12 bpm, tidal volume of 0.5 litre, minute volume of 6.1 litre min^{-1} and 100% oxygen to maximize nitrogen dioxide production. Positive end-expiratory pressure (PEEP) was not used.

We compared the absorbance characteristics of 1 kg of soda lime (Draeger-sorb, PN 6750701, Hemel Hempstead) in a scavenging canister (East Health Care, Littlemore, Oxford), activated charcoal (Carbomix, Penn Pharmaceuticals, Gwent) in a 300-mm length of 22-mm corrugated ventilator tubing (Intersurgical, Berkshire) and a commercially available filter, ABEK HgCONO-P3 (No. 67-35-813, Drager Industrial Ltd, Kilty Brewster Industrial Estate, Blyth, Northumberland), used in industry to absorb nitric oxide and nitrogen dioxide (fig. 1).

Over a continuous 170-h period, 1% nitric oxide in nitrogen (BOC, Special Gases, Guildford) was introduced into the ventilator circuit containing the ABEK filter (fig. 2) at a flow rate of 0.05 litre min^{-1}. The resultant nitric oxide and nitrogen dioxide concentrations were monitored proximal and distal to the ABEK filter with an electrochemical detector (Micromedical, Kent) at increasing intervals for a total of 170 h continuously. The monitors were calibrated using Spectraseal calibration gases (BOC, Special Gases, Guildford), nitric oxide in nitrogen at 86.1 ppm and nitrogen dioxide in air at 17.6 ppm. The proximal nitric oxide concentration was maintained between 55 and 70 ppm producing nitrogen dioxide concentration between 9 and 12 ppm.

Using the same conditions and experimental design, the 1-kg canister of soda lime and a 300-mm length of 22-mm corrugated tube containing activated charcoal were tested for absorbance. The tests

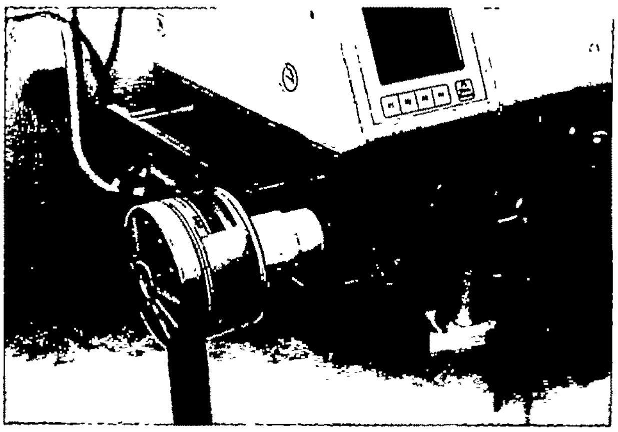

Figure 1 The ABEK HgCONO-P3 filter.

Correspondence to S. S.

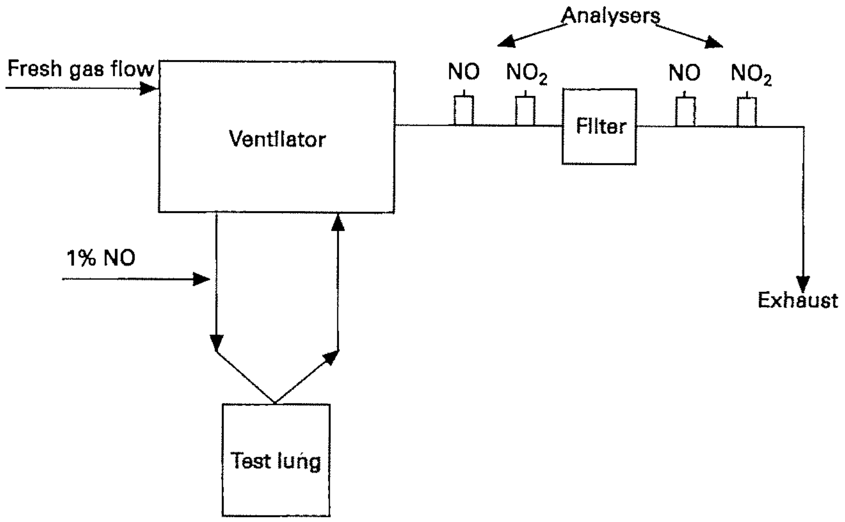

Figure 2 Circuit design for administering and measuring nitric oxide and nitrogen dioxide, and testing the degree of absorption.

were aborted when no absorption was apparent for either soda lime or charcoal.

In a separate series of experiments, the pressure created by fresh gas flows of 10–120 litre min^{-1} through the ABEK HgCONO-P3 filter were measured using a pressure meter (Druck, DPI 701, Druck Ltd, Leicester). Humidified gas at 37 °C and 80% humidity was passed at 19 litre h^{-1} through the filter for 35 h (1.5 litre of water was consumed) making the filter wet, and the expiratory pressures created by the filter at various flows were measured again. Humidity was measured with a relative humidity meter (Vaisala HM34, Cambridge) with an accuracy of ±3%.

Results

With a fresh gas flow of 9.0 litre min^{-1}, the calibration gas of nitric oxide in nitrogen at 86.1 ppm was passed through the soda lime canister and the concentration in the exhaust decreased to a low of 75 ppm, but for only 1 min. After 3 min the concentration had returned to 83 ppm and after 10 min there was no absorption. The test was repeated with a calibration gas of 17.6 ppm of nitrogen dioxide in nitrogen (BOC, Guilford). By 16 min, 14.6 ppm of nitrogen dioxide were detected distal to the soda lime canister. These tests were repeated using activated charcoal and no reduction in exhaust gas concentration was detected at any time.

Using the ABEK HgCONO-P3, we were able to completely scavenge both nitric oxide and nitrogen dioxide from levels of 55–70 ppm and 9–12 ppm, respectively, to less than 0.4 ppm for both gases for a continuous period of 170 h. By multiplying nitric oxide/nitrogen dioxide concentrations by the time intervals between readings, the volume of nitric oxide absorbed over this 170-h period was estimated to be 3.92 litre, and 0.67 litre for nitrogen dioxide.

The ABEK filter produced a linear increase in pressure with increasing flow rate when both dry and wet; when dry, resistance was 0.086 kPa litre min^{-1}; when wet, having been humidified for 35 h, resistance was 0.091 kPa litre min^{-1} (fig. 3). At 10 litre min^{-1}, the pressure generated within the test circuit was 0.1 kPa and at 60 litre min^{-1} 0.45 kPa.

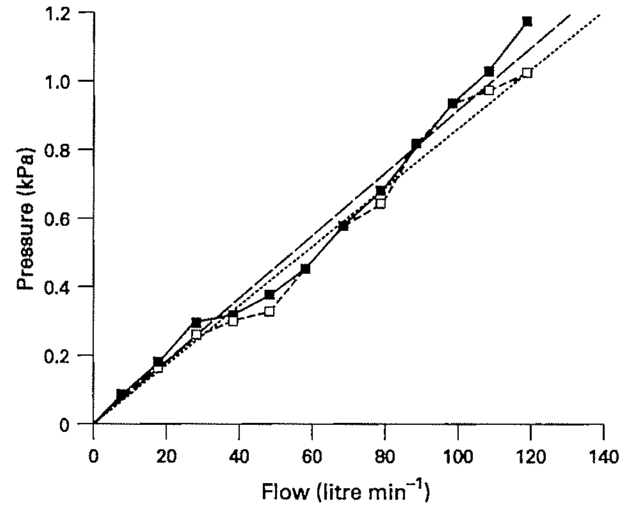

Figure 3 Pressures created by various flow rates through the filter were measured. Humidified gas at 37 °C and 80% humidity was passed through the filter for 35 h (a total of 1.5 litre of water) and the pressure at various flows measured again. The resistance of the filter when dry (□) was calculated to be 0.086 kPa litre^{-1} min^{-1} and when wet (■) 0.091 kPa litre^{-1} min^{-1}. (Regression coefficient, r^2=0.98 for both curves.)

Discussion

Current recommendations state that in a well ventilated environment, administration of nitric oxide poses no health hazard and that scavenging is not necessary. However, there are situations where nitric oxide may be delivered in less than ideal circumstances; in ambulances during transport of neonates; in a catheter laboratory; and in isolation cubicles with inadequate ventilation. For these situations scavenging of nitric oxide is desirable.

We have tested three methods and have found a commercially available filter which removes all nitric oxide and nitrogen dioxide. We can also support previous reports that soda lime and charcoal are of little value. The initial reduction in nitric oxide concentration we observed in the first minute of exposure to soda lime may have been caused by oxidation of nitric oxide to nitrogen dioxide by residual oxygen in the absorber rather than true absorption. Alternatively, the indicator dye within the soda lime may be independently involved in scavenging[4–6]. Charcoal from organic sources, for example coconut, can be activated by heating to high temperatures to create absorptive pockets of varying size on the charcoal particles. Larger molecules are removed more easily, ethanol being at the lower limit of effective removal and smaller molecules such as nitric oxide are not effectively scavenged.

We found the ABEK HgCONO-P3 filter the most effective method of scavenging nitric oxide and nitrogen dioxide. The ABEK HgCONO-P3 filter contains microglass fibres coated with copper and chromium salts. The filter also contains manganese dioxide and copper oxide as catalysts. Scavenging nitric oxide itself is difficult; it is much easier to scavenge nitrogen dioxide. The filter oxidizes nitric oxide to nitrogen dioxide which may then be absorbed by the copper and chromium salts.

$$2NO+O_2 \rightarrow 2NO_2$$

$$2NO_2+H_2O \rightarrow HNO_3+HNO_2$$

$$2HNO_3+CuX/CrX \rightarrow Cu(NO_3)/Cr(NO_3)+H_2O$$

It is estimated by the manufacturers that the filter can take up to 4–5 litre of nitric oxide and nitrogen dioxide in total, at a flow rate of 8 litre min^{-1}.

All our ventilators, Evita 1 and Evita 2 (Draeger Medical, Hemel Hempstead, Herts) Servo 900c (Siemens, Bracknell, Berkshire) and Brompton Manley (Porton, Denmark) are now fitted with the filter on the expiratory port whenever nitric oxide is used. The extra expiratory resistance introduced of approximately 0.01 kPa $litre^{-1}$ min^{-1} or 0.6 kPa at 60 litre min^{-1} is an acceptable level for the advantage of complete removal of nitric oxide and nitrogen dioxide from the environment. Although the filter lasts for up to 170 h we change it every 96 h. The current price is approximately £20.00.

Having performed a risk analysis, the recommendation of the NHS Estates is that scavenging is not necessary in an adequately ventilated environment (personal communication, Mr L. W. M. Arrowsmith, Chief Engineer, NHS Estates). This view is supported by other clinical reports where nitric oxide has been found to be negligible in the environment during inhaled treatment[4]. However, by using the ABEK filter we are guaranteed a nitric oxide free environment. Although we accept that exposure to nitric oxide in a well ventilated area may carry no significant risk, we suggest the use of the ABEK filter on the expiratory exhaust limb of ventilators when delivering nitric oxide to further reassure all those working with nitric oxide.

CORRESPONDENCE

The care of patients and transport by air

Sir,—I read with great interest the recent review on pre-hospital monitoring of trauma patients[1]. This raised many important issues which need to be addressed further as expectations of out of hospital care increase. In Scotland there has been a fully integrated air ambulance service following a major reorganization in 1993. In addition to providing a primary patient transport service, there are also a large number of secondary inter-hospital transfers. Because of the distances involved and terrain, many of these involve air travel, using fixed-wing or rotary aircraft. In addition to adopting the Association of Anaesthetists' guidelines on minimum standards of monitoring, it has also been suggested that the recommendations for assistance should be followed in such situations[2].

Dr Morley highlighted in his review that monitoring can interfere with aircraft electrical systems. Most monitors give out a small amount of electrical activity to the surroundings; this is not true of defibrillators which, despite having been used successfully in-flight, still pose a greater hazard. It is recommended that authority is gained from the aircraft captain before defibrillators are discharged when airborne[3].

In addition to the function of monitors in the air environment, associated alarm systems have also come under scrutiny. The noise levels present in the back of an aircraft can render auditory alarms ineffective. It has also been demonstrated that relying on visual scanning for detection of problems leads to delays before alarm conditions are detected. Consideration is currently being given to incorporation of alarms into intercom systems to further increase safe practice[4].

All adverse events are more likely with prolonged journey times. With the move to centralize specialist facilities and notably paediatric intensive care units[5], patient transfer requiring sophisticated monitoring is set to increase. Only by continued vigilance and debate will standards improve to keep pace with these developments.

Sir,—Dr Shirley raises some interesting points which merit further comment. HEMS was certainly preceded by some air ambulance services in the UK, although it differs in several important respects. Most obvious of these is the presence of a full-time medical staff, trained specifically for the purpose of primary retrieval by helicopter of major trauma victims. It is difficult to exclude other factors when considering the specific added effect of a physician on an aeromedical prehospital team. One American study of blunt trauma patients found that patient mortality was 35% less than predicted by trauma score and injury severity score (TRISS) methodology when the attending aeromedical team incorporated a doctor. In addition, mortality in this group was significantly lower than in a group of patients, with similar TRISS scores, attended by a flight nurse/flight paramedic team. The doctors were able to perform a wider range of practical procedures than their paramedical counterparts, including thoracostomy, cricothyroidotomy and pericardiocentesis[1].

On the issue of defibrillators, HEMS use the Lifepak LP10-23 (Physio-Control Corporation International, Redmond, WA, USA), which is specifically approved by the Civil Aviation Authority for the HEMS aircraft, an Aerospatiale Dauphin SA 365N. The defibrillator monitoring unit initially caused low level interference in the 120-MHz radio frequency band and this has been resolved by special modifications. Similar problems have been encountered on testing the Lifepak LP10-59 in the Bölkow 105DBS used by Cornish First Air (personal communication, R. Dawnay, Snaefell Aviation Design). Interestingly, in-flight defibrillation can only be heard as a faint click on the aircraft headsets.

Since HEMS began operations in 1989, only 18 patients have undergone defibrillation. In most instances, the defibrillator was used on scene, not in the aircraft. The three survivors had all crashed their cars after sustaining cardiac arrests while driving and their injuries were only minor. The dismal prognosis of genuine traumatic cardiac arrest has been reported elsewhere[2].

Auditory monitor alarms are ineffective in the HEMS Dauphin. All staff on board wear helmets. Noise levels in the aircraft are very high because of removal of the soundproofing that normally forms part of the shell of the helicopter. This modification helped to lighten the aircraft, thereby improving performance and increasing potential patient load. Staff can communicate using helmet-based headsets and microphones. To avoid unnecessary disturbance to the pilot, incorporation of any alarm system into the intercom would have to be restricted to the headsets of the doctor and paramedic.

Effect of naloxone on nitrous oxide analgesia

Sir,—We would like to comment on the article by Yagi and colleagues[1]. These authors were unable to show naloxone inhibition of the analgesic effects of nitrous oxide when measurements of analgesia were obtained 5 min after injection of naloxone. In fact, in figure 3 they showed a non-significant increase in analgesia after administration of naloxone[1]. Interestingly, these authors used very low doses of naloxone. We have shown previously that with similar doses of naloxone in human volunteers, the peak effect of naloxone was measurable only within the first 2–3 min after bolus injection. This effect was not apparent after 5 min[2,3]. Although in a minority of subjects nitrous oxide analgesia was attenuated by naloxone[2] the majority of subjects showed a transient increase in nitrous oxide analgesia[2,3]. These observations were confirmed later by others in animals[4]. From our findings we proposed the existence of two opioid systems, in dynamic equilibrium: one analgesic and the other pain producing[2,3].

Sir,–In a previous article[1] we reported that the clinical dose of naloxone did not antagonize the analgesic action of nitrous oxide when the pain threshold test was performed 5 min after injection of naloxone in humans. As Gillman and Lichtigfeld pointed out, the dose (0.01 mg kg^{-1}) of naloxone used in the study may not have been adequate to fully antagonize the effects of the opioid[2]. We chose this dose according to Jaffe and Martin[3] who indicated that naloxone 0.4–0.8 mg i.v. in humans can prevent or reverse the effects of mu opioid agonists. The onset of action of naloxone is fast and seen within 1 or 2 min after injection[3,4]. The duration of antagonistic effects is approximately 45 min after an i.v. dose of 0.4 mg[5]. In our previous study, measurement of pain threshold was commenced 5 min after administration of naloxone. Measurement of analgesia was obtained during the period of naloxone-induced antagonism. We also evaluated antagonism of nitrous oxide analgesia with higher doses (5 and 10 mg kg^{-1}) of naloxone by a radiant heat tail-flick test in rats (unpublished data). The results indicated that naloxone did not antagonize the analgesic action induced by nitrous oxide, even at high doses.

Gillman, Kok and Lichtigfeld[6] showed that the peak effect of naloxone was measurable only within the first 2–3 min after bolus injection with clinical doses of naloxone in human volunteers, but not after 5 min. The majority of subjects showed a transient increase in nitrous oxide analgesia. This interesting peak effect of naloxone might be an agonistic effect seen at high doses of naloxone. Naloxone enters the brain very rapidly. The initial brain concentration of naloxone was reported to be much higher (4.6 times) than that in serum[4]. Therefore, the brain concentration of naloxone may transiently reach a high level which may produce agonist effects during the short period after bolus injection of clinical doses. High doses of naloxone produce increased arterial pressure and arrhythmias which may be caused by the release of sudden intense sympathetic activity. Enhancement of sympathetic neurones by naloxone in the central nervous system may explain the transient increase in nitrous oxide analgesia 2–3 min after injection of naloxone.

Difficult tracheal intubation

Sir,—Difficult tracheal intubation is a major cause of anaesthetic-related morbidity and mortality, and any change which may lead to a reduction is to be welcomed. However, we were interested that when West and colleagues studied a tracheal tube designed specifically for this reason, they used a size 8 tube for females and size 9 for males[1]. While we know of no firm evidence that decreasing the size of the tracheal tube facilitates intubation in cases of difficulty, it does seem to be true in both our experience and that of others[2]. Furthermore, it has been known for many years that small tracheal tubes can be used safely and without complication during positive pressure ventilation[2]. It has become routine practice at this institution to use 6-mm tubes in females and 6.5-mm in males. We believe that West and colleagues would have found an increased success rate and shortened learning time had they used smaller tracheal tubes in their simulation of a difficult intubation.

The authors' incidence of 33% for sore throat is similar to that quoted in other studies[3], but 1–3% of patients may still have hoarseness up to 6 months after intubation[4]. This value may be expected to be even higher in cases of difficult intubation where greater degrees of laryngeal trauma are likely to occur[3]. We believe that decreasing the size of the tracheal tube makes intubation easier and reduces the incidence of laryngeal damage. Stout and coworkers[5] have shown that the incidence of hoarseness and sore throat may be reduced substantially by using tracheal tubes of size 7 or less. We believe that small tracheal tubes can be used routinely, and should be used when laryngoscopy is difficult.

5. Stout DM, Bishop MJ, Dwersteg JF, Cullen FC. Correlation of endotracheal tube size with sore throat and hoarseness after general anesthesia. *Anesthesiology* 1987; **67**: 419–421.

Sir,—Our thanks to Drs Broomhead and Vaughan for their comments. The crucial step is to get the introducer into the right hole; when that is achieved, intubation with our tube is easy; that is its main advantage. It seems unlikely that smaller tubes would have altered the intubation time. With a Magill tube, when the introducer is in place, there is still the problem of preventing the bevel snagging on the cords and a smaller tube is often helpful, but with the new method a smaller tube is needed only if the larynx is abnormally small. The problem is simplified because instead of two possible causes of resistance, there is only one. Occasionally, some resistance is felt and a smaller tube is needed. Recent data[1] suggest that over the past decade the incidence of failed intubation in obstetrics has increased. The authors imply that part of the explanation is that junior staff have less experience of obstetric general anaesthesia than in the past. If that is correct then it underlines our conclusions.

On the other hand, routine use of a small tube implies that there is never any need to change tubes, which is perhaps an advantage. The authors also refer to Stout and colleagues[2] who found that with size 7 tubes the incidence of sore throat was 22% compared with 33% in our study. But this could be fortuitous (P=0.1); a larger sample might show a real difference. Thus the case for smaller tubes is not proved but we agree that it merits further study.

May we add that the most serious cause of trauma is the novice who attempts to handle difficult intubations with no clear picture of the problem or its solution. This is perhaps the strongest argument in favour of our training drill.

Cost of volatile anaesthetic agents

Sir,—I read with interest Dr Barker's letter on the cost of volatile anaesthetic agents[1]. When the costs of various agents are listed, one is tempted to make comparisons, and economic concerns are of increasing importance in our practice. However, for fair comparison of the available agents, we need to consider the amount of anaesthetic required to provide a similar depth of anaesthesia and this extends beyond making comparisons of similar potencies at set fresh gas flow rates. Differences in solubility of various agents in the blood and tissues become important. The amount of anaesthetic agent required may be divided into that required to provide adequate anaesthesia at the start (to load up the circuit and the patient's lungs), to that required to replace anaesthetic taken up into the blood and then into the tissues of the body, and also make account of that supplied in excess of uptake and therefore lost from the circuit and wasted. The relative cost of the available agents varies with the fresh gas flow chosen.

Estimates have been made of the volume of liquid anaesthetic required based on uptake kinetics and circuit performance at various fresh gas flow rates to sustain an alveolar concentration of 1 MAC for four of the volatile agents listed by Dr Barker[2]. I have included the price per millilitre of liquid anaesthetic, from the British National Formulary[3], to calculate the cost of the volatile agent required (table 1).

There are limitations to the calculations: at low fresh gas flows, conventional vaporizers may be unable to supply sufficient agent, for example at 0.2 litre min^{-1} at 1 MAC, isoflurane vaporizers cannot supply a sufficient amount of isoflurane for the first hour, whereas desflurane vaporizers are unable to do so for the first 10 min. The increased fresh gas flow required to compensate for the limitations of the vaporizers would increase the estimated cost noted in table 1, but this would be greatest for the more soluble volatile agents. In addition, there is some concern on the use of sevoflurane at low fresh gas flows[4]. Table 1 shows, as would be expected, that for any given volatile agent, cost increases with increased fresh gas flow, but also that the relative cost of the less soluble (and newer) volatile agents is reduced at lower fresh gas flows. This illustrates that when comparing the costs of volatile anaesthetic agents, consideration must also be given to uptake kinetics and fresh gas flows used.

Table 1 Cost of volatile agent required to maintain an alveolar concentration of 1 MAC, of the chosen volatile agent, at various fresh gas flow rates, for periods of 30 or 60 min

	Fresh gas flow rate (litre min^{-1})				
	0.2	1	2	4	6

ERRATUM

British Journal of Anaesthesia 1996; **76** (Suppl. 2): A.45

In the methods section of this abstract, the dose of morphine was reported incorrectly: morphine 0.9 mg/kg should read *morphine 0.09 mg/kg*.

We apologize to the authors for this confusion.

British Journal of Anaesthesia 1996;77:438–439

BOOK REVIEWS

Clinical Orthopedic Anesthesia. J. E. TETZLAFF. Published by Butterworth-Heinemann, Massachusetts. Pp. 406; indexed; illustrated. Price £45.00.

This book is intended for the trainee approaching a subspecialty attachment in orthopaedic anaesthesia and is produced in a notebook sized format with a ring binding to make it easy to use in the operating theatre. It is an attractive format but I hope that the binding is more durable than that of my road atlas.

Dr Tetzlaff has written all of the 22 chapters with the assistance of four contributors, and all are based at the Cleveland Clinic. There is therefore a consistency of style which makes a welcome change from multi-authored texts so that the book is easy and enjoyable to read. The authority of the text is derived from Dr Tetzlaff's clear experience of orthopaedic anaesthesia and his personal view of clinical problems is welcome. The book represents US practice and British readers will find many differences from their own: most notably the complete absence of any reference to the use of the laryngeal mask airway.

Chapters 1 and 2 deal comprehensively with the preoperative preparation of patients for general and regional anaesthesia, respectively. The word "mandatory" is overworked and must give lawyers lots of ammunition, although the general stance of the book is very defensive: all chapters have comprehensive sections dealing with complications of the techniques discussed. While all systems are covered in these chapters, there is too little attention given to the special clinical problems of orthopaedic anaesthesia; thus muscular dystrophy and myopathies merit only one paragraph with no mention of cardiomyopathy and there are two paragraphs on haemophilia and sickle cell disease. The bone problems of end-stage renal failure and renal transplantation are omitted.

Chapter 3 is a long and very thorough description of positioning of patients, with heavy emphasis on complications, and is better suited to a general textbook of anaesthesia: there is little use of the lithotomy position in orthopaedic surgery. This chapter should have been followed by one on tourniquets which does not appear until chapter 14.

The next group of chapters are concerned with regional anaesthesia drugs and techniques. The chapter on pharmacology is long winded and much of the information on the drugs could have been summarized in a table. The complication of methaemoglobin formation with prilocaine is discussed but the effect on oximetry readings is omitted. Lignocaine is recommended for i.v. regional anaesthesia despite its well-known toxicity, which should preclude its use. A good section on spinal anaesthesia is followed by a word-processor error on page 117 where the treatment of hypotension caused by high spinal anaesthesia includes measures to *decrease* capacitance vessel tone.

The chapter on upper limb blocks is confident and interesting, and marred only by dislocation between text and illustrations, which is probably unavoidable in a small format book. The chapter on lower limb regional anaesthesia fails to discriminate between useful blocks and those of little relevance, such as obturator nerve block. The inclusion in occasional chapters of sections headed "controversy" is a good idea and adds to interest. The suggestion that continuous extradural anaesthesia prevents development of phantom limb pain after amputation could have been discussed.

Chapters 9 and 10 discuss anaesthesia for hip fracture and hip and knee replacement but this arrangement of information inevitably leads to much repetition from earlier chapters about spinal and extradural anaesthesia.

Chapter 11 is a very useful chapter on shoulder surgery, informed by a great deal of experience, such as how to drape the patient who is undergoing shoulder surgery under regional block. Spinal surgery is well described in chapter 12, with a good section on spinal cord monitoring. The order of chapters thereafter seems random, thus "Scoliosis" is not chapter 13 but 22 and chapters devoted to complications, "Deep venous thrombosis" and "Fat embolism" are 16 and 20.

The chapter on blood conservation, transfusion and coagulopathy (chapter 15) is interesting and important, with discussion of predonation of blood and cell salvage techniques, which are of growing importance in Britain. The chapter on paediatric orthopaedics (chapter 19) is too short and sketchy to be useful.

This book provides a good basis for a junior trainee about to embark on his first orthopaedic surgical list and the descriptions of surgical procedures are particularly good. Further reading is hampered as referencing is capricious and rarely up to date: the chapter on oncology has 23 references only one of which is in the last 10 yr. The book could have been more concise with less repetition if better cross referencing had been used and more use made of tables for comparative facts. Is it worth including references more than 10 yr old? There are some surprising omissions; the problems associated with extensive plasters and anaesthesia for replantation of severed parts, while anaesthesia for day surgery is dealt with feebly. Finally, the use of "anaesthesia providers" for "anaesthetists"" brings home the fact that the Health Service "reforms" grew out of US practice!

A. Loach

Clinical Anesthesiology, 2nd Edn. G. E. MORGAN JR AND M. S. MIKHAIL. Published by Appleton and Lange, Stamford, CT. Pp. 882; indexed; illustrated. $US45.

Some things are better avoided. You should never have to apologize for a "busy" slide. Nor should you tell audiences at lectures repeatedly that you do not have the time to cover everything. To these infelicities can be added that it is not a good idea to suggest to potential buyers of your book that there are already enough books on anaesthesia. Because there are: both in the UK and in the US markets, there are enough omnibus books on anaesthesia, at basic, intermediate and advanced levels, that the specialty would lose nothing if no new omnibus books appeared for 10 yr.

So I suggest that if Morgan and Mikhail attempt a third edition of their book they send out a new invitation for the foreword, which not only contains the sentence "Oh no, not another textbook of anesthesia!", complete with exclamation mark, but then gives the lead editors of three competitors.

Morgan and Mikhail have produced an attractive (if difficult to place) book covering the whole of anaesthesia in about 900 pages, including index. They have written the whole text, except for the two chapters on local and regional anaesthesia, covering the basic sciences, monitoring, legal matters and all of clinical anaesthesia. There are thus two pages on lung transplantation and a page on cardiac transplantation. This gives an insight into the American approach to disease and death: the opening sentence to the section on cardiac transplantation is that it is "the treatment of choice for patients with end-stage heart disease who are unlikely to survive the next 6–12 months." The only other comment on selection of patients for cardiac transplantation is that they should have no end-organ damage or other major systemic disease. This illustrates the strength and weakness of the book: it is comprehensive, but many sections are superficial. Hyoscine is described as "preventing motion sickness"; the anticholinergic drugs are described as mydriatics, with no distinction between systemic and topical use.

The book is difficult to place because there is not enough detail in the basic sciences for the primary FRCA, the clinical sections are too advanced for the primary FRCA, but are not detailed enough for the final FRCA. The American perspective is unhelpful if the book is used as a primer for British anaesthesia, although maybe this is realized: the price is given in dollars.

The book is well laid out, with contrasting blue type highlighting important points. The two-author approach makes for an easy style, but perhaps explains some statements that struck me as rather extreme. Should women having spinal anaesthesia for Caesarean section really receive 1500–2000 ml of Hartmann's solution before the onset of block? Is there really a risk of an allergic reaction to local anaesthetic used for skin infiltration before extradural injection? Treatment of a high spinal includes the advice to position the patient head down.

The new drugs are all there, although perfunctorily. There is a useful index of critical topics. Each chapter ends with a case discussion, some of which are imaginative enough that they must have happened, for example, the patient who died when an adrenaline infusion was labelled nitroglycerin. But there are no proper references, only reading lists, and it is almost lazy to give a reading list for cardiovascular physiology that consists of only other general textbooks.

The publishers advertise the book as suitable, in the American market, for medical students, residents, physicians and nurse anaesthetists. It has far too much for British medical students; our residents and physicians do not buy books on anaesthesia and the emphases are wrong for our anaesthetic nurses and ODAs. But there is a place for this book. Paradoxically, it is a reasonable book for someone who already has a good knowledge of anaesthesia, but wants an all-in-one book for occasional information, of the right size to fit in a briefcase. Until I buy a portable computer with a CD-ROM, and until I am as happy flicking through screens of text as I am flipping over the pages of a book, I suspect Morgan and Mikhail's *Clinical Anesthesiology* may do a bit of travelling with me.

N. W. Goodman

Baillière's Clinical Anaesthesiology: International Practice and Research, vol. 10, No. 1. The Lung in Anaesthesia and Intensive Care. R. G. Pearl (editor). Published by Baillière Tindall (W B Saunders Co Ltd), London. Pp. 236; indexed; illustrated. Price £30.

This volume is intended to contain reviews of recent advances in knowledge of the lung, which also show how these advances can affect patient care. A good review such as this is very difficult to write. The author needs to have extensive knowledge and even more importantly must provide a critical and balanced account so that the reader can obtain a coherent and intelligible view of the topic. The best example, close to this ideal, is the chapter by Pickworth and Jones on "Respiratory care", which is discursive, critical and wide-ranging. It covers topics such as respiratory secretions, oxygenation, physiotherapy and bronchodilators. Another useful contribution comes from Gal, on anaesthesia for patients with lung disease, covering the subject in a workman-like and clinically based way supported by good basic knowledge. Falke provides a first-class review of recent advances in the treatment of acute (no longer adult) respiratory distress syndrome, carefully avoiding unsubstantiated recommendations and indicating the many points where further study is required. In particular, he provides a good table of suggestions for treatment.

However, in this chapter and in others the editor could have helped by providing one of the principles of good aircraft design, which is to "simplify and add lightness". A chapter on the pulmonary circulation, which is truly a field of considerable recent advance, is fascinating but very closely packed and would have been much better expanded so that some of the important concepts could have been set out more fully. Here the clinical implications are not clearly indicated but perhaps we are still too close to the experimental information for this.

Unfortunately, to a greater or lesser extent, the remainder of the contributions do not meet the ideal. Hedenstierna, with the topic "Effects of anaesthesia on respiratory function", concentrates particularly on studies from his department on gas exchange and atelectasis, including the possible adverse effects of increased inspired oxygen fraction. The clinical relevance of these observations, and their exact relationship to postoperative complications, remain to be clarified. Other contributors to this volume have been set difficult tasks to cover vast subject areas and have not had the wisdom to limit their coverage. For example, mechanical ventilation for critical illness cannot be addressed easily in 23 pages, particularly if the first three are on history. To a lesser extent, the chapters on thoracic surgery and thoracic trauma are also cramped and limited, and are too general to be of clinical value. The chapter on respiratory monitoring is superficial and has some remarkable gaps, and the chapter on paediatric anaesthesia resembles a rushed examination answer with no light of clinical acumen visible, and no sign of a senior hand in the plan or execution.

In his preface, the guest editor suggests that large advances have taken place in the past 10 yr in the topics that are covered. A quick glance at the reference lists indicates that if this is true, it is not well reflected by some of the contributions, with one chapter having less than 30% of original references after 1986. More than 25% of the references for another chapter consist of references to standard textbooks.

In summary, only four of the 10 chapters meet my criteria of readability, topicality and sufficient critical thought. I would advise readers to look elsewhere, such as recent textbooks, for better coverage of the areas attempted by the other six chapters. Overall, the "topicality" of this book is limited and I would not buy it for myself, although I shall certainly go to my review copy for information on the pulmonary circulation and ARDS.

G. B. Drummond

Chemical Warfare Agents. Toxicology and Treatment. T. C. Marrs, R. L. Maynard and F. R. Sidell. Published by John Wiley and Sons, Chichester. Pp. 234; indexed. Price £40.00.

The use of chemical warfare agents is prohibited by several international treaties or conventions. Despite these prohibitions the number of countries who have acquired chemical weapons continues to increase. Regrettably there is a lack of sound moral or ethical compulsion to refrain from the use of such weapons and there is a continuing probability that chemical agents will be used in so called Third World conflicts. The very existence of these chemical weapons implies that they are likely to fall into the hands of terrorists and be used against civilian populations. Sarin has been used for such a purpose in recent years, in 1994 and 1995 in Japan, resulting in 15 deaths and hundreds of casualties.

This excellent book covers the toxicology of the commonest chemical warfare agents, including mechanisms of action, pathology and treatment of the resultant poisoning. Emphasis is placed on the more practical aspects of treatment and the particular difficulties of treatment in the field are not neglected. This book will be of interest to military medical officers and those practitioners engaged in civil defence planning. The chapters on organophosphate compounds will be of particular interest to anaesthetists.

The three authors of this book are experts in this field; two are British and the other is American. It was slightly irritating to find trans-Atlantic differences in spelling in the text. There are a total of 571 references in the 10 chapters of this book. Many of these references have not been in the public domain until recently and much of the work on these agents performed on human volunteers could not be repeated today. The authors are to be congratulated on the clarity of their style. The subject has been presented in a logical and easily readable format. There are no photographs but the text is illustrated by clear tables and figures.

The anaesthetist has the basic skills and resuscitative abilities to play an essential part in the treatment of chemical casualties. He or she should be involved in the training of paramedical staff, and the organization of civilian mass casualty disaster plans should include the mass toxic and mass traumatic catastrophes. This book is an excellent, authoritative source of information for such a purpose and good value for money.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 77, No. 4 OCTOBER 1996

EDITORIAL

Ketamine: its mechanism(s) of action and unusual clinical uses

Since Domino, Chidiff and Corssen[1] reported the first clinical use of ketamine more than 30 yr ago, there have been many clinical and laboratory studies to determine both its mechanism(s) of action and define the most appropriate clinical use of this unusual anaesthetic agent. Although disturbing emergence reactions are associated with its use, ketamine has several clinically useful properties, including analgesia and less cardiorespiratory depressant effects than other anaesthetic agents, in fact it causes some stimulation of the cardiovascular system[1,2]. Clinically, ketamine has been reported to produce not only general but also local anaesthesia[3-5]. It also interacts with *N*-methyl-D-aspartate (NMDA) receptors[6-8], opioid receptors[9,10], monoaminergic receptors[11], muscarinic receptors[10,12,13] and voltage-sensitive Ca^{2+} channels[14,15]. However, unlike other general anaesthetic agents, ketamine does not interact with GABA receptors[16]. Clinically, ketamine is administered as a racemate composed of two optical isomers, S(+) and R(−), and there are some pharmacological differences between these[2] (see below).

In this editorial, in addition to the well established NMDA receptor inhibition, we review other potential pharmacological targets for ketamine and discuss the unusual clinical uses of this agent.

NMDA RECEPTOR ANTAGONISM

The NMDA receptor, a member of the glutamate receptor family, is an example of an ion channel-coupled receptor with excitatory properties[17] which has been implicated in the mechanism of general anaesthesia[16], analgesia[18] and also in neurotoxicity[7]. Ketamine is a non-competitive antagonist of the NMDA receptor Ca^{2+} channel pore[7]. In addition, at clinically relevant concentrations, ketamine interacts with the phencyclidine (PCP) binding site[9] leading to significant inhibition of NMDA receptor activity[8]; this occurs only when the channel has been opened[18]. This interaction with the PCP binding site appears to be stereoselective with affinity (K_i) values of 3.2 μmol litre^{-1} and 1.1 μmol litre^{-1} for S(+) and R(-) ketamine, respectively. An *in vivo* study in the lamprey eel[19] also showed that ketamine inhibits NMDA receptor-mediated neuronal events by 50% (IC_{50}) at 10–20 μmol litre^{-1}.

ANALGESIA AND INTERACTIONS WITH OPIOID RECEPTORS

Ketamine has been reported to interact with mu (μ), delta (δ) and kappa (κ) opioid receptors[10]. It has been shown *in vivo* that S(+)ketamine is 2–3 times more potent than R(-) ketamine as an analgesic[2]. In agreement with these clinical observations, it has been shown that ketamine produces 2–3 fold stereoselectivity at μ and κ receptors but not at δ receptors[10]. The interaction with opioid receptors is clearly complex and several studies[10,20] have suggested that ketamine may be an antagonist at μ receptors and an agonist at κ receptors. Smith and colleagues[20] found that morphine but not ketamine analgesia was antagonized by microinjection of naloxone into the periaqueductal grey (PAG) region of the rat brain, which contains μ but not κ receptors. Moreover, microinjection of ketamine into the PAG did not produce analgesia but antagonized the effects of morphine. These observations suggest that the analgesic effects of ketamine are not mediated via μ opioid receptors in the CNS. Clearly, further detailed studies with δ and κ agonists are required. While the σ receptor is no longer classified as an opioid receptor, ketamine also interacts with this receptor although the interaction is weak ($\mu > \kappa > \sigma > \delta$) and stereoselectivity is reversed: S(+)<R(−)[10].

ANALGESIA AND MONOAMINERGIC RECEPTORS

Crisp and colleagues found that ketamine (3.0 μmol litre^{-1})-induced spinal analgesia, measured as an increase in tail flick latency in rats, was reversed dose-dependently by administration of s.c. methysergide (serotonin antagonist), phentolamine (α-adrenoceptor antagonist) and naloxone (IC_{50} values 8.0 μg kg^{-1}, 0.88 mg kg^{-1} and 3.0 mg kg^{-1}, respectively)[11]. However, they also found that spinal ketamine did not increase tail-flick latency in rats with bilateral dorsal funiculus lesions (DFL) in a system where morphine was effective. These data suggest that the antinociceptive action of ketamine may involve descending inhibitory monoaminergic pain pathways. One possible flaw in this argument is that ketamine-sensitive opioid receptors on interneurones modulating descending antinociceptive pathways could not be excluded. Specifically, is the naloxone reversible action of ketamine secondary to its ability to interact with interneurones to block amine uptake, that is indirect?

LOCAL ANAESTHETIC ACTION

It is known that ketamine at high doses possesses local anaesthetic properties and these have been compared with lignocaine and procaine[3]. For example, spinal administration of 1.25% ketamine and lignocaine in dogs produced rapid, reversible and predictable segmental paralysis without any apparent reduction in consciousness[3]. In addition, ketamine and procaine inhibited, with identical IC_{50} values, the compound action potential of the frog sciatic nerve preparation[3]. In agreement with the mechanism of action of local anaesthetic agents, it has been shown that high-dose ketamine blocks Na^+ channels in frog neurones and in lipid bilayers (containing human Na^+ channels) with IC_{50} values in the mmol $litre^{-1}$ range[21 22]. Moreover, Durrani and colleagues reported that ketamine (>0.3%) produced adequate i.v. regional anaesthesia with complete sympathetic, sensory and motor block[5].

MUSCARINIC RECEPTORS

Ketamine anaesthesia is antagonized by anticholinesterase agents[12] which increase endogenous acetylcholine concentrations and there is evidence for an interaction of ketamine with muscarinic receptors[10 13]. Indeed, ketamine produced stereoselective interaction with muscarinic receptors in guineapig brain membranes in a series of binding experiments (K_i of S(+) and R(−)ketamine: 20 and 37 μmol $litre^{-1}$, respectively). In addition, Durieux[13] reported that clinically relevant concentrations of ketamine inhibited muscarinic signalling through M1 receptors expressed in *Xenopus* oocytes (IC_{50} 5.7 μmol $litre^{-1}$), the most prominent subtype in the cortex and hippocampus. Whether ketamine is an agonist or antagonist is unclear. However, as ketamine produces anticholinergic symptoms (postanaesthetic delirium, bronchodilatation and a sympathomimetic action) and ketamine anaesthesia is reversed by anticholinesterases, an antagonist action is likely.

VOLTAGE-SENSITIVE CA^{2+} CHANNELS (VSCC)

Interaction of ketamine with voltage-sensitive Ca^{2+} channels (VSCC) has not been studied extensively. Baum and Tecson[14] reported a small reduction (20%) in the peak current in guineapig myocardium with ketamine 10 and 100 μmol $litre^{-1}$. In addition, Yamakage, Hirshman and Croxton[15] reported that ketamine (>10 μmol $litre^{-1}$, IC_{50} 1 mmol $litre^{-1}$) significantly reduced the peak Ca^{2+} current in porcine tracheal smooth muscle cells. We have demonstrated previously, in cultured neuroblastoma cells, that ketamine produced non-competitive inhibition of K^+-stimulated increased intracellular Ca^{2+} (mediated by L channels), with an IC_{50} of 209 μmol $litre^{-1}$ [23]. The role of VSCC in the action of ketamine remains to be explored fully but non-competitive channel block (similar to the NMDA receptor) is possible.

Clinical use of ketamine

PAIN CONTROL

Systemic administration

Subanaesthetic doses of ketamine have been shown to be either potent analgesics[24] or ineffective[25] in the postoperative period. Recently, Arendt-Nielsen and colleagues[18] reported that a bolus of ketamine 0.5 mg kg^{-1} i.v. followed by continuous infusion at 9 μg kg^{-1} min^{-1} inhibited central temporal summation which is used as an index of dorsal horn responsiveness in humans. These authors demonstrated that ketamine could only inhibit NMDA receptor activity when the receptor-operated ion channel had been opened by nociceptive stimulation, and used this to explain why ketamine only marginally affects acute/phasic pain, and attempts to produce pre-emptive analgesia with ketamine were ineffective. This is clearly a controversial area warranting further study.

Extradural administration

The efficacy of extradural ketamine is also controversial. Naguib and colleagues[26] reported that extradural ketamine 30 mg produced potent postoperative pain relief without respiratory depression or psychic disturbance, while Schneider and Diltoer[27] showed that extradural ketamine (30 mg with 30 mg h^{-1}) provided inadequate analgesia with an associated "unpleasant feeling". Although ketamine has been reported to interact with opioid receptors[9 10], the affinity for opioid receptors may be 10 000 fold weaker than that of morphine[9]. Pharmacokinetic studies of extradural ketamine[28] and morphine[29] in dogs showed that 30 min after extradural injection the concentration ratio of cerebrospinal fluid/plasma was approximately 0.5 and 40, respectively. Therefore, it seems unlikely that extradural ketamine produces analgesia via opioid receptor occupation in the spinal cord and an effective (at the opioid receptor) extradural dose of ketamine is likely to produce not only spinal but also systemic effects, which might include general anaesthesia.

Intrathecal administration

Ketamine has been administered intrathecally (5–50 mg in 3 ml, approximately 0.2–2% solution) with or without adrenaline 0.1 mg for war casualties with lower limb injuries[4]. Ketamine 50 mg with adrenaline (but not ketamine alone) produced sensory and motor block without respiratory depression or hypotension lasting 45–90 min. Unlike the study of Dowdy, Kaya and Gocho[3] in dogs, central effects such as dizziness and drowsiness were reported in humans[4]. In animal studies[11 30 31], most investigators found that in the absence of adrenaline, ketamine-induced motor block was variable and shortlived[11 31], presumably related to increased systemic absorption. Therefore, intrathecal ketamine should be used in conjunction with adrenaline.

In summary, use of i.v., i.m., extradural or intrathecal ketamine for postoperative pain relief is clearly of limited value.

NEUROPROTECTIVE ACTION

As activation of NMDA receptors is implicated in cerebral ischaemic damage, NMDA receptor antagonists, including ketamine, have neuroprotective potential. In a study using MK-801 (an NMDA antagonist) and ketamine, Church, Zerman and Lodge reported neuroprotection after transient cerebral ischaemia in rats[32]. However, they also observed that high doses of ketamine and MK-801 produced behavioural disturbances. Hoffman and colleagues[33] showed that ketamine improved neuronal outcome from incomplete cerebral ischaemia in rats by a mechanism related to a decrease in plasma catecholamine concentrations. In contrast, Jensen and Auer[34] failed to demonstrate any protection against ischaemic damage in rats using ketamine. It is difficult to explain the discrepancy in these two studies[32 34] (both in rats), especially as the mechanisms for producing ischaemia, ischaemic time and the ketamine administration regimen were very similar. Further mechanistic studies are required to determine any neuroprotective efficacy.

CRITICAL ILL PATIENTS

Septic shock

Ketamine has been shown to reduce the need for inotropic support in septic patients[35], an effect that may be related to inhibition of catecholamine uptake[36]. In addition, infusion of ketamine resulted in better sedation, increased arterial pressure and diminution of bronchospasm in a patient with acute lymphatic leukaemia who developed bilateral fulminating pneumonia with marked agitation, hypotension and bronchospasm[37]. In this patient infusion of midazolam failed to provide adequate sedation. Several animal studies also indicated that ketamine anaesthesia may reduce pulmonary injury via a reduction in endotoxin-induced pulmonary hypertension and extravasation[38] and produce haemodynamic stability (presumably via reduction in catecholamine reuptake[36]) in a model of endotoxic shock[39]. In a recent study, Schmidt and colleagues showed that ketamine reduced endotoxin-mediated leucocyte adhesion to vessel walls[40].

Haemorrhagic shock

The sympathomimetic effects of ketamine[1] may be advantageous in patients with haemorrhagic shock compared with other conventional anaesthetics. Several clinical reports indicated that induction of anaesthesia with ketamine produced either no change or a slight increase in arterial pressure and heart rate[2]. However, ketamine should be used cautiously for shock patients as severe hypotension may occur on induction of anaesthesia. Ketamine-induced hypotension in shock may result from loss of sympathoadrenal activity that accompanies loss of consciousness[35].

Asthma

Ketamine has been used successfully in the treatment of status asthmaticus[41]. Laboratory studies indicated that the spasmolytic[42 43] and anti-inflammatory actions[38 40 44] of ketamine may contribute to its efficacy in asthma. The mechanism by which ketamine produces airway relaxation is still unclear although several mechanisms[15 42 43] have been suggested, including increased catecholamine concentrations, inhibition of catecholamine uptake, voltage-sensitive Ca^{2+} channel block and inhibition of postsynaptic nicotinic or muscarinic receptors.

In this editorial we have described the pharmacology of ketamine and discussed its clinical use. However, our knowledge of the mechanism(s) of action of ketamine is still far from complete and we hope further research with this interesting compound may provide clues to the mechanism(s) of ketamine anaesthesia and analgesia.

CLINICAL INVESTIGATIONS

Morphine consumption in patients receiving rectal paracetamol and diclofenac alone and in combination

J.E. MONTGOMERY, C.J. SUTHERLAND, I.G. KESTIN AND J.R. SNEYD

Summary

Paracetamol and diclofenac have different mechanisms of action, and the combination may be more effective than each drug used alone in treating postoperative pain. In a double-blind, controlled design, we studied 60 patients undergoing elective abdominal gynaecological surgery, who received suppositories of paracetamol 1.5 g, diclofenac 100 mg or a combination of the two before the start of surgery. Patients received morphine in the intraoperative period, and cumulative morphine use from a patient-controlled analgesia system was recorded to measure the analgesic effect of the suppositories. Morphine consumption was greatest in the group that received paracetamol alone and lowest in the group given the combination ($P<0.01$). There was no difference in the incidence of morphine-related side effects between the groups. We conclude that a diclofenac–paracetamol combination reduced the amount of morphine used compared with paracetamol alone. (*Br. J. Anaesth.* 1996;**77**:445–447)

Key words

Analgesics opioid, morphine. Analgesics non-opioid, diclofenac. Analgesics non-opioid, paracetamol. Pain, postoperative.

Non-steroidal anti-inflammatory drugs (NSAID), such as diclofenac, are effective in the treatment of postoperative pain. If given with opioids, the amount of opioid required is reduced with a consequent reduction in side effects[1–3]. In clinical studies, some patients with osteoarthritic pain found paracetamol to be as efficacious as NSAID, and it does not have the side effects of gastric irritation, altered platelet function or exacerbation of asthma[4 5]. Diclofenac and paracetamol have different mechanisms of action and the combination may be more effective than either drug used alone. We have undertaken a prospective, randomized, double-blind, comparative study to assess the analgesic efficacy of paracetamol alone and in combination with diclofenac.

Patients and methods

With Ethics Committee approval and written informed patient consent, we studied 60 women, ASA I or II, aged 25–65 yr, undergoing elective abdominal gynaecological surgery. We excluded women weighing more than 100 kg, those unable to use a patient-controlled analgesia system (PCA) for postoperative pain control and those with a history of peptic ulceration, bleeding disorders, impaired renal or hepatic function, or sensitivity to NSAID or paracetamol. Patients received temazepam 20–30 mg, 1 h before operation and anaesthesia was induced with thiopentone 3–5 mg kg^{-1}. Vecuronium 0.1 mg kg^{-1} was given to facilitate orotracheal intubation. Morphine 0.1–0.15 mg kg^{-1} was given as an i.v. bolus before the start of surgery; additional boluses were given during surgery if required up to a total of 0.2 mg kg^{-1}. Anaesthesia was maintained with 0.5–2% enflurane and 60% nitrous oxide in oxygen.

Patients were allocated randomly to one of three groups by opening a sealed envelope, after induction of anaesthesia. Allocation was decided using random numbers generated by Claris Works software. Group P received a rectal suppository of paracetamol 1.5 g; group D received a rectal suppository of diclofenac 100 mg; and group PD received rectal suppositories of paracetamol 1.5 g and diclofenac 100 mg. The suppositories were given before the start of surgery.

At the end of surgery, residual neuromuscular block was antagonized with glycopyrronium 0.5 mg and neostigmine 2.5 mg. In the recovery area patients received morphine 2 mg i.v. at 5-min intervals until they described their pain as mild or absent. A PCA system (Graseby 3300, Graseby Medical Ltd, Watford, Herts) programmed to give a bolus of morphine 1 mg with droperidol 50 µg, with a 5-min lockout time and no background infusion, was connected to a dedicated i.v. cannula. Prochlorperazine 12.5 mg i.m. every 6 h if required and oxygen for the first 6 h were prescribed.

The amount of morphine given before connection to the PCA system and duration of anaesthesia and recovery were recorded. Hourly cumulative morphine requirements were recorded from the electronic memory of the PCA system. At 6 and 24 h after operation, patients were visited by an investigator who was unaware of the treatment group, and asked to complete two 10-cm visual analogue scales (VAS), one for pain and one for nausea. Both scales ranged from none to worst possible. The VAS for pain was recorded on deep breathing, as this has been shown to be more reproducible than a pain

Correspondence to J. R. S.

score obtained at rest[6]. At these times the investigator also recorded a sedation score: 0=fully awake; 1=drowsy; 2=sleeping but responds to gentle stimulus; 3=sleeping no response to gentle stimulus. The nurses recorded routinely pain and sedation scores and ventilatory frequency every hour for 6 h, and every 2 h thereafter.

The sample size was chosen by *a priori* power calculation to provide 80% probability of demonstrating a reduction in the use of morphine by 30% when $\alpha=0.05$. Results were analysed using repeated measures one-way analysis of variance for morphine consumption, one-way analysis of variance and Fisher's exact test; paired comparisons were made using Student's t test with Bonferroni correction for parametric data and Dunn's test for non-parametric data. The level of significance was 5%.

Results

One woman, who received both paracetamol and diclofenac, was excluded from the analysis as she was unable to use the PCA because of severe vomiting and requested alternative analgesia 19 h after operation. Of the remaining 59 women, 20 received paracetamol, 20 received diclofenac and 19 received both.

There were small but statistically significant differences in age and body mass index between the three groups. Women who received both paracetamol and diclofenac were significantly older than those who received paracetamol (mean age 44.5 yr compared with 38.1 yr, $P=0.02$) (table 1). Body mass index for those given paracetamol was significantly less than for either of the other groups (22 compared with 26.1 and 24.4, $P<0.02$) (table 1). Duration of anaesthesia and amount of time spent in recovery were similar in all three groups (table 1).

The amount of morphine required before the start of the PCA was similar in each group (mean 12.5 mg, 14.8 mg and 13.4 mg) (table 2). Patients receiving paracetamol used significantly more morphine over the 24 h than those given paracetamol and diclofenac ($P<0.05$) (fig. 1, table 2). Women given diclofenac used an intermediate amount of morphine, although this was not significantly different from the two other groups (fig. 1). VAS pain scores were similar between groups (table 2).

There were no differences between the groups in any of the measures of nausea and vomiting (table 3), and sedation scores were similar between groups. No patient had a ventilatory frequency of less than 10 bpm. One patient, who received both paracetamol and diclofenac, required transfusion because of excessive blood loss during difficult surgery. No other patient required blood transfusion.

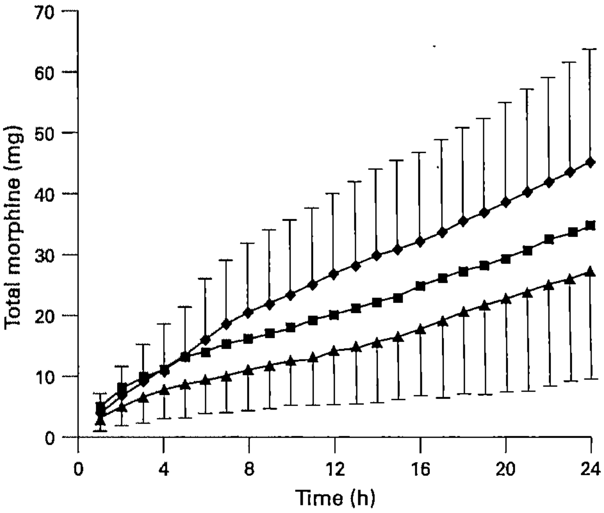

Figure 1 Cumulative morphine consumption (mean, SD) in the paracetamol (♦), diclofenac (■) and combination (▲) groups . For clarity error bars are omitted from the diclofenac group. At 6, 12, 18 and 24 h, the SD values of this group were 7.0, 9.0, 12.4 and 15.1 mg, respectively

Discussion

The use of a combination of paracetamol with other NSAID has been shown to improve analgesia in dental and other pain models[7–9]. In our study, patients used a PCA system and therefore the effects of the drugs were measured by morphine consumption, not by differences in analgesia. Diclofenac and paracetamol have different mechanisms of action and their actions may therefore be additive or synergistic. The use of the combination reduced the amount of morphine required during the first 24 h after operation compared with paracetamol alone. Patients who received both drugs used less morphine than those who received diclofenac alone, but this was not statistically significant. We would need to study approximately 100 patients per group for these differences to be statistically significant.

We did not include a placebo control group, who would have received morphine PCA alone, as a previous study has shown that diclofenac reduces morphine requirements, with reduced pain scores at 4 h after surgery[3].

The dose of paracetamol used (1.5 g) was higher than the normal oral paracetamol dose, as the bioavailability of suppositories is lower than tablets[10] and only a single dose was given. Recent studies in children receiving rectal paracetamol have shown that doses as high as 35 mg kg^{-1} may be needed to achieve plasma concentrations in the therapeutic range[11]. It may be that the initial dose of rectal paracetamol needs to be larger than currently recommended to provide better analgesia; further studies are needed to assess this.

Patients in the paracetamol group had a significantly lower body mass index than the two other groups, however, the effective dose of morphine is not necessarily dose related[12]. Women in the paracetamol group were also slightly younger than in the combination group, which would be likely to increase morphine consumption. However, morphine consumption is very variable between patients and the age difference was small, therefore we believe that this was unlikely to have had an important effect. The incidence and severity of nausea and vomiting were similar to those reported in other studies where droperidol was used in the PCA and were similar between groups[13]; if droperidol had not been included it may have been possible to show between-group differences.

In conclusion, the use of a diclofenac–paracetamol combination reduced the amount of morphine required for adequate analgesia by about one-third compared with paracetamol alone.

Postoperative pulmonary function after laparoscopic and open cholecystectomy

A. J. KARAYIANNAKIS, G. G. MAKRI, A. MANTZIOKA, D. KAROUSOS AND G. KARATZAS

Summary

In this prospective, randomized study, we compared 42 patients undergoing laparoscopic cholecystectomy and 40 undergoing open cholecystectomy to determine if laparoscopic cholecystectomy results in less respiratory impairment and fewer respiratory complications. Pulmonary function tests, arterial blood-gas analysis and chest radiographs were obtained in both groups before operation and on the second day after operation. Postoperative pain scores and analgesic requirements were also recorded. After operation, a significant reduction in total lung capacity, functional residual capacity (FRC), forced expiratory volume in 1 s (FEV_1), forced vital capacity (FVC) and mid-expiratory flow ($FEF_{25-75\%}$) occurred after both laparoscopic and open cholecystectomy. The reductions in FRC, FEV_1, FVC and $FEF_{25-75\%}$ were smaller after laparoscopic (7%, 22%, 19% and 23%, respectively) than after open (21%, 38%, 32% and 34%, respectively) cholecystectomy. Laparoscopic cholecystectomy was also associated with a significantly lower incidence (28.6% *vs* 62.5%) and less severe atelectasis, better oxygenation and reduced postoperative pain and analgesia use compared with open cholecystectomy. We conclude that postoperative pulmonary function was impaired less after laparoscopic than after open cholecystectomy. (*Br. J. Anaesth.* 1996;**77**:448–452)

Key words

Lung, atelectasis. Complications, respiratory. Surgery, laparoscopy. Surgery, gastrointestinal. Lung, function.

Cholecystectomy performed via laparotomy is associated with postoperative pulmonary dysfunction which increases the risk of postoperative pulmonary complications. The site and size of the surgical incision, severity of postoperative pain and impaired diaphragmatic function are the most important factors known to impair pulmonary function after conventional open cholecystectomy[1–5].

Laparoscopic cholecystectomy is a new technique that has become the treatment of choice for symptomatic cholelithiasis[6]. The procedure is associated with the absence of skin incision, less pain, shorter hospitalization and faster recovery compared with open cholecystectomy[6–8]. Minimal pulmonary dysfunction after laparoscopic cholecystectomy in healthy patients has been reported by several authors[9–14]. However, in most studies only expiratory lung volumes were evaluated and postoperative respiratory complications were not studied. In addition, these were observational or non-randomized studies, limited to a small number of patients, and could have exaggerated the advantages of laparoscopic cholecystectomy.

We have therefore compared changes in respiratory function after laparoscopic and conventional open cholecystectomy in a prospective, randomized study.

Patients and methods

All patients with symptomatic cholelithiasis, undergoing elective cholecystectomy under general anaesthesia, were considered for entry into this study. Exclusion criteria were acute cholecystitis, choledocholithiasis, age more than 65 yr and obesity (body mass index >29 kg m^{-2}). Patients with a history of previous pulmonary disease, those smoking more than 10 cigarettes per day and patients not accepting randomization were also excluded. The study was planned according to the Helsinki declaration and was approved by our hospital's Research Ethics Committee. After giving informed consent, suitable patients were allocated randomly, by selecting closed envelopes, to a surgical team capable of performing each procedure.

Anaesthetic and operative procedures were standardized for each group. Diazepam 10 mg was given orally for premedication 60 min before surgery. General anaesthesia was induced with fentanyl 2 μg kg^{-1} and thiopentone 5 mg kg^{-1}. Suxamethonium 1 mg kg^{-1} was given to facilitate intubation of the trachea. Anaesthesia was maintained with 1% isoflurane and 60% nitrous oxide in oxygen, fentanyl and pancuronium. The lungs of all patients were ventilated mechanically with a tidal volume of 8–10 ml kg^{-1} and ventilatory frequency was adjusted to maintain an end-tidal carbon dioxide partial pressure of 4.0–4.3 kPa. During operation, patients were monitored continuously for heart rate, arterial pressure, oxygen

saturation (as measured by pulse oximetry) and partial pressure of carbon dioxide in exhaled gas (end-tidal carbon dioxide). Arterial blood samples for gas analysis were obtained just before insufflation, during dissection of the cystic pedicle and before desufflation.

All operations were performed in the morning after an overnight fast. All patients had a nasogastric tube and urinary catheter inserted, and these were removed immediately after surgery. Open cholecystectomies were performed through a transverse right subcostal incision, 10–12 cm long, with partial transection of the ipsilateral rectus abdominis muscle. Laparoscopic cholecystectomies were performed via a four trocar technique, as described previously[15], pneumoperitoneum was established with carbon dioxide insufflation and the intra-abdominal pressure was maintained at 14 mm Hg.

PULMONARY FUNCTION STUDIES

Static and dynamic lung volumes and flow rates were measured using Jaeger's Bodybox and pneumotachograph (Bodyscreen II, Jaeger, Germany). Measurements were made with the patient in the sitting position, according to the guidelines of the American Thoracic Society[16]. Forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1), mid-expiratory flow ($FEF_{25-75\%}$), functional residual capacity (FRC), residual volume (RV), total lung capacity (TLC) and airway resistance (*R*aw) were measured and the greatest value of three attempts was recorded, except for FRC which was defined as the mean of three measurements. RV/TLC and FEV_1/FVC ratios were also calculated. Arterial blood-gas analysis was performed just before the spirometric studies using an automatic analyser (ABL-3, Radiometer, Copenhagen, Denmark). All tests were performed in our respiratory laboratory by the same physician who was unaware of the nature of the study.

Posteroanterior and lateral chest radiographs were obtained at maximal inspiration with the patient in the upright position. Chest radiographs were interpreted by a qualified radiologist who was unaware of the type of procedure and whether the x-ray was performed before or after operation. Atelectasis was graded as micro-, focal, segmental or lobar. Pneumonia was defined as the simultaneous presence of radiological and physical signs, and positive culture results.

All studies were performed on the day before surgery and in the morning of the second postoperative day. Postoperative spirometry was performed if the VAS pain score, estimated at rest just before testing, was less than 4 cm.

PAIN ASSESSMENT

Intensity of postoperative pain was estimated using a linear 0–10 cm (0=no pain, 10=severe pain) visual analogue scale (VAS). Assessments were made when the patient arrived at the recovery ward, 4 and 12 h after the end of surgery, and thereafter at 08:00, 14:00 and 20:00 every day after operation. To standardize postoperative analgesia, pethidine 0.5 mg kg^{-1} i.m. was administered to all patients, as requested by the patient. Pain charts were collected every day by an independent observer and the daily recorded numerical pain scores were summed for each patient. Analgesic use was also calculated on a daily basis as the total quantity of pethidine administered.

STATISTICAL ANALYSIS

All data are presented as mean (SD) values except for pain scores and pethidine consumption where the median (interquartile range) value is used. Statistical analysis was performed using the Statgraphics 5.1 statistical software package (Statistical Graphics Corporation, Rockville, MD, USA). Quantitative data were analysed by paired and unpaired *t* test and categorical data by chi-square test. Differences in pulmonary function variables within each group were evaluated by the paired *t* test. Perioperative changes were calculated and statistical comparisons between groups were made using the unpaired *t* test. The overall incidence and severity of atelectasis between groups were compared by the chi-square test for trend. The Mann–Whitney *U* test was used to compare pain scores and analgesic requirements. Significance was presumed at $P<0.05$.

Results

During the study period (March 1992 to November 1993), 147 patients fulfilling the selection criteria were admitted for elective cholecystectomy. Informed consent to randomization was obtained from 98 patients. Seven patients (two allocated for laparoscopic and five for open cholecystectomy) declined to take part after randomization. Two patients from the laparoscopic cholecystectomy group were excluded because of incomplete recording of pulmonary function tests. Three patients randomized for laparoscopic cholecystectomy required conversion to open cholecystectomy as a result of difficulties in defining anatomy. These patients were also excluded. Four patients scheduled for open cholecystectomy were excluded from the study because they underwent common bile duct exploration. Thus 82 patients completed the study: 42 patients underwent laparoscopic and 40 open cholecystectomy. The two study groups were similar in patient characteristics, and anaesthetic and operative times. Duration of postoperative hospital stay was significantly shorter after laparoscopic cholecystectomy (table 1).

Preoperative pulmonary function tests and arterial blood-gas values were normal and did not differ significantly between the two groups. After operation, a significant reduction ($P<0.05$) in TLC, FRC, FEV_1,

Pa_{O_2} (kPa)	11.33 (0.77)	10.65 (0.83)*	−0.68 (0.50)†

FVC and FEF$_{25-75\%}$ occurred after laparoscopic (table 2) and open cholecystectomy (table 3). However, mean reductions in FRC, FEV$_1$, FVC and FEF$_{25-75\%}$ after laparoscopic cholecystectomy (0.20 (0.40) litre (7 (13)%), 0.64 (0.65) litre (22 (17)%), 0.66 (0.52) litre (19 (16)%) and 0.74 (0.65) litre (23 (21)%), respectively) were significantly ($P<0.05$) smaller compared with those after open cholecystectomy (0.60 (0.40) litre (21 (12)%), 1.12 (0.62) litre (38 (17)%), 1.07 (0.56) litre (32 (19)%) and 1.00 (0.54) litre (34 (15)%), respectively). The RV/TLC ratio increased significantly in both groups ($P<0.05$). Changes in *R*aw, RV and FEV$_1$/FVC ratio were minimal and not significant in both groups. Arterial blood-gas analysis revealed better oxygenation after laparoscopic cholecystectomy (Pa_{O_2}=11.15 (0.65) *vs* 10.65 (0.83) kPa; $P<0.05$). Arterial pH and Pa_{CO_2} remained unchanged in both groups.

Table 4 Postoperative atelectasis after laparoscopic (LC) or open (OC) cholecystectomy. *$P < 0.05$ between groups (chi-square test for trend)

	LC (n=42)	OC (n=40)
Microatelectasis	7	14
Focal	3	7
Segmental	2	3
Lobar	0	1
Normal	30	15*

All preoperative chest radiographs were interpreted as normal. The overall incidence of postoperative atelectasis was significantly higher after open cholecystectomy (62.5% *vs* 28.6%; overall chi-square=10.09, df=4, $P<0.05$) (table 4). Atelectasis was also more severe after open cholecystectomy (chi-square for trend=7.05, df=1, $P<0.05$). Patients who developed atelectasis in the open cholecystectomy group had lower Pa_{CO_2} values compared with those without atelectasis (10.2 (0.9) *vs* 11.0 (0.8) kPa, $P<0.05$). In contrast, postoperative Pa_{CO_2} values in the laparoscopic cholecystectomy group were not significantly different between patients with and without atelectasis (10.9 (0.7) *vs* 11.3 (0.6) kPa). No patient was diagnosed as having pneumonia.

Postoperative pain scores and pethidine analgesia use during the study were significantly less in the laparoscopic cholecystectomy group (table 5).

Discussion

When this study was designed the authors had experience of performing 40 laparoscopic cholecystectomies. At that time many surgeons were critically examining the benefits of the procedure and there were surgeons at our institution who were not performing laparoscopic cholecystectomy. A randomized study of laparoscopic compared with open cholecystectomy was justified. As the study proceeded, ethical problems arose, as experienced by other authors[17]. In addition, the wide media publicity resulted in high motivation among patients to undergo only laparoscopic cholecystectomy. The highest rate of non-acceptance and all withdrawals after randomization were observed during the last 6 months of the study. Men were more keen to participate in the study and this was reflected in the relatively higher than expected male/female ratio in this study.

To our knowledge, there has been no other randomized study comparing pulmonary function after laparoscopic and open cholecystectomy. Results from this study indicated that considerable impairment of pulmonary function occurred after laparo-

scopic cholecystectomy in otherwise healthy patients. The patterns of postoperative alterations were qualitatively similar but quantitatively less than those after open cholecystectomy. In previous observational[13,14] and non-randomized controlled[9–12,18,19] studies, the postoperative reduction in FVC, FEV_1 and $FEF_{25-75\%}$ ranged from 20% to 40% on the first or second postoperative day after laparoscopic and from 40% to 70% after open cholecystectomy in healthy patients. A significant reduction in TLC after laparoscopic (8% to 17%) and after open (22%) cholecystectomy was also observed[13,19], while RV was unchanged[13,14]. FRC has been reported to decrease 24 h after laparoscopic cholecystectomy by 7% to 15% of preoperative values[13,14] compared with a reduction of 36% after open cholecystectomy[18]. The patterns and magnitude of the changes in pulmonary function after laparoscopic or open cholecystectomy observed in this study are in agreement with those mentioned above. The small discrepancies may possibly be related to differences in patient selection criteria, duration of anaesthesia and surgery, and measurements at different postoperative times. However, the most important finding is that laparoscopic cholecystectomy is associated with less impairment of pulmonary function compared with open cholecystectomy.

Upper abdominal surgery performed through a subcostal or midline incision is associated with significant alterations in pulmonary function. A restrictive breathing pattern with reduced inspiratory capacity is evident immediately after surgery[1,2]. A shift from abdominal to thoracic breathing occurs because of the reduced diaphragmatic contribution to tidal volume[4,5,20]. Although the aetiology of pulmonary dysfunction after upper abdominal surgery is not completely elucidated, postoperative pain[3,20,21] and diaphragmatic dysfunction[4,5] are considered to be the major contributing factors. Pain scores and analgesic requirements in this study were reported up to the second postoperative day as at that time most of the patients undergoing laparoscopic cholecystectomy were discharged from hospital. Decreased pain scores and reduced analgesic requirements, observed during this period of time, confirmed the clinical observations that laparoscopic cholecystectomy was accompanied by less postoperative pain. However, it is not evident if less postoperative pain is the only factor responsible for less impairment of pulmonary function after laparoscopic cholecystectomy. Extradural analgesia provides adequate pain relief but does not improve pulmonary function after laparoscopic cholecystectomy[10]. Therefore, diaphragmatic dysfunction after laparoscopic cholecystectomy should be considered also. Diaphragmatic contribution to tidal volume during quiet breathing was found to be unchanged immediately after laparoscopic cholecystectomy[22]. However, 3 h after surgery a shift from abdominal to thoracic breathing associated with a 30% reduction in total tidal volume and an increased breathing frequency were observed[23]. This rapid and shallow breathing pattern led to an increase in end-tidal carbon dioxide concentration by 9%. There was no evidence of altered contractility and changes in breathing pattern were attributed to reflex inhibition of diaphragmatic inspiratory activity. Impaired diaphragmatic function early after laparoscopic cholecystectomy with gradual restoration over 24 h was documented also by direct diaphragmatic electromyography[24]. Alterations in rib cage–abdominal partitioning with reduction in abdominal tidal volume during resting and coached abdominal breathing by 32% and 29%, respectively, and shortening of the inspiratory time were observed 24 h after laparoscopic cholecystectomy[25]. These findings suggest that diaphragmatic dysfunction, similar to that in the open procedure, does occur after laparoscopic cholecystectomy. This is not unexpected as the intra-abdominal site of intervention is the same in both procedures. Manipulation and local stimulation of the gallbladder and its bed during laparoscopic cholecystectomy may elicit reflex inhibition of the diaphragm, as has been shown in animal studies[26].

Postoperative alterations in pulmonary function are clinically important if they contribute to respiratory complications. The decrease in FRC and its relation to the closing capacity have been shown to correlate well with postoperative atelectasis and hypoxaemia[2,27,28]. The development of atelectasis after laparoscopic cholecystectomy has been evaluated in two other studies. Johnson and colleagues[14] reported that segmental atelectasis developed in three of 31 patients undergoing laparoscopic cholecystectomy. In the study of Schauer and colleagues[19], radiological atelectasis of varying degrees occurred in 40% of patients after laparoscopic cholecystectomy compared with 95% of patients after open cholecystectomy. This high rate of atelectasis was probably a result of the fact that many patients in that study had risk factors for postoperative pulmonary complications. In our study in healthy patients, the incidence and severity of postoperative atelectasis were significantly reduced and Pa_{O_2} values were higher after laparoscopic cholecystectomy. Better oxygenation after laparoscopic cholecystectomy compared with open cholecystectomy has been also reported by other authors[9,11,18]. Although these findings parallel the changes in FRC, it is difficult to ascertain if the smaller reduction in FRC after laparoscopic cholecystectomy observed in our study translates into fewer respiratory complications.

Acknowledgements

The authors are grateful to Dr H. Taktikou-Kourkoulakou (Respiratory Laboratory, "Laikon" Hospital, Athens) for performing lung function studies, Mrs A. Gosling (Department of Medical Statistics and Evaluation, Royal Postgraduate Medical School, London) for statistical advice and Dr R. Mathie (Department of Surgery, Royal Postgraduate Medical School, London) for revision of the manuscript.

Influence of motivation of care providers on the incidence of postoperative hypoxaemia in the recovery room†

A. T. Rheineck-Leyssius, C. J. Kalkman and A. Trouwborst

Summary

We have studied the influence of motivation of care providers on the incidence and duration of postoperative hypoxaemia in the recovery room. In a prospective, switch-back designed cohort study, we have compared the incidence of low pulse oximeter saturation values (Sp_{O_2}) during pre-intervention, intervention and post-intervention phases. Low Sp_{O_2} values were classified as either hypoxaemia ($Sp_{O_2} \leq 90\%$, minimum duration 1 min) or artefact. Pulse oximetry trend data from 1350 patients, 450 in each group, were analysed. During the intervention phase, motivation was increased by adding an explicit instruction to prevent and treat low Sp_{O_2} values and making personnel aware that they were being studied (Hawthorne effect). The incidence of hypoxaemia decreased significantly from 17.8% during the pre-intervention phase to 11.6% during the intervention phase (relative risk (RR) 0.65, 95% confidence interval (CI) 0.47–0.90; $P<0.01$). The incidence of severe hypoxaemia ($Sp_{O_2} \leq 85\%$, 1 min) decreased from 7.8% to 3.3% (RR 0.43, CI 0.24–0.76; $P<0.01$). The number of patients who had severe hypoxaemia for more than 5 min decreased from 13 to 1 (RR 0.08, CI 0.02–0.36; $P<0.01$). In the post-intervention period, the incidence of hypoxaemia returned to pre-intervention values. The results of this study suggest that motivation of care providers to prevent and treat low Sp_{O_2} is an important determinant of postoperative hypoxaemia in the recovery room. (*Br. J. Anaesth.* 1996;**77**:453–457)

Key words

Hypoxaemia. Surgery, postoperative period. Monitoring, oxygen.

Pulse oximetry is used in the recovery room to alert staff to life-threatening respiratory events and to detect milder forms of hypoxaemia that may require treatment[1–3]. Although the pulse oximeter is highly sensitive for hypoxaemia, its specificity is low. Especially in the early postoperative phase, pulse oximeter artefacts may produce oxyhaemoglobin saturation (Sp_{O_2}) values that do not represent hypoxaemia[4 5]. In a recent study the average frequency of pulse oximeter alarms ($Sp_{O_2} \leq 90\%$) being sounded in the recovery room was once every 8 min, with 77% of alarms being false[6]. We suspected that a very high incidence of false alarms could encourage recovery room nurses to accept low Sp_{O_2} values as "normal" or "inevitable" and decrease their motivation to treat hypoxaemia.

This prospective cohort study was designed to test if motivation of care providers plays a role in preventing hypoxaemia. The study had a switch-back design (pre-intervention, intervention, post-intervention). Care providers (recovery room nurses and anaesthetists) were unaware of Sp_{O_2} data collection in the pre-intervention period. In the intervention period an explicit instruction to maintain $Sp_{O_2}>90\%$ accompanied each patient, and care providers were purposely made aware that they were being studied. The null hypothesis was that the intervention would not change the incidence or duration of hypoxaemia. The post-intervention period served to ascertain if any possible change in the incidence of hypoxaemia occurring during phase 2 persisted after the incentives to prevent and treat low Sp_{O_2} values were removed.

Patients and methods

The study was performed in a 650-bed community hospital. Six full-time anaesthetists (minimum experience 6 yr post-graduation) are on staff. There are 10 operating rooms and a nine-bed recovery room. Neurosurgical procedures or cardiac surgery are not performed. Neither the types of case nor the anaesthetic technique changed over the three study phases. Patients undergoing operations under general, spinal or extradural anaesthesia, who were

†Presented in part at the Annual Meeting of the American Society of Anesthesiologists, San Francisco, CA, October, 1994.

monitored for at least 10 min in the recovery room, were eligible to enter the study. There were no exclusion criteria based on age or clinical condition of the patient.

For each of the three study phases, Sp_{O_2} data from 450 consecutive patients were retrieved from pulse oximeter memory (3–4 weeks for each phase).

During phase 1, anaesthetists and nurses were unaware of Sp_{O_2} data collection. The default lower alarm limit of the pulse oximeter was 90%. There were no specific written guidelines regarding treatment of postoperative hypoxaemia. This study phase was designed to determine the incidence of hypoxaemia during routine postoperative care. After analysis of these data, care providers were informed of the incidence and duration of postoperative hypoxaemia, and the study design was explained. No attempt was made to link hypoxaemia to individual anaesthetists or nurses.

Phase 2 of the study, the intervention period, was conducted immediately after completion of phase 1. An explicit written instruction to maintain $Sp_{O_2}>90\%$ accompanied each patient, but no specific instructions regarding the methods of maintaining normoxaemia were given. Anaesthetists and nurses were now aware that pulse oximetry data from the next 450 patients would be retrieved and analysed. In this way a positive bias on performance, resulting from the knowledge of being studied (Hawthorne effect) was purposely introduced. After completion of phase 2, data were analysed and the results presented to care providers. From that time, the written instruction to prevent hypoxaemia was omitted from the postoperative orders.

Phase 3 started 2 months after completion of phase 2. There was no written instruction to prevent hypoxaemia in the postoperative orders. Anaesthetists and nurses were again unaware that pulse oximetry data were collected.

The hospital Ethics Committee advised that only patients in phase 2 were required to give informed consent, as data obtained in phases 1 and 3 consisted of anonymous pulse oximeter trend data and no randomization was involved.

RECOVERY ROOM AND DATA ACQUISITION

One nurse takes care of a maximum of two postoperative patients at a time. If necessary, postoperative mechanical ventilation is available for two patients. Supplementary oxygen is not administered during transport from the operating theatre to the recovery room. In the recovery room supplementary oxygen is administered by nasal cannula to all patients during the initial postoperative period. The minimum duration of stay for an individual patient is ordered by the responsible anaesthetist at the time of arrival.

Routine pulse oximetry monitoring had been established 4 yr previously. A Criticare 504 pulse oximeter with system software version 3.1 (Criticare Systems, Inc., Waukesha,WI, USA) was used for monitoring Sp_{O_2}. This monitor shows a plethysmographic waveform and does not apply autoscaling. Signal averaging has a default value of 12 s. Monitoring started immediately after arrival of the patient and was continued until the time of discharge. The probe of the pulse oximeter was applied to a finger of the hand opposite to the arterial pressure cuff. The Sp_{O_2} lower alarm limit used at the start of monitoring was 90%. This level was the default lower alarm limit on all oximeters for the past 4 yr. It was chosen to reflect a threshold that would undisputedly suggest a need for therapy. A loud audible alarm sounds when Sp_{O_2} decreases below the lower alarm limit or when the pulse oximeter is unable to measure Sp_{O_2} because of a low signal-to-noise ratio or disconnection of the probe from the finger.

Sp_{O_2} and pulse frequency, together with time, were stored every 5 s in the memory of the pulse oximeter. At the end of the day, when the last patient had been discharged to the ward and personnel had left the recovery room, these data were transferred from pulse oximeter memory to a personal computer for off-line analysis.

DATA ANALYSIS

Individual Sp_{O_2} trend arrays were validated before analysis. Episodes with $Sp_{O_2}\leq 90\%$ were classified as either hypoxaemia or artefact. The algorithm used to exclude episodes with artefact used the following criteria: (1) transient outlier: a single datum point (5-s resolution) changed more than 4% from the surrounding data; (2) low signal-to-noise ratio: loss of signal occurred 20 s before until 20 s after the episode of low Sp_{O_2}; and (3) decrease in Sp_{O_2} of more then 10% within 5 s. Two arbitrary levels of hypoxaemia were defined and for each patient the cumulative duration of hypoxaemia was calculated. Hypoxaemia was defined as episodes of $Sp_{O_2}\leq 90\%$ lasting at least 1 min. Severe hypoxaemia was considered to be present when Sp_{O_2} values were at or below 85% for at least 1 min.

In each study phase the following were determined: number of patients who were hypoxaemic at any moment during pulse oximetry monitoring in the recovery room; number of patients who arrived hypoxaemic in the recovery room; and number of hypoxaemic patients, after excluding data recorded during the first 3 min of monitoring in the recovery room.

STATISTICAL ANALYSIS

Data are presented as counts and percentiles. Differences between phases were analysed using chi-square and Kruskal–Wallis tests. $P<0.05$ was considered significant. Group size was calculated to achieve 85% power to detect a 50% decrease in the incidence of hypoxaemia. The incidence of hypoxaemia during phase 2 was expressed as relative risk to phase 1. The confidence interval for relative risk was calculated using the Mantel–Haenszel chi-square statistic.

Results

Patient data, anaesthesia data and duration of postoperative monitoring are shown in table 1. Median duration of stay in the recovery room in phase 2 was 6 min longer ($P<0.01$).

The audible Sp_{O_2} alarm was triggered 766 times during phase 1 (mean 2.1 times per hour of monitoring), 411 times during phase 2 (1.2 per hour) and

Regional anaesthesia (n)	44	40	39
Median duration of anaesthesia (10th–90th percentiles) (min)	44 (10–91)	46 (10–90)	46 (9–92)
Median duration of monitoring (10th–90th percentiles) (min)	37 (14–96)	43** (18–108)	39†† (14–108)

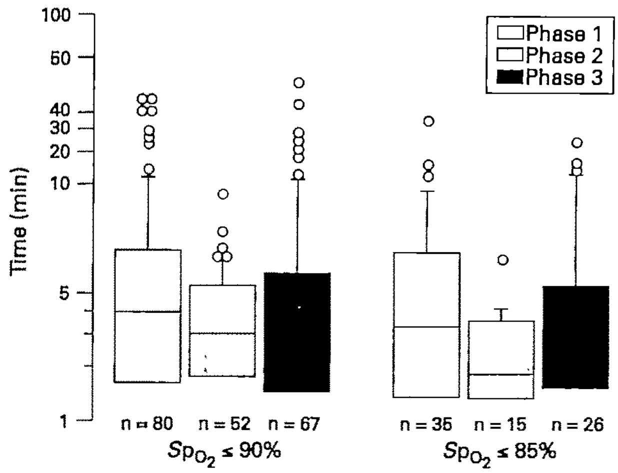

Figure 1 Cumulative duration of hypoxaemia for two thresholds ($Sp_{O_2} \leq 90\%$ and $Sp_{O_2} \leq 85\%$) during the three study phases. Median duration of hypoxaemia was not different between study phases, but the number of patients who were hypoxaemic for more than 5 min was reduced in phase 2. Box plots show medians (horizontal line in box), 25th and 75th percentiles (lower and upper box margins) and 90th percentiles (upper error bar). Open circles=individual patients in the upper 10th percentile. The y-axis has a logarithmic scale in minutes. Below the boxes the absolute numbers of hypoxaemic patients in each study phase are given.

588 times during phase 3 (1.5 per hour). In 53% of patients, the Sp_{O_2} signal was lost transiently at some time during monitoring. There were no differences in the incidence or duration of "no signal conditions" (median duration 40 s) between the three phases of the study. The incidence of artefacts was reduced in phase 2 (table 2).

Table 2 shows the number of hypoxaemic patients in each phase. In phase 1, 17.8% of patients experienced hypoxaemia. During phase 2 it decreased to 11.6% (relative risk (RR) 0.65, 95% confidence interval (CI) 0.47–0.90; P<0.01). More severe hypoxaemia ($Sp_{O_2} \leq 85\%$) was noted at some time in 7.8% of patients during phase 1; in phase 2 it decreased to 3.3% (RR 0.43, CI 0.24–0.76; P<0.01). The reduction in postoperative hypoxaemia during phase 2 was not persistent: the incidence of hypoxaemia in phase 3 was not significantly different from phase 1. The number of patients who arrived hypoxaemic in the recovery room was less in phase 2 compared with phase 1. When data recorded during the first 3 min of monitoring were excluded from analysis, the reduction in hypoxaemia in phase 2 compared with phase 1 remained.

Median duration of hypoxaemia was not different between the three study groups. However, the 90th percentile of the duration of severe hypoxaemia was 19 min in phase 1, 3.5 min in phase 2 and 21 min phase 3 (fig. 1). Severe hypoxaemia lasting more than 5 min occurred in 13 patients during phase 1 compared with in one patient during phase 2, and in six patients during phase 3 (RR 0.08, CI 0.02–0.36; P<0.01).

Discussion

We have found that an explicit instruction to maintain Sp_{O_2}>90%, combined with the knowledge of being studied, may reduce the incidence of postoperative hypoxaemia by as much as 50%. The recurrence of hypoxaemia 4 months after intervention further supports the hypothesis that motivational factors of care providers is an important determinant of the incidence of postoperative

hypoxaemia. With this sample size the study lacked sufficient statistical power to determine if some residual effect of the intervention was present in phase 3, and it is possible that a larger study population might have shown such an effect. However, a larger study population would have required a longer data collection period, during which time changes in recovery room personnel could not be avoided.

Subjects who are aware of being studied behave differently, and usually performance increases (Hawthorne effect). In several studies on the incidence of postoperative hypoxaemia, the investigators used bedside observers to record the actions of personnel and to verify that a valid pulse oximeter signal was present[2,3,7]. However, the presence of an observer might introduce a Hawthorne effect and the possibility exists that studies involving direct observation of personnel do not reflect the actual situation during routine postoperative care. The aim of the pre-intervention phase was to document existing practices. Therefore, anaesthetists and nurses were not informed that pulse oximetry data were collected and no observers were present to document patient care. Although this study design precluded matching of pulse oximetry data from individual patients with specific therapeutic interventions, the absence of observers made it possible to document real practice and to introduce a positive study bias during the intervention. No specific instructions regarding particular methods to prevent or treat hypoxaemia were given. In this way we tried to ensure that any change in the incidence of hypoxaemia was the result of an action initiated by an individual anaesthetist or nurse, for example administration of reversal drugs or stimulation of the patient, rather than adherence to a specific set of changed postoperative guidelines.

The positive study bias introduced during phase 2 not only influenced postoperative care, but also altered intraoperative care. Anaesthetists were aware of the ongoing data collection and there was a substantial reduction in the incidence of hypoxaemia on arrival in the recovery room. Anaesthetists may have modified their anaesthetic technique, for example they may have administered a lower dose of opioid which may decrease the incidence of postoperative respiratory depression. Another possible explanation for the reduction in hypoxaemia on arrival might be delayed transport from the operating theatre to the recovery room, with treatment of early hypoxaemia in the operating room rather than in the recovery room. The occurrence of hypoxaemia during transport from the operating to the recovery room has been reported previously[7]. The results of this study showed that increased motivation to prevent hypoxaemia reduced the incidence of hypoxaemia during transportation from 3% to less than 1%.

When the contribution of hypoxaemia on arrival in the recovery room is included in the calculation of the incidence of hypoxaemia during the entire recovery period, it could obscure the possible influence of actions initiated by recovery room nurses. Therefore, we have recalculated the incidence of hypoxaemia after excluding data from the first 3 min after arrival. During these 3 min the effect of supplementary oxygen or stimulation of the patient on Sp_{O_2}, or both, would be expected to become apparent. The reduction in hypoxaemia remained after exclusion of data recorded during the first minutes after arrival, suggesting that both anaesthetists and nurses contributed to the decreased incidence of hypoxaemia.

When pulse oximeter data are not validated by verifying the presence of a plethysmographic signal of sufficient quality, the incidence of hypoxaemia is overestimated because of inclusion of episodes with erroneously low Sp_{O_2} values. In one study 9% of pulse oximetry data obtained during emergence from anaesthesia appeared to be invalid[8]. In other studies, up to 75% of low Sp_{O_2} episodes during postoperative care in the recovery room and ICU were false[5,6]. In this study, we used computer analysis of the individual trend data arrays in an attempt to eliminate artefacts. Extra attention to correct application of the finger probe or successful reduction in patient movement in phase 2 decreased the incidence of artefacts by 50%. None the less, the possibility remains that part of the reduction in hypoxaemia during phase 2 may be attributed to a decrease in the number of non-rejected artefacts; however, if application of the artefact algorithms before analysis of hypoxaemia would be insufficient to eliminate all artefacts (and a large number of artefacts remained), the result would be to dilute the apparent effect of the intervention. Most Sp_{O_2} artefacts in the recovery room are of short duration, and are ignored when a minimum duration criterion is in effect. Pan and Gravenstein found that excluding discrepant data less than 12 s decreased the frequency of artefacts by 63% and less than 30 s by 93%[8]. In this study we chose to exclude low Sp_{O_2} episodes lasting less than 60 s in order to reduce the influence of artefacts and to focus attention on clinically more relevant episodes of hypoxaemia.

When used as a physiological monitor, the pulse oximeter should direct the attention of personnel to patients who are at risk for prolonged hypoxaemia. Severe hypoxaemia lasting more than 5 min occurred significantly less often during phase 2, suggesting that patients who were at risk for prolonged severe hypoxaemia gained specifically from the increased attention to early recognition and treatment of hypoxaemia. We can only speculate why pulse oximetry monitoring did not always result in timely interventions to prevent prolonged hypoxaemia during phase 1. Pulse oximetry has often been introduced in the recovery room without clear guidelines on the type of interventions that are required when low Sp_{O_2} values are present. The frequent occurrence of low Sp_{O_2} values without a direct negative effect on patient outcome may have resulted in complacency. A second explanation might be that some of the low Sp_{O_2} values that reflect true hypoxaemia are incorrectly interpreted as artefact. This study cannot differentiate between the relative contribution of the Hawthorne effect and the impact of the explicit instruction to prevent desaturation. However, in several studies that have shown a reduction in postoperative hypoxaemia by pulse oximetry, personnel were observed continuously and motivated explicitly to reduce hypoxaemia[2,3].

In conclusion, the results of this study suggest that motivation of care providers to prevent and treat low Sp_{O_2} values is an important determinant of the incidence of postoperative hypoxaemia in the recovery room.

Extradural clonidine combined with sufentanil and 0.0625% bupivacaine for analgesia in labour

D. CHASSARD, L. MATHON, F. DAILLER, F. GOLFIER, J. P. TOURNADRE AND P. BOULÉTREAU

Summary

We have studied the use of clonidine combined with low doses of sufentanil and bupivacaine in 45 parturients requiring extradural analgesia for the first stage of labour, in a double-blind, randomized study. We gave 0.0625% bupivacaine 10 ml containing 1:200 000 adrenaline and sufentanil 10 μg (1 ml) to which was added 0.9% saline, or clonidine 100 or 150 μg (1 ml). We compared the quality (VAS scores) and duration of analgesia, motor block, maternal haemodynamic state (mean arterial pressure and heart rate) and fetal and maternal side effects. Mean duration of anaesthesia was prolonged slightly: 105 (SD 21) min without clonidine, 130 (26) min with clonidine 100 μg ($P<0.05$ *vs* control) and 144 (40) min with clonidine 150 μg ($P<0.01$ *vs* control, ns *vs* 100 μg). There were no differences in VAS scores, onset times, heart rate, ventilatory frequency, motor block, sedation, pruritus or bradycardia between the groups. Analgesia was associated with a reduction in mean arterial pressure with clonidine. However, these adverse side effects were of minor clinical importance regardless of the extradural clonidine dose, except for a high incidence of fetal heart tracing abnormalities when clonidine 150 μg was used. These effects associated with a limited effect on analgesia may curtail the widespread use of clonidine as an adjunct to extradural 0.0625% bupivacaine with sufentanil 10 μg during labour. (*Br. J. Anaesth.* 1996;**77**:458–462)

Key words

Anaesthesia, obstetric. Anaesthetics local, bupivacaine. Anaesthetic techniques, extradural. Analgesics opioid, sufentanil. Pharmacology, clonidine.

Opioids are commonly combined with local anaesthetics to enhance extradural anaesthesia during labour[1 2]. Extradural clonidine, an alpha$_2$ adrenergic receptor agonist, produces analgesia without the motor block associated with high doses or concentrations of local anaesthetics[3] or side effects such as nausea, pruritus and risk of respiratory depression associated with the opioids[4]. Therefore, a combination of clonidine and opioids may be an attractive alternative for analgesia in labour but to date there have been no studies designed to assess the safety and efficacy of clonidine combined with low concentrations (<0.125%) of local anaesthetic during analgesia in labour.

The aim of this study was to evaluate the maternal, fetal and neonatal effects of clonidine 100 or 150 μg administered extradurally in combination with 0.0625% bupivacaine and adrenaline 1:200 000 with sufentanil 10 μg during the first stage of labour.

Patients and methods

The study was approved by the hospital Ethics Committee. After obtaining written consent, we studied 45 women, ASA I or II, with a singleton vertex pregnancy of at least 37 weeks' gestation, who requested extradural analgesia in labóur. A sample size calculation was performed using the Instat computer software package (GraphPad Instat, San Diego, CA, USA). Power analysis showed that a sample size of 15 patients per treatment group should provide 95% power (assuming $\alpha=0.05$) to detect a 30-min difference (SD) in duration of analgesia.

All patients had uncomplicated pregnancies and normal fetal heart tracings. We excluded patients receiving antihypertensive drugs, those with baseline heart rates <55 beat min^{-1} and patients who had already received opioid analgesia during this labour.

Each parturient received i.v. infusion of Ringer's lactate 500 ml over 10 min before induction of extradural anaesthesia and was positioned in the sitting position. The extradural space was cannulated at L2–3 or L3–4 using loss of resistance to saline (5 ml) and 3 cm of catheter was left in place. The parturient was then repositioned to lie with a left lateral tilt.

A double-blind, randomized study design was used. Parturients were allocated randomly according to a list of random numbers into three groups (sealed opaque envelopes). All injectates were prepared by an anaesthetist not involved in data collection.

Each syringe of coded study solution was prepared freshly. Each parturient received a test dose of 2% lignocaine 2 ml with 1:200 000 adrenaline. Five minutes later, each received a 12 ml solution comprising 0.0625% bupivacaine 10 ml with sufentanil 10 μg (1 ml) to which was added clonidine 100 μg, clonidine

150 μg or 0.9% saline (1 ml). Bupivacaine 0.0625% solutions were prepared by diluting 0.25% solutions, without preservatives, with 0.9% saline and adrenaline was then added (1:200 000). Arterial pressure and heart rate were monitored with a non-invasive monitor (Cardiocap II, Datex, Helsinki) 5, 10, 20, 30, 40, 60, 80, 100 and 120 min after extradural injection, and then every 20 min until the need for an additional extradural anaesthetic injection. When additional analgesia was requested, the study was terminated. Subsequent top-up doses were not standardized, allowing the anaesthetist to use either 0.0625% or 0.125% bupivacaine as necessary.

Motor block (modified Bromage score[5]: 0=ability to move hips, ankles and knees; 1=inability to raise extended leg; 2=inability to flex knee; and 3=inability to flex ankle, foot or knee), sedation (1=wide awake, 2=dozing, 3=asleep, 4=unrousable), cephalic dermatomal level of anaesthesia (cold test), ventilatory frequency and oxyhaemoglobin saturation (pulse oximeter, Cardiocap II, Datex, Helsinki) were recorded at the same times. Basal values were those obtained immediately before extradural injection.

Pain was assessed on a linear visual analogue scale (VAS). Each patient was presented with a line 100 mm long and was told that the left end represented no pain and the right end the worst pain imaginable. They were asked to make a mark on the line to indicate the intensity of pain at the peak of a contraction. Patients could request additional analgesia (0.25% bupivacaine via the extradural catheter) if pain relief was unsatisfactory by 15 min after injection of the study drug. At the end of the study, both the patient and nurse made an overall global rating of the treatment (poor, fair, good, very good, excellent).

The time from administration of study drug to request for additional analgesia was noted (duration of analgesia). Side effects such as pruritus, nausea and vomiting were recorded at completion of the study. Bradycardia was defined as the occurrence of a maternal heart rate >60 beat min^{-1} and treated with atropine i.v. Hypotension, defined as a decrease in systolic arterial pressure of at least 20% or a systolic arterial pressure <100 mm Hg, was treated with i.v. ephedrine as necessary.

Continuous electronic cardiotocograph monitoring using an external transducer was used for all patients throughout labour (Hewlett Packard 80034 A). Tracings were analysed by an obstetrician who was unaware of which solution was being administered (F. G.). Analysis compared tracings obtained 30 min before extradural injection with those recorded during analgesia. Changes in baseline fetal heart rate (FHR) (during the interval between uterine contractions), long-term variability (normal pattern >5 beat min^{-1}) and number of tracings with accelerations, early and late decelerations were noted. Variable decelerations were ranked on a scale using the method described by Klavan, Laver and Boscola[6] (mild=decelerations whose nadir >80 beat min^{-1}; moderate=nadir <70 beat min^{-1}, duration between 30 and 60 s or nadir between 70 and 80 beat min^{-1} and duration >60 s; severe=nadir <70 beat min^{-1}, duration >60 s).

Mode of delivery and Apgar scores at 1 and 5 min were recorded. All neonates were examined (general and neurological examinations) 2 h after delivery by a paediatrician who was unaware of patient group assignment.

STATISTICAL METHODS

For all calculations, the Instat computer software package (GraphPad Instat, San Diego, CA, USA) and Solo statistical software (BMDP, Los Angeles, CA, USA) were used. Intragroup comparisons for continuous variables and VAS scores were performed by analysis of variance (ANOVA) for repeated measures, followed by *post hoc* tests for comparison with baseline (Student–Newman–Keuls multiple comparison test). Significance of differences between groups was tested by analysis of variance for repeated measures (ANOVA). The Mann–Whitney *U* test was also used for comparison between groups when necessary (loss of subjects in group A after 100 min).To compare the duration of analgesia we used product limit survival analysis (Kaplan–Meier analysis) followed by Wilcoxon' s test. Where appropriate, Fisher's exact test was performed. Results are expressed as mean (SD).

Results

The groups were comparable in age, weight at term, weeks of pregnancy, parity, VAS pain scores and stage of cervical dilatation at the time of entry into the study (table 1). All patients enrolled in the study were included in data analysis.

Onset times for analgesia did not differ between groups: 6 (2), 6 (2) and 7 (3) min, respectively, for the control and clonidine 100 μg and 150 μg groups. Mean duration of anaesthesia was 105 (21) min (range 70–140 min) for patients who did not receive clonidine, and 130 (26) min (range 100–185 min) (*P*<0.05 *vs* control) and 144 (40) min (range 100–230 min; *P*<0.01 *vs* control, ns *vs* clonidine 100 μg) for patients who received clonidine 100 μg and 150 μg, respectively. The percentage of patients not requesting additional analgesia was greater in the bupivacaine–clonidine 150 μg than in the other

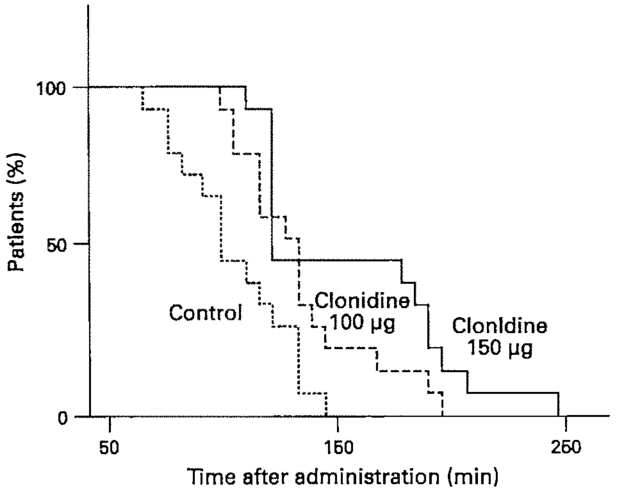

Figure 1 Percentage of patients not requesting additional analgesia after extradural injection of 0.0625% bupivacaine and sufentanil with saline (control) or clonidine 100 µg or 150 µg (50th percentiles for the three groups were: 100 min for the control group, 120 min for the clonidine 100 µg group and 127 min for the clonidine 150 µg group).

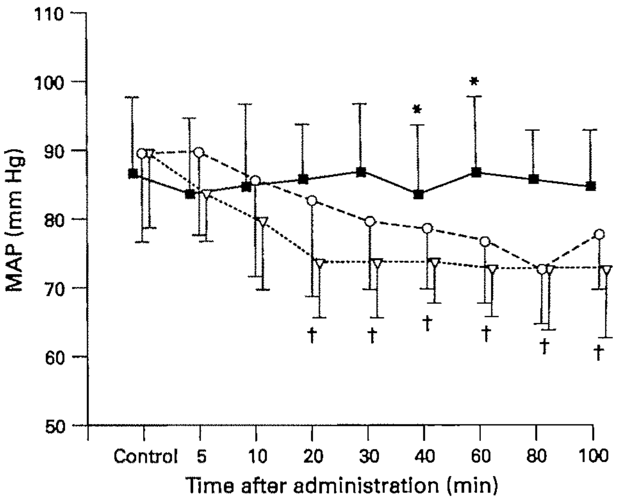

Figure 2 Mean arterial pressure (MAP) before (Control) and after extradural injection of 0.0625% bupivacaine and sufentanil with saline (■), clonidine 100 µg (○) or clonidine 150 µg (▽). *$P<0.05$ clonidine 150 µg *vs* control group; †$P<0.05$ clonidine 100 µg *vs* control group.

groups when analysed by Kaplan–Meier survival analysis followed by Wilcoxon's test (fig.1). No patient failed to achieve analgesia throughout the study in both groups. Mean VAS scores decreased significantly within 5 min after administration of drug. By 80 min, although both clonidine groups had lower pain scores than the control group, this was not statistically significant until 100 min (table 2). At 100 and 120 min, pain scores between groups 100 and 150 µg were not significantly different. Overall, the degree of maternal and nurse satisfaction was high in all groups.

Maternal heart rates were comparable in all three groups before administration of the study drug: 85 (14) beat min^{-1} for the control group, 82 (12) beat min^{-1} for the clonidine 100 µg group and 86 (11) beat min^{-1} for the clonidine 150 µg group. Atropine was administered for bradycardia in one patient in the clonidine 150 µg group.

Mean arterial pressure (MAP) was comparable in all groups at baseline: 87 (10), 90 (13) and 89 (10) mm Hg, respectively. From baseline to time 120 min, there were no significant changes in MAP in the control group, whereas it decreased significantly at 20 min in the clonidine 100 µg group (82 (14) mm Hg; $P<0.05$) (fig. 2). From 20 to 140 min this decrease remained significant, being highly significant at 40 min (79 (8) mm Hg; $P<0.001$). In the clonidine 150 µg group, MAP decreased more rapidly (at 5 min: 83 (6) mm Hg; $P<0.05$) and was highly significant at 20 min (73 (8) mm Hg; $P<0.001$). In all three groups, MAP was not different over the first 20 min (fig. 2).

One patient in the control group, two in the clonidine 100 µg group and one in the clonidine 150 µg group needed ephedrine for transient hypotension (ns).

There was no change in Sp_{O_2} at any time. Basal ventilatory frequency was comparable between groups and no significant change was noted throughout the study in the control and clonidine 100 µg group. In the clonidine 150 µg group, there was a significant decrease in ventilatory frequency in the first 80 min: 17 (5) bpm at 40 min *vs* 21 (3) bpm at baseline ($P<0.01$). However, inter-group comparisons showed no significant differences over the first 100 min.

In the control group, no patient had a Bromage score exceeding 1. Only one patient in each of the clonidine groups had a score of 2; no patient had Bromage score 3. Sedation scores were comparable between groups. No patient in the control group, one in the clonidine 100 µg group and two in the clonidine 150 µg group had a sedation score of 3.

Differences in FHR patterns were noted between groups. A decrease in long-term variability ($P<0.04$) and bradycardia (FHR <120 beat min^{-1}) were more usual in the clonidine 150 µg group ($P<0.02$). The numbers of tracings with variable ($P<0.01$) and late decelerations ($P<0.04$) were significantly more frequent in the clonidine 150 µg group, while early decelerations were more frequent in the clonidine 100 µg group. For variable decelerations, five were moderate and two mild in the clonidine 150 µg group, four mild and one moderate in the clonidine 100 µg group and three moderate and one mild in the

Sedation score 3 (asleep)	0	1	2

control group. However, no deceleration was classified as severe or needed emergency treatment.

The incidence of side effects was low (table 3). Thirteen patients in the control group had spontaneous vaginal delivery compared with 11 in the clonidine 100 μg group and 12 in the clonidine 150 μg group (table 1). Neonatal Apgar scores at 1 and 5 min did not differ between groups and neurological assessments were normal for all babies at 2 h.

Discussion

Local anaesthetics given extradurally are used widely for analgesia in labour. Fentanyl[7 8] and sufentanil[9] are frequently added to local anaesthetic solutions to potentiate their analgesic effects, allowing a reduced local anaesthetic concentration with less motor block[10–12]. However, the risk of delayed respiratory depression, pruritus and vomiting limits the use of opioids during labour[4]. These adverse effects have stimulated the search for alternative drugs[13] or methods[14] to provide analgesia during labour. We speculated that extradural clonidine, an alpha$_2$ agonist, might provide effective analgesia when combined with sufentanil and low-dose bupivacaine. Extradurally administered clonidine may be ideally suited for obstetric use because it does not interfere with proprioception and does not induce motor block or respiratory depression[15 16].

After extradural administration, clonidine 300 μg alone has been demonstrated to have no effect on fetal physiological indices in sheep[13]. Few studies have assessed the combination of clonidine and local anaesthetics in humans during labour. Brichant and colleagues found that clonidine 75 μg was the optimal dose to add to 10 ml of 0.125% bupivacaine, providing a duration of analgesia of 110 min[17]. Compared with 0.125% bupivacaine alone, clonidine 120 μg combined with 0.125% bupivacaine increased the mean duration of analgesia from 53 to 110 min; analgesia was unsatisfactory in 15% of the clonidine–bupivacaine group compared with 59% in the bupivacaine group[18]. In contrast, a low dose of extradural clonidine (less than 30 μg) failed to increase the duration of analgesia of a sufentanil 10 μg–0.125% bupivacaine mixture[19] or of 0.125% bupivacaine alone[17], while Celleno and colleagues[20] showed considerably prolonged analgesia when clonidine 75 μg was added to fentanyl 100 μg–0.125% bupivacaine (177 *vs* 89 min). The mean duration of analgesia obtained in our study was approximately 130–140 min, longer than that observed with 0.125% bupivacaine and clonidine alone[17 18]. Our results showed that clonidine 100 and 150 μg with a sufentanil 10 μg–0.0625% bupivacaine–adrenaline solution significantly improved the duration of analgesia in the first stage of labour.

Analgesia in the control group was satisfactory without any significant change in MAP. Addition of clonidine 100 or 150 μg prolonged analgesia but caused significant haemodynamic changes. Comparisons between groups showed that this decrease was more important in the clonidine 150 μg group than in the clonidine 100 μg group. Extradural clonidine 700 μg alone decreased arterial pressure and heart rate in volunteers[15] while minor changes in haemodynamic state were reported with extradural clonidine during pregnancy in a sheep model[3]. Doses of clonidine 30–150 μg did not alter haemodynamic state when combined with 0.125% bupivacaine during labour[17 18] and the addition of sufentanil 10 μg[19] or fentanyl 50 μg[20] to clonidine (30 and 75 μg, respectively)–0.125% bupivacaine mixtures did not increase the need for ephedrine treatment during labour. Hypotension during extradural anaesthesia is greater after adrenaline–local anaesthetic solutions than after free adrenaline solution[21]. Extradurally administered clonidine has a U-shaped dose–response for arterial pressure[15] and may explain the decrease in MAP in our study. Although we observed a decrease in MAP, the change in MAP was modest and the incidence of ephedrine treatment was similar in all groups.

While extradural administration of opioids is associated with respiratory depression[4], extradural clonidine did not appear to have a marked effect on ventilation. It has been reported that clonidine does not potentiate morphine or alfentanil-induced respiratory depression[22 23]. In this study, although clonidine was combined with sufentanil, no episode of desaturation was noted and ventilatory frequencies did not differ between groups.

An additional side effect of extradural clonidine is sedation[21]. The incidence of sedation was similar between groups in our study. Other side effects were of minor importance.

Approximately 20% of normal gravidas develop fetal heart rate patterns which place the fetus “at risk” during labour. Most frequently, these patterns occur as a result of either umbilical, maternal or uteroplacental circulatory problems[6]. FHR abnormalities such as variable or late decelerations, bradycardia or change in baseline variability may occur. In this study we found that extradural clonidine, particularly clonidine 150 μg, was associated with such FHR abnormalities. It is unclear at present if these changes were caused by a direct effect of clonidine on the cardiovascular system of the fetus or an effect on oxygen supply. It has been reported that extradural clonidine 150 μg induced serum clonidine concentrations close to 1 ng ml-1 in postoperative patients[24]. In pregnant sheep, clonidine 1 ng ml^{-1} did not decrease uterine blood flow[13] but a direct effect of such concentrations on fetal and uterine blood flow has not been evaluated in labouring parturients. In contrast, a decrease in long-term variability and bradycardia are expected responses after administration of tranquillizers, clonidine, opioids and extradural local anaesthetics[25 26]. In addition, our clinical study contrasts with those of Cellano and colleagues and O' Meara and Gin who showed no effect of clonidine 150 or 120 µg on FHR when given extradurally[18 20]. These differences could be attributed to the different time course of analgesia for the three groups which made intergroup comparisons difficult and to an additional effect of sufentanil on FHR.

Antiemetic effect of subhypnotic doses of propofol after thyroidectomy†

P. EWALENKO, S. JANNY, M. DEJONCKHEERE, G. ANDRY AND C. WYNS

Summary

Postoperative nausea and vomiting (PONV) are unpleasant, often underestimated side effects of anaesthesia and surgery, not devoid of medical complications. Prevention with antiemetics is only partially effective. Propofol has been shown recently to possess antiemetic properties in several situations. In this prospective, randomized, controlled trial, we have compared the antiemetic efficacy of subhypnotic doses of propofol, with Intralipid as placebo, after thyroidectomy. We studied 64 patients of both sexes, aged 22–71 yr, ASA I or II, undergoing thyroidectomy. After premedication with a benzodiazepine, balanced anaesthesia was produced with isoflurane and nitrous oxide in oxygen, and supplementary analgesia with fentanyl i.v. as required. Postoperative analgesia was provided with non-opioids, and piritramide 0.25 mg kg^{-1} i.m. on demand. Patients were allocated randomly and blindly to receive a 20-h infusion of either propofol or 10% Intralipid 0.1 ml kg^{-1} h^{-1}. Intralipid, the excipient of propofol, was chosen as placebo as it is devoid of antiemetic effects. Sedation scores, respiratory and cardiovascular variables, and incidence of PONV were assessed every 4 h for 24 h. Pulse oximetry and ECG were monitored continuously. Both groups were comparable in characteristics, surgical and anaesthesia procedures, amount of opioids given during and after operation, and total amount of the study drug infused after operation. Occurrence of PONV was similar before the start (propofol 41%, Intralipid 50%) and after completion (propofol 0.64%, Intralipid 1.6%) of infusion and decreased with time in both groups during the infusion. However, symptoms were reduced to nil with propofol but persisted and were more severe with Intralipid during infusion ($P \le 0.01$). The overall incidence of PONV during infusion was 10% (three of 32 patients) in the propofol group and 65% (21 of 32 patients) in the Intralipid group. Cardiovascular and respiratory variables, and Sp_{O_2} were unaltered, and sedation decreased similarly with time in both groups. We conclude that propofol, given at subhypnotic doses, effectively reduced the incidence of PONV without untoward sedative or cardiovascular effects. (*Br. J. Anaesth.* 1996;**77**:463–467)

Key words

Vomiting, nausea. Vomiting, nausea, anaesthetic factors. Anaesthetics i.v., propofol. Surgery, thyroidectomy.

Postoperative nausea and vomiting (PONV) are common, often neglected side effects of surgery. Their incidence has been estimated, in multicentre studies, to be as high as 40–60%[1]. Apart from the distressing inconvenience, the muscular efforts accompanying these symptoms may contribute to medical complications such as aspiration pneumonia, wound dehiscence, bleeding and even wound infection[2]. Thyroidectomy is associated with a high rate of PONV and prevention with antiemetics such as metoclopramide or alizapride reduces their frequency from 60% to only approximately 40%[3].

Propofol has been associated with a reduced rate of PONV when used as a continuous infusion to provide anaesthesia[4–9]. This advantage is limited to the early postoperative period, up to 6 h after completion of surgery[8]. In contrast, propofol has been used successfully at subhypnotic doses (0.5–1 mg kg^{-1} h^{-1}) for the prevention and treatment of chemotherapy-induced emesis[10 11] and after surgery[12 13].

We have evaluated, in a randomized, prospective study, the antiemetic properties of propofol infused continuously at subhypnotic doses compared with a placebo, in thyroidectomized patients. Intralipid 10% was chosen as placebo as, being the excipient of propofol, it is indistinguishable from the drug and has proved to be devoid of antiemetic and emetogenic effects[14].

Patients and methods

After obtaining institutional approval from the Ethics Committee, we studied 66 patients of both sexes, ASA I–II, aged 22–71 yr, undergoing thyroidectomy. Patients with allergy or intolerance to any of the products to be used during or after operation, or those receiving neuroleptics, were excluded. All patients gave informed consent before participation and were allocated randomly to receive either propofol or placebo after operation.

†Presented in part at the European Society of Anaesthesiologists Annual Congress, CNIT Paris, France, 29 April–3 May, 1995 (*British Journal of Anaesthesia* 1995; 74 (Suppl. 1); A279.

The anaesthetic procedure was the same for all patients. Premedication comprised midazolam i.m., 30 min before induction of anaesthesia. Oral diazepam, 60 min before induction, was given to a few patients reluctant to have an injection. In the operating theatre, patients received an i.v. balanced electrolytic solution (Plasmalyte, Travenol, Baxter) via a peripheral vein and standard monitoring was commenced (ECG lead II, heart rate, automatic arterial pressure, pulse oximetry). Anaesthesia was induced with fentanyl 2 μg kg^{-1} i.v. and thiopentone 3–5 mg kg^{-1} i.v. A single dose of atracurium 0.4–0.5 mg kg^{-1} was used to facilitate tracheal intubation and neuromuscular block was not used thereafter. After tracheal intubation with a cuffed armoured tube, anaesthesia was maintained with 0.5–2% isoflurane and 60–70% nitrous oxide in oxygen administered via a respirator. Ventilatory variables and respiratory gases were monitored conventionally. Supplementary analgesia during surgery was provided with boluses of fentanyl 50–100 μg i.v.

At the end of operation, after tracheal extubation, patients were transferred to the surgical intensive care unit for 24 h. Postoperative monitoring was standard and comprised ECG, pulse oximetry and regular assessment of conscious status, arterial pressure, ventilatory frequency and fluid balance. Analgesia consisted of intra-rectal administration of indomethacin 100 mg twice daily or propacetamol 1 g i.v. every 4 h, or both. If inadequate, additional doses of piritramide (Dipidolor, Janssen Pharmaceutica) 0.1–0.25 mg kg^{-1} i.m. were given at the request of the patient at a maximum frequency of every 4 h.

When patients were considered sufficiently oriented by the nursing staff, an infusion of propofol or 10% Intralipid, prepared and provided according to the randomization schedule, was started at a rate of 0.1 ml kg^{-1} h^{-1} via a syringe pump.

Factors contributing to PONV, such as clinical status (euthyroidism, hyperthyroidism treated or not), previous history of PONV, date of last menses for women, duration of anaesthetic and surgical procedure, occurrence of hypotension during anaesthesia (defined as a decrease in systolic arterial pressure of more than 20% from baseline), difficulty of tracheal intubation (graded as easy, moderately difficult, difficult) and administration of opioid analgesia were recorded in order to assess the comparability of the two groups.

During the whole infusion period, the incidence and severity of PONV and eventual side effects were assessed as follows: every 4 h, patients were questioned and asked if they had experienced nausea and vomiting during the preceding period; in addition, any episode occurring outside the observation time and not self-reported was taken into account and noted. As the observation lasted at least 24 h, the assessment could not be made by only one investigator, but was made by trained nurses and controlled subsequently by the chief nurse (C. W.) and another investigator, preferentially always the same (S. J.). Nausea and vomiting were assessed using the score of Bellville[15]: 0=no symptoms; 1=nausea (subjective unpleasant sensation with awareness of urge to vomit); 2=retching (spasmodic contractions of abdominal wall and diaphragmatic muscles without expulsion of gastric content); 3=vomiting (same as (2) but with forceful expulsion of gastric contents). Whenever symptoms occurred, metoclopramide 10 mg i.v. was given as rescue drug, every 4 h if necessary.

Sedation was evaluated simultaneously using a four-point rating scale[10]. A score of 1 (patient fully awake) or 2 (patient sleepy, but rousable by verbal stimulation) was considered adequate. If the sedation score reached 3 (sleepy, not responding to verbal, but well to painful stimulation), the infusion rate of the study drug was reduced by half and stopped if the score was 4 (not rousable, not responding to painful stimulation).

Pain and satisfaction scores were also assessed after 10 and 20 h of infusion of the study drug, using a visual analogue scale (VAS) from 0 (no pain) to 10 (worst conceivable pain). During the night, if the patient was found quietly asleep, he/she was not awakened and only monitoring signs were noted. At the end of the infusion period, patients were observed for an extra 4-h period to assess evolution of PONV.

STATISTICAL ANALYSIS

Parametric data were submitted to analysis of variance. When the F ratio reached statistical significance, a t test (two-sided unpaired Student's test or two-tailed Fisher's exact test) was applied. Non-parametric data were analysed where applicable by the chi-square or Wilcoxon rank sum test. $P \leq 0.05$ was considered statistically significant.

Results

There were 32 patients in each group. Sex distribution, age, weight, height and ASA status were comparable. There was no difference in clinical status or other preoperative factors predisposing to PONV. Duration of anaesthesia and surgery, intubation difficulty, hypotensive episodes, and peroperative use of fentanyl were similar in both groups (table 1).

Patients received the same amount of propofol or Intralipid at the same rate and during the same period. Infusion of the study drug was started at the same time in both groups (with a median time of 30

Before the start of infusion of the study drug, PONV had occurred in 45% of patients: 13 of 32 (41%) patients in the propofol group and 16 of 32 (50%) patients in the Intralipid group (ns). During the first period, two patients were still symptomatic (one nauseous, one vomiting) in the propofol group compared with 10 (three nauseous, seven vomiting) in the Intralipid group. One patient was slightly nauseous during the second period, and then the incidence decreased to nil in the propofol group during the rest of the infusion. PONV decreased with time in the Intralipid group but persisted during the whole infusion period. Repeated symptoms were more frequent in the Intralipid group. The differences were statistically significant throughout infusion. After cessation of infusion, PONV was observed in two (6%) patients (one relapse, one nausea "de novo") in the propofol group, compared with five (15%) in the Intralipid group (ns). The overall number of patients with PONV during the whole observation period in the propofol group was 14 (44%) and 27 (84%) in the Intralipid group ($P<0.05$). When only the infusion period was considered, there was a total of three (10%) symptomatic patients in the propofol group P compared with 21 (65%) in the Intralipid group ($P<0.01$) (table 3).

Slight sedation (sedation score of 2) was observed equally in both groups, particularly during the immediate postoperative period and decreased with time in a similar manner. There was no statistically significant difference either in the amount of opioid received (table 4) or the degree of sedation (table 5) at any time. After 10 h of infusion, the median VAS pain score was 0 (range 0–3) in the propofol group and 2 (range 0–6) in the Intralipid group; at 20 h the values were 0 (0–3) and 1 (0–6), respectively. These

slight differences were not significant. There were no differences between groups in cardiovascular variables and Sp_{O_2} which remained within the normal range throughout the 24 h of observation.

Discussion

We have found that in thyroidectomized patients, PONV was very common, and that propofol, at subhypnotic doses, was effective in comparison with placebo in controlling the incidence, without unwanted sedative, respiratory or cardiovascular side effects.

Different pre- and peroperative factors may contribute to PONV and, if not correctly taken into account, introduce bias in the interpretation of results[1 16]. We found no difference in the preoperative state of patients or in their per- and postoperative courses. In particular, the amount of opioids used before and after operation did not differ between the two groups. As our patients represented a very homogeneous population, any difference in the occurrence of emetic symptoms may reasonably be attributed to the study drug.

We showed previously, in a controlled, randomized study, that thyroidectomy was a surgical procedure associated with a high incidence of PONV (up to 60%) when every mild symptom was taken as positive. This high incidence is probably related to the age range and sex of the patients (mostly middle-aged women) and intense peroperative vagal stimulation (surgical handling of the neck structures). In that study, prophylaxis with alizapride, a conventional antiemetic agent, reduced the incidence to only 40% compared with placebo[5]. In this study, 45% of patients (29 of 64) had PONV before the start of infusion of the study drug. Of the 13 (41%) symptomatic patients in the propofol group before infusion, only two were still vomiting during the first observation period. Only one patient was still slightly nauseous during the second observation period and then she became totally asymptomatic; however, she relapsed after the end of infusion. Otherwise, rapid and complete control of PONV was obtained with infusion of propofol at a rate of 1 mg kg^{-1} h^{-1}. In the control group, the overall incidence of PONV was 84% (51% before infusion and the remainder during infusion). This confirms the high incidence of PONV after thyroidectomy when no prophylaxis is used. In this group, PONV persisted throughout the infusion period, although there was a decrease in the frequency and severity of symptoms with time. As the two groups were comparable for all factors contributing to PONV, it may reasonably be concluded that the relief of symptoms was related to the antiemetic properties of propofol.

It is usually recommended that an antiemetic be given prophylactically before surgery or chemotherapy to improve the efficacy of the drug. As we wanted the effect of the drug to be dissociated completely from residual sedation caused by narcosis and no interference, the drug was given only when patients were sufficiently awake (sedation score of 1 or 2). Even with this less favourable regimen, complete response was obtained within less than 2 h in 94% of patients (30 of 32) and reached 100% success rate subsequently.

The mechanisms by which propofol acts as an antiemetic are unclear. The mechanisms of vomiting are complex and have been reviewed elsewhere[1]. Propofol is not thought to have vagolytic properties[12]. Borgeat and colleagues suggested that propofol may have failed as an antiemetic in patients who had undergone laparoscopic gynaecological procedures because of uninhibited vagal stimulation[12]. In our study, propofol was completely successful in the treatment of emetic symptoms after thyroidectomy, a procedure also accompanied by intense surgical stimulation of vagal afferents. However, the location and nature of this stimulation are not comparable with laparoscopy and do not involve irritation or distension of gastrointestinal structures that may convey chemoception or nociception via other afferents than parasympathetic. This suggests that the failure of propofol in the study of Borgeat and colleagues may not have been related wholly to absence of vagal inhibition. Other mechanisms for the non-hypnotic actions of action of propofol, including its antiemetic properties, have been reviewed recently[17 18]. A sedative effect of propofol, as sometimes suggested[17], can be ruled out in our patients as first, the degree of sedation was the same in both groups and second, sedation decreased with time in all patients whereas the efficacy of propofol increased. None of our patients had a sedation score higher than 2. Low doses of propofol may induce anxiolysis[19] sufficient to modify cortical afferents to the vomiting centre. Although we did not specifically test the anxiety status of our patients, clinical data describe no behavioural difference and indirectly indicate that an anxiolytic effect, if present, is not important enough to be the principal factor. A dopamine D2 receptor antagonist effect has also been suggested[20], but not proved. Propofol has also been shown to possess weak anti-serotonin ($5HT_3$) properties[21], suggesting a possible effect on the CTZ, but not enough to fully explain the efficacy of the drug in emetic syndromes refractory to $5\text{-}HT_3$ antagonist therapy[11]. The exact mechanisms by which propofol acts remain subject to speculation and await further studies.

The exact concentration at which propofol exerts its antiemetic properties is not well documented[22]. A blood concentration of 197 ng ml^{-1} has been reported in one patient after 48 h of propofol infused at a rate of 1 mg kg^{-1} h^{-1} for the treatment of refractory PONV[13]. An i.v. bolus of 10 mg (sometimes repeated once) is usually effective for approximately 30 min in the treatment of chemotherapy-induced emesis[12]. From the pharmacokinetic models available, it is suggested that the effective concentration range is very low, certainly less than 0.5 µg ml^{-1}[23]. These values are lower than those recommended for sedation[24]. As already mentioned, in this study, the efficacy of propofol increased while sedation decreased with time. This provides another argument against an association between the sedative and antiemetic properties of propofol.

Can infusions of propofol of prolonged duration interact with lipid metabolism because of the emulsion (10% Intralipid) formulation of the drug? After several days of sedation with propofol in intensive care units, at a dose range of 1–3 mg kg^{-1} h^{-1}, no subsequent modifications in triglycerides or fatty accumulation were reported[25]. Hence, no changes would be expected in our patients, as propofol was infused at lower doses for a shorter period of time.

The lowest rate necessary to achieve an antiemetic effect and the corresponding plasma concentration of propofol need to be defined more precisely if propofol is to be considered an acceptable regimen for the prevention and treatment of PONV in patients at risk of such symptoms. We did not study the financial impact (benefits *vs* costs) of this therapy and this should be done, including not only the cost of the drug and the material used but all other relevant factors[11 26 27]: efficacy, psychological satisfaction, decreased strain on the nursing staff, postoperative surgical course (haematoma, healing) and duration of hospital stay. At present, considering the efficacy and high degree of acceptance and satisfaction of the treatment, we believe that propofol may be proposed prophylactically as an antiemetic agent in patients identified at high risk of PONV or as rescue drug in case of failure of conventional antiemetic therapy. It should be noted that 5-HT$_3$ antagonists have also been used successfully in this situation, although the success rate did not reach 100%[28]. To our knowledge, no controlled study has directly compared the respective efficacy and costs of propofol and 5-HT$_3$ antagonists.

Use of a mechanical simulator for training in applying cricoid pressure

N. Ashurst, C. C. Rout, D. A. Rocke and E. Gouws

Summary

Using an airway management training model, we have assessed anaesthesia personnel in their use of correct cricoid force and ability to retain this skill after a short training programme. A perspex device, working on a hydraulic principle, was used to measure cricoid pressure when applied to the model. After initial assessment at two levels of cricoid force (20 and 40 N), participants undertook additional training on 3 consecutive days. Thereafter, available participants underwent reassessment at 14–21 days. Forty-nine anaesthetic assistants and anaesthetists underwent initial assessment and 18 completed the full training and reassessment. Untrained, the majority (63%) of participants applied inadequate cricoid force with a wide variation (mean 16.8 (SD 9.3) (range 4.5–43.0) at 20 N and 32.9 (13.3) (14.9–74) at 40 N). After a single training session there was a marked improvement in application of cricoid force. Two additional training sessions did not provide further improvement. After 14–21 days the ability of participants to apply correct cricoid force was retained by 72% of subjects. Those who applied inadequate cricoid force initially were more likely to do so even after training. Most subjects applied too great a cricoid force in the first 5 s of application followed by a progressive loss of force during the next 20 s. This trend improved after training. We conclude that the majority of untrained personnel apply inadequate cricoid force, placing patients at risk of aspiration of gastric contents. While a simple training programme improved application of cricoid force, retained for up to 3 weeks, there was often a substantial decrease in the force applied to the cricoid during a single application, even after training. (*Br. J. Anaesth.* 1996;**77**:468–472)

Key words

Larynx, cricoid pressure. Anaesthetist, training. Model, simulation. Complications, regurgitation. Intubation tracheal, training.

Use of cricoid pressure, as described by Sellick in 1961[1], is the cornerstone of rapid sequence induction to minimize the risk of pulmonary aspiration of gastric contents. The force required to occlude the oesophagus has been described "as moderate then firm pressure" [1] or "pressure which would cause pain when applied to the bridge of the nose" [2]. Quantitatively, Wraight, Chamney and Howells showed that a force of 44 newtons (N) should protect 50% of patients from regurgitation[3] while Vanner and colleagues[4] showed that 40 N would increase upper oesophageal sphincter pressure (UOSP) above awake levels in 100% of subjects. However, for the awake patient 40 N is poorly tolerated[5] and may cause coughing or vomiting[3]. In addition, Vanner and colleagues showed that UOSP decreased during induction of anaesthesia with thiopentone and suggested that 20 N be applied to the awake patient increasing to 40 N on loss of consciousness[6]. In clinical practice, Howells and colleagues[7] demonstrated that the force applied by anaesthesia assistants varies widely, resulting in a proportion of patients remaining at risk of regurgitation because of inadequate pressure. Devices have been described[3 4 7] which allow the exact force to be applied but manual application remains the commonest method.

To reduce the proportion of patients at risk of inhalation during induction, the person applying cricoid pressure should do so correctly. This study was designed to assess, using a model, the performance of anaesthesia staff and assistants in applying cricoid pressure. Participants then underwent a training programme using the model, which was subsequently used to evaluate retention of training.

Subjects and methods

To measure the force applied to the cricoid cartilage, we designed a device which was easy to use and calibrate, and was accurate over the intended range of forces (5–60 N). The perspex device worked on the hydraulic principle (fig. 1) and allowed cricoid pressure to be applied using a three-finger technique onto the cricoid cartilage of a model (Laerdel airway management trainer, fig. 2). The device was light (50 g) and applied a minimal force (0.49 N) when placed alone on the cricoid. The yoke transmitted the force from the cricoid to the plunger which abutted the diaphragm, increasing the fluid pressure within the device in a linear fashion (r=0.98). Pressure changes were transduced electronically and displayed as a moving line on an oscilloscope (Datascope 2000 pressure transducer). The absolute pressure (in mm Hg) was displayed also and recorded. For all measurements the level of the cricoid on the model

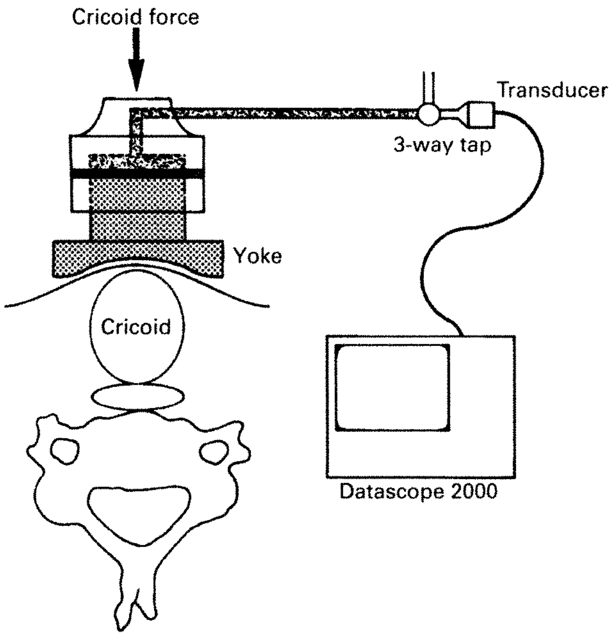

Figure 1 Cricoid force was applied to the yoke via the perspex device. The pressure developed was transduced and displayed as a moving line on an oscilloscope.

was 95 cm above ground and the transducer was zeroed at this level before each attempt. The device was calibrated using a set of electronic scales before each assessment (1 kg=9.81 N) (manufacturer's specifications available on request).

Both anaesthetists and anaesthesia assistants (nursing staff) were studied. The former are expected to be able to teach the correct force to be applied while the latter regularly apply cricoid pressure as part of their nursing duties. The end-point of the study was the ability of participants, without reference to the recording device (i.e. blinded), to apply two forces, 20 N and 40 N, within the range 2.5–5 N, respectively. Each subject was assessed before training, over the 3 days of training (consecutively if possible), and 14–21 days after the third day of training.

On day 1 the initial untrained assessment was made by blinding the subject to the pressure reading on the oscilloscope and asking the subject to apply, for a period of 20 s, what they considered their "normal" cricoid force. Each was then asked to apply "half their normal" force for 20 s. These two measurements were repeated three times. The mean force of three readings obtained over the last 15 s of application was recorded. After this initial assessment, each participant then viewed the oscilloscope screen unblinded and was allowed three attempts at attaining both 20 and 40 N. Participants were again blinded to the oscilloscope screen and asked to apply "half" and then "full" cricoid pressure three times. The forces developed were again recorded. If two of the three recorded forces and the mean force were appropriate (20±2.5 N and 40±5 N) the participant was considered trained for that day. If the targets were not met then additional cycles of unblinded training were followed by blinded reassessment until the participant was trained. The number of training cycles each day was recorded.

On days 2 and 3 the subjects first performed a blinded assessment at 20 and 40 N to assess retention from the previous day. If training targets were not met further training cycles were conducted as above. Two to 3 weeks later (according to staff availability) subjects were reassessed to determine retention of training. All assessments were performed by the same assessor (N. A.).

The numbers of subjects applying cricoid pressure correctly were compared on each day of training with the initial assessment using McNemar's chi-square test, with Bonferroni's correction for repeated measures. Mean force applied at each target value was compared with the target value using z tests, and repeated measures analysis of variance was used to compare mean values on each assessment with initial performance.

Results

Forty-nine staff participated in the initial assessment: 29 were anaesthetic assistants (all female) and 20 were anaesthetists (eight female) of varying years of experience. Eighteen of the subjects (six anaesthetic assistants, 12 anaesthetists) were available to complete the full training and reassessment.

Neither sex nor rank (i.e. assistants *vs* anaesthetists) significantly influenced the ability to apply the correct force during any part of the study. While not quantitatively assessed, we observed that most subjects applied a much greater force at the beginning of application than at the end of the 20s period and there was often an "overshoot" of applied force in the initial 5 s. This decline in applied force with time was still present after training but was less marked. Figure 3 shows examples of forces applied.

At the initial assessment, mean applied cricoid forces of 16.8 (SD 9.3) (range 4.5–43.0) N and 32.9 (13.3) (14.9–74) N were significantly ($P<0.01$ and <0.001, respectively) below the targets of 20 N and 40 N, respectively. The majority of subjects (67% at 20 N and 61% at 40 N) were unable to achieve the lowest force considered acceptable (17.5 N and 35 N, respectively). Only five subjects (10%) at 20 N and nine subjects (18%) at 40 N were able to apply pressures within the correct ranges.

Figure 4 shows the applied cricoid force at the targets of 20 and 40 N at the initial assessment and subsequent assessments after training for the 18 subjects who completed the training in full. At the initial assessment the only difference between the results of the 18 subjects who completed the study and the total of 49 subjects was that the difference between the mean force applied and 20 N was not statistically significant. Following training after the initial assessment on day 1 and subsequent training on days 2 and 3, there was a significant increase in the mean cricoid force applied at both the 20 and 40 N targets compared with the initial assessment. At the 40 N target, the mean values after training were within an acceptable range of the target value (35–45 N). At the 20 N target, however, mean values were greater than the upper limit of the acceptable range (17.5–22.5 N). Mean values at the 40 N target were significantly different from 40 N at the initial assessment ($z=3.02$, $P<0.01$) and after training on day 1 ($z=3.01$, $P<0.01$) but not on days 2 ($z=2.16$, $0.05>P>0.01$) or 3 ($z=1.96$, $0.05>P>0.01$). At the 20 N target, mean values did not differ significantly from

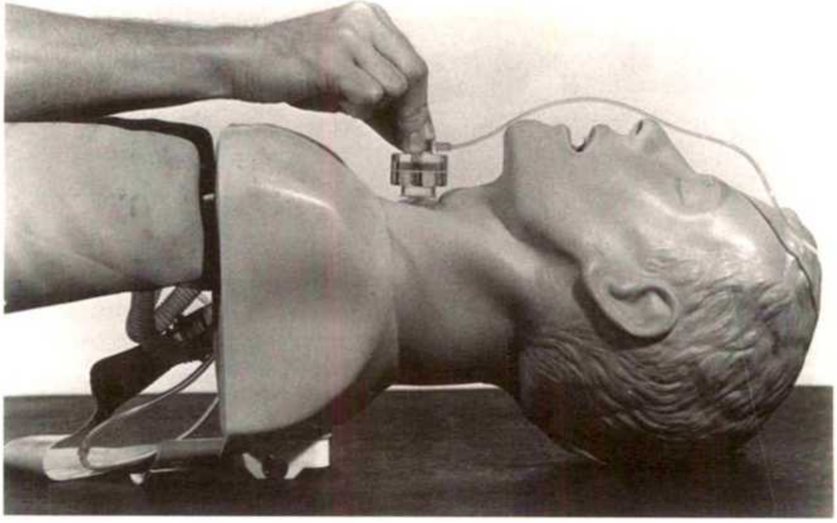

Figure 2 The cricoid measuring device was applied to an airway training model using a three-finger technique.

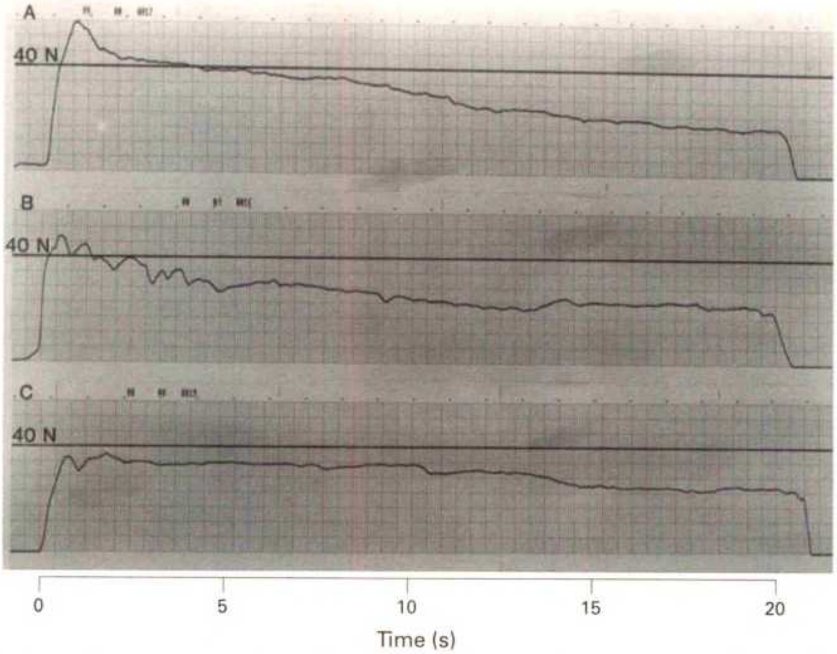

Figure 3 Three typical tracings of inadequate application of cricoid force. A and B show the marked initial overshoot and later decline of cricoid force while C shows the force to be low throughout, even though the subject had undergone training.

the target at the initial assessment (z=1.61, ns) or on day 1 (z=2.01, 0.05>P>0.01) but were significantly different on days 2 (z=3.11, P<0.01) and 3 (z=4.43, P<0.01).

There was a statistically significant (P<0.0125) reduction in the variability of applied pressures (coefficient of variation) at the 40 N target on days 1, 2 and 3 compared with the initial assessment. Coefficient of variations were 0.38 at the initial assessment, 0.13 on day 1, 0.17 on day 2 and 0.12 on day 3. At the 20 N target, however, a similar reduction in the coefficient of variation was seen only on days 1 and 3 (coefficient of variation for the 20 N target: initial 0.52; day 1, 0.27; day 2, 0.39; day 3, 0.25).

At the final assessment, 2–3 weeks after the last training cycle, the mean forces applied were within the acceptable range for both the 20 N and 40 N targets. At the 40 N target the mean force applied (38.9 (5.9) N) on the final assessment remained significantly higher than that obtained at the initial assessment (31.4 (12.0) N). Seven of the 18 subjects

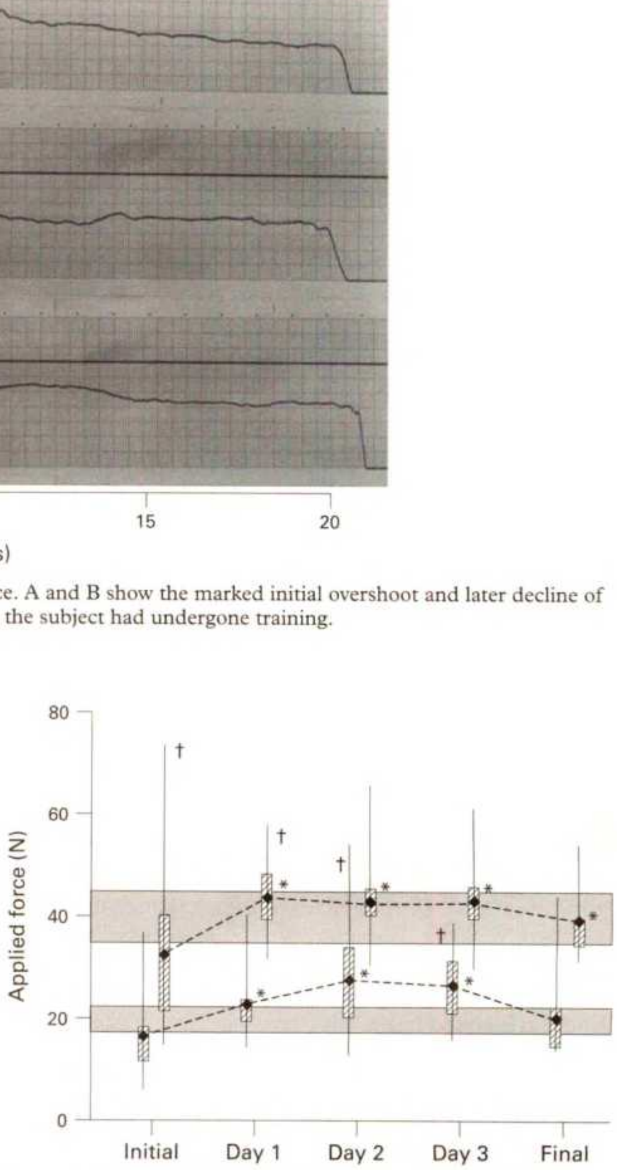

Figure 4 Cricoid force (mean, range and interquartile range) applied at the initial and subsequent assessments at the 20 N (bottom curve) and 40 N (top curve) targets. *P<0.05 compared with initial assessment; †P<0.05 compared with target value.

applied inappropriate cricoid force both at the initial and final assessments. At the final assessment two applied too much force, four applied 34 N and one 32 N. At the 20 N target there was no statistically significant difference between the mean force applied on the final day (20.3 (7.0) N) compared with the initial assessment (16.7 (8.7) N). However, at both 20 and 40 N targets the mean applied force was no longer significantly different from the target force (z=0.16 at 20 N, and 0.81 at 40 N, ns).

At the initial assessment only one subject at the 20 N target and three subjects at the 40 N target achieved cricoid forces within the acceptable range (table 1). Performance improved on subsequent days but a statistically significant (P<0.0125) improvement in the number of subjects achieving acceptable forces was only seen in the 40 N group on the final assessment. There was a trend towards an increase in the number of subjects applying too great a force during the training period but the sample was of insufficient size to obtain statistical significance.

One subject who applied a force within the acceptable range for the 20 N target at the initial assessment was outside the range at the final assessment. Between 1 and 3 training cycles were required after assessment on each day to achieve an applied force within the acceptable range at both the 20 N and 40 N targets. No statistically significant reduction in the number of training cycles required was observed during the training period.

Discussion

For cricoid pressure to prevent pulmonary aspiration of gastric contents, the UOSP generated must be greater than the pressure within the lower oesophagus. Wraight, Chamney and Howells[3] calculated that the maximum possible passive oesophageal pressure generated in a gravid patient given suxamethonium was 7.84 kPa, and showed further that this UOSP was generated in 50% of subjects given 44 N of cricoid force. Taking into account the force generated by a tracheal tube and accepting the resting awake UOSP of 38 mm Hg as an adequate target, Vanner and colleagues[4] showed that 100% of subjects with 40 N of cricoid force and 23 of 24 subjects with 35 N of cricoid force developed an adequate UOSP (>38 mm Hg). In a cadaver study, Vanner and Pryle[8] demonstrated that only 30 N was needed to develop an UOSP >35 mm Hg but how well cadavers at 4 °C correlate with anaesthetized patients is debatable. As all patients receiving a force greater than 35 N develop a sufficient UOSP to prevent aspiration, we used a target of 40±5 N as our upper target range for training. Our lower training target range of 20±2.5 N was used as a result of the study of Vanner and colleagues[6] who demonstrated that UOSP decreases before loss of consciousness thereby increasing the risk of regurgitation at this time, confirming earlier suggestions that cricoid force should be applied before loss of consciousness[1]. However, a full force of 40 N is tolerated poorly by awake patients[8] and may increase the risk of inducing airway obstruction[5], vomiting and even oesophageal rupture[8]. It seems prudent therefore to apply *moderate* (20 N) force before loss of consciousness, increasing to 40 N at the onset of anaesthesia.

Sixty one percent of the initial 49 participants failed to reach an adequate (> 35 N) force, 53% failing even to reach 30 N before training. This compares with the study of Howells and colleagues[7] where 47% of staff failed to reach 44 N and with the study of Vanner and colleagues[4] where 50% failed to increase UOSP above 35 mm Hg. The wide variation in applied force seen in our study compares well with the results of Howells and colleagues[7]. However, mean force was within acceptable limits in their study whereas in ours the mean force was below the target levels.

In the 18 subjects who completed training we saw a significant improvement in the applied force on day 1. The mean cricoid force was now within the correct range and the variability between subjects reduced. Only one subject now provided possibly dangerously low cricoid force (32 N). This confirms Sellick's suggestion that the application of cricoid force can be taught within a short period. However, 44% of subjects now applied forces in excess of 45 N which may damage the cricoid tissues or cause difficulty with intubation. It may be that some are untrainable and one advantage of the training programme would be to identify these staff.

The short training programme used in our study showed that after 14–21 days the ability to apply correct cricoid force was retained by most subjects. However, 28% of subjects still applied a force less than 35 N. As none of these subjects applied grossly inadequate force (<30 N) we consider this to be acceptable. This study was not designed to answer the question of how often training should be repeated, but work by Berden and colleagues[9] suggests that resuscitation skills in nurses are maintained for between 3 and 6 months and it would seem reasonable therefore that training should be repeated at least every 6 months. The evidence from this study is that retention of training deteriorates more rapidly.

The decrease in the applied force over the period of 20 s seen in our study has been observed previously[5]. The results give rise to concern about the

quality of cricoid force applied over a protracted period during, for example, a difficult intubation.

The inadequate force applied, the wide individual variability seen particularly at 20 N, and the decline in applied force with time in untrained personnel strengthen the argument for the need for a mechanical device to allow correct cricoid force to be applied consistently. However, a questionnaire conducted by Howells and colleagues suggested that only 33% of anaesthetists in the UK and USA believed a mechanical device would be useful and only 46% believed a training device necessary[7]. Many devices[2-4 10] have been described and demonstrated to be effective in training subjects to apply correct cricoid force but none have been adopted into general practice possibly because they have been associated with laryngeal distortion and difficult intubation[10]. Our device being smaller and lighter may allow more accurate placement, reducing laryngeal distortion, although this has yet to be assessed.

We conclude that training improves performance but retention of the skill of applying appropriate cricoid pressure for any length of time cannot be guaranteed. Indeed some staff may be untrainable. Our results imply that staff applying cricoid pressure should undergo a frequent training programme, the interval of which remains to be determined but may need to be monthly. Introducing such training programmes into clinical practice may well be logistically prohibitive. Alternatively such programmes may form part of courses in airway management. In addition, the value of introduction of such training programmes in the context of improved morbidity or mortality from such a rare event as acid aspiration is unlikely to be significant. Nevertheless if cricoid pressure is to be applied then only appropriate techniques can be acceptable. While the idea of applying moderate cricoid pressure (20 N) before induction is laudable, the difficulty experienced by our subjects in attaining this pressure suggest that this goal may be difficult to achieve.

Endotoxaemia and postoperative hypermetabolism in coronary artery bypass surgery: the role of ketanserin

H. M. Oudemans-van Straaten, P. G. M. Jansen, H. te Velthuis, Chr. P. Stoutenbeek, D. F. Zandstra, S. J. H. van Deventer, A. Sturk, Ch. R. H. Wildevuur and L. Eijsman

Summary

In a randomized, double-blind clinical study in 29 patients undergoing elective coronary artery surgery, we assessed the role of ketanserin, an inhibitor of serotonin-induced vasoconstriction and weak α_1 sympathetic blocker, in reducing endotoxaemia and postoperative hypermetabolism. Male patients without major organ dysfunction were allocated randomly to receive either ketanserin or placebo. Hypermetabolism was defined as an increase in oxygen consumption in the early postoperative hours ($\Delta\dot{V}o_2$). Circulating endotoxin (P=0.04) and postoperative $\Delta\dot{V}o_2$ (P=0.03) were lower in the ketanserin patients. Endotoxaemia was associated also with low vascular filling. From these preliminary results we conclude that treatment with ketanserin during cardiac surgery may reduce but not abolish endotoxaemia and postoperative hypermetabolism. (*Br. J. Anaesth.* 1996;**77**:473–479)

Key words

Surgery, cardiovascular. Complications, endotoxaemia. Oxygen, consumption. Metabolism, oxygen consumption. Pharmacology, ketanserin.

The postoperative course after cardiac surgery may be complicated by a systemic inflammatory response[1 2]. This hypermetabolic response is multifactorial. It may be caused by rewarming after hypothermia[3], complement activation on contact of blood with material from the extracorporeal circuit[4–6] or reperfusion after ischaemia. It has also been associated with endotoxaemia and subsequent cytokine release[7]. Circulating endotoxin during cardiac surgery possibly originates from the patient's own gut flora. Endotoxin permeating from the gut stimulates the host to produce inflammatory mediators that cause the systemic inflammatory response[7–9].

One of three factors appear to be necessary for permeation of endogenous bacterial endotoxin from the gut into the systemic circulation: first, bacterial overgrowth in the gut lumen, second, loss of gut barrier function, and third, decreased ability of the reticuloendothelial system to detoxify the permeated endotoxin. The first factor is probably not important during cardiac surgery, but the two other factors may be. Both might be caused by splanchnic hypoperfusion, as may occur during cardiac surgery[10–12]. In a previous study it was found that during cardiac surgery intestinal permeability between cells increased. The amount of circulating endotoxin was related to this increase[13]. Increased intestinal permeability was associated with pharmacologically induced vasoconstriction and hypovolaemia during operation.

In rats, ketanserin has a beneficial effect on the occurrence of ischaemic lesions in the gastric mucosa[14 15]. Ketanserin inhibits the action of serotonin on the vasoconstricting 5-HT$_2$ receptor and on platelet aggregation. It also inhibits the potentiating vasoconstrictive effects of serotonin on noradrenaline and angiotensin, and has a weak α_1 receptor inhibiting effect at higher concentrations[16]. As a result, ketanserin inhibits vasoconstriction and platelet aggregation. This effect is particularly prominent in vessels with decreased endothelial-mediated vasodilatation[17].

The first aim of this study was to assess if i.v. administration of ketanserin reduces the degree of endotoxaemia during elective coronary artery bypass surgery and ameliorates the postoperative hypermetabolic response. The second aim was to assess if, in addition to ketanserin, other factors, such as haemodynamic state and duration of CPB[13 18], are associated with endotoxaemia. Therefore, we have measured the concentration of circulating endotoxin, haemodynamic state and postoperative increase in oxygen consumption in patients receiving i.v. ketanserin or placebo before, during and after coronary bypass surgery.

Patients and methods

Male patients, aged 45–75 yr, undergoing elective coronary artery bypass grafting without valve re-

placement, were eligible for inclusion in the investigation when the following criteria were met: left ventricular ejection fraction more than 40% or an end-diastolic pressure in the left ventricle less than 20 mm Hg, and normal organ function. Patients were excluded if they had unstable angina pectoris, major coagulopathy, history of inflammatory bowel disease or alcohol abuse, had used corticosteroids, antibiotics, ketanserin or aprotinin in the week before operation, had ingested acetylsalicylic acid within 4 days before surgery, or had a QT interval on the electrocardiogram of more than 500 ms (QT prolongation is reported with higher doses of ketanserin). Written informed consent was obtained from each patient and the study was approved by the Ethics Committee of the Free University Hospital, Amsterdam.

As it is not known if ketanserin has any effect on endotoxaemia, we undertook a pilot study. Patients were allocated randomly to receive, in a double-blind design, either ketanserin or a similar volume of placebo. Randomization was performed by Janssen Pharmaceutica BV. In the ketanserin group, patients received ketanserin 0.1 mg kg^{-1} h^{-1} i.v. for 4 h, beginning after induction of anaesthesia and insertion of the pulmonary artery catheter preceding sternal incision. To limit the hypotensive effects of ketanserin, the dose was reduced to 0.05 mg kg^{-1} h^{-1} after 4 h. The infusion was stopped 18 h after operation.

Endotoxin was measured in blood at baseline (directly after admission to the operating room), during cardiopulmonary bypass (CPB) (10 min after the onset of CPB and on termination of CPB), and in the intensive care unit (ICU) (30 min, 2 h and 18 h after admission). In addition, a sample of the prime fluid of the heart–lung machine was obtained before connection to the patient (ET prime).

Clinical measurements were made at baseline (after induction of anaesthesia and insertion of the pulmonary artery catheter), 30 min after termination of CPB and in the ICU (at fixed times of endotoxin sampling and additionally at 4 and 8 h after admission to the ICU).

The amount of endotoxin appearing in the systemic circulation and the postoperative hypermetabolic response were the end-points of the study. We chose endotoxaemia as the primary end-point as we hypothesized that inhibition of vasoconstriction would improve intestinal and hepatic perfusion and reduce the subsequent permeation of endotoxin from the gut into the systemic circulation. The amount of circulating endotoxin concentration during operation and the concentration of endotoxin at the time of patient admission to the ICU (ET_{ICU}) were measurements of special interest. Postoperative hypermetabolism was chosen as the clinical endpoint as it was shown that postoperative hypermetabolism was associated with the endotoxin-related inflammatory response[7]. Because we studied patients at low risk of postoperative complications, we did not expect to find an effect on duration of ICU stay.

On the morning of surgery, patients received their usual cardiac medication and lorazepam. Anaesthesia was induced with fentanyl 30 μg kg^{-1} and pancuronium 0.1 mg kg^{-1}, and maintained with a continuous infusion of midazolam and additional doses of fentanyl up to 50 μg kg^{-1}. Volatile anaesthetics, nitrous oxide or corticosteroids were not given. The lungs were ventilated with 40% oxygen and a positive end-expiratory pressure of 5 cm H_2O. A pulmonary artery catheter was inserted after induction of anaesthesia and tracheal intubation.

CPB was performed with moderate systemic hypothermia (28–30 °C), non-pulsatile flow and cold crystalloid cardioplegia for myocardial protection. The CPB circuit consisted of a membrane oxygenator (Avecor, Plymouth, MN, USA), a roller pump (Stockert) with an arterial filter and polyvinyl tubing. The circuit was primed with Ringer's lactate 2000 ml, 20% human albumin 200 ml, 20% mannitol 100 ml, 8.4% sodium bicarbonate 50 ml and bovine heparin 5000 u. A standard cannulation technique was used with a two-stage venous cannula, an arterial cannula in the ascending aorta and subtotal bypass. During CPB, pH was regulated according to the α-stat concept. Rewarming was started just before the last distal anastomosis was made by slowly increasing temperature, at first to 32 °C and then to 39.5 °C. Rewarming was continued until nasopharyngeal temperature was >36.5 °C.

After releasing the aortic cross-clamp, nitroglycerine 2 mg h^{-1} and dopamine 2 μg kg^{-1} h^{-1} were started. Fluid therapy was titrated according to cardiac filling pressures and cardiac index. Target values were as follows: central venous pressure (CVP) 8–10 mm Hg, pulmonary artery occlusion pressure (PAOP) 12 mm Hg and cardiac index (CI) >2.5 litre min^{-1} m^{-2}. In the ICU all patients were warmed externally with a heating mattress until rectal temperature exceeded 36.5 °C and the difference between rectal and toe temperature was less than 5 °C. All patients received controlled mechanical ventilation for at least 8 h after operation. Doses of dopamine and nitroglycerin were increased when cardiac index remained low after adequate filling. Packed cells were transfused to maintain haemoglobin >8.8 g dl^{-1}. In order to relieve pain and stress, prevent shivering and obtain a reliable value of oxygen consumption and cardiac output, patients were sedated with morphine 5–10 mg i.v. and diazepam 5–10 mg i.v. for 8 h after operation. After that, when temperature and circulation were stable, patients were allowed to wake up, pressure support ventilation was started and the trachea was extubated generally in the morning after operation.

Blood for measurement of endotoxin was obtained from a newly inserted radial artery catheter or from the arterial cannula of the extracorporeal circuit. Blood samples were collected in tubes (Monovette, Sarstedt, Nümbrecht, Germany) containing pyrogen-free heparin (Thromboliquine, Organon, Oss, The Netherlands) at a final concentration of 30 u. ml^{-1}, under endotoxin-free conditions, and were immersed immediately in ice. Platelet-rich plasma was prepared directly by centrifugation (4 °C) at 190 *g* for 10 min and stored immediately at −70 °C. Endotoxin was measured with an optimized chromogenic assay (Coatest Endotoxin, Kabi-Chromogenix, Mölndal, Sweden) based on the lipopolysaccharide-dependent activation of Limulus amoebocyte lysate (LAL) and subsequent measurement of the activated LAL enzyme(s) with a chromogenic substrate. This assay has been described previously[19]. The LAL material contained in this batch of Coatest endotoxin kits is insensitive to LAL-reactive material such as β-glucan[20]. The assay has a detection limit of 0.036 EU ml^{-1} (endotoxin units per millilitre of platelet rich plasma). This corresponds to 3 pg ml^{-1} of the endotoxin standard used in this study.

Haemodynamic measurements included heart rate, arterial pressure, CVP, pulmonary artery pressure, PAOP and cardiac output using an arterial and pulmonary artery catheter. Cardiac output was measured by the thermodilution method using room temperature injectate. The mean of four measurements was calculated. Cardiac index (CI) was calculated from cardiac output: CI=cardiac output/total body area.

Oxygen consumption ($\dot{V}O_2$) was measured continuously by respiratory gas analysis with an open circuit indirect calorimeter (Deltatrac, Datex Instrumentarium, Helsinki, Finland) as long as the patient was undergoing artificial ventilation. This metabolic monitor has been validated previously[21] and described in detail[22]. FI_{O_2} was always less than 50%. Minute volume and FI_{O_2} remained constant for 60 min before measurements were obtained. Calibrations were made before starting, after transport of the patient and instrument to the ICU and at 8-h intervals thereafter. A meticulous check on gas leakage was made; minute volume, as measured by the ventilator and the calorimeter, was checked routinely. Care was taken that the patient was sedated adequately and shivering was prevented. The Deltatrac calorimeter averages $\dot{V}O_2$ measurements over a period of 1 min, and the mean of at least five measurements was taken. These values were also compared with the continuously printed values to exclude short-term variability. Values of $\dot{V}O_2$ were adjusted for total body area (ml min^{-1} m^{-2}).

Hypermetabolic response was assessed by the postoperative increase in oxygen consumption from baseline ($\Delta\dot{V}O_2$)[7]. Oxygen supply was calculated according to the following equation: oxygen supply = CI × (1.39 × haemoglobin (g dl^{-1}) × arterial oxygen saturation+0.0031 × Pa_{O_2}

DATA ANALYSIS

Statistical analysis was performed using Statview SE+ Graphics computer software (Abacus concepts, Berkeley, CA, USA). Data are presented as mean (SEM). Individual measurements were compared between groups using a two-tailed Student's *t* test for unpaired observations and serial measurements between groups with a two-way analysis of variance (ANOVA) with a design for repeated measures. For single measurements of special interest in a series, Bonferroni's correction for repeated measurements was made. To quantify the amount of endotoxin in the systemic circulation during operation between groups, the area under the curve (AUC) was calculated for the concentration–time curve[23]. To correct for differences in the duration of CPB, AUC was divided by total time[23].

In the analysis of $\Delta\dot{V}O_2$, measurement of $\Delta\dot{V}O_2$ 2 h after admission to the ICU was of special interest, as this value was related to the inflammatory response to endotoxaemia[7]. The time pattern of $\Delta\dot{V}O_2$ in the ketanserin group was different from that in the placebo group, making a two-way ANOVA for repeated measures inappropriate. We therefore compared mean postoperative $\Delta\dot{V}O_2$ (AUC from 30 min to 8 h after ICU admission) between groups.

Regression analysis was performed in the entire group of patients (ketanserin and placebo) to investigate if variables, other than ketanserin, could explain the remaining variability of ET_{ICU} and $\Delta\dot{V}O_2$. A two-sided *P* value of less than 0.05 was considered statistically significant.

Results

We studied a total of 31 consecutive male patients undergoing CPB for elective coronary artery bypass grafting. Study medication was stopped prematurely in two patients (one in each group) because of severe bleeding and myocardial ischaemia before the onset of CPB. These patients were excluded from the study before unblinding and analysis. In total, 14 patients were treated with ketanserin and 15 patients received placebo. In one placebo patient, the endotoxin results could not be measured for technical reasons. All other data were evaluated.

There were no significant differences in patient characteristics, preoperative myocardial function, surgical characteristics (table 1) or baseline haemodynamics (table 2). All patients were discharged from the ICU on the first day after operation and all survived. Re-operation for postoperative bleeding was necessary once in each treatment group. In the ketanserin group, two patients had peroperative myocardial infarction as a result of incomplete revascularization.

COMPARISON OF ENDOTOXIN CONCENTRATIONS

Circulating endotoxin, analysed using two-way analysis of variance for repeated measures with all measurements included, was lower in patients treated with ketanserin than in placebo patients (P=0.04). There was no significant group–time interaction (P>0.5) (fig. 1). In nine of 14 patients in the placebo group, and in two of 14 patients in the ketanserin group, endotoxin concentration was positive 10 min after the start of CPB compared with baseline (P<0.05). At the end of CPB, endotoxin concentration was positive in 12 of 14 patients in the placebo group and in eight of 14 in the ketanserin group (ns). The mean concentration of circulating endotoxin during operation (AUC/time) was 0.130

Table 1 Patient data (mean (SEM or range) or number))

EU ml^{-1} in the ketanserin group and 0.193 EU ml^{-1} in the placebo group, indicating a 33% reduction in endotoxaemia during operation in patients treated with ketanserin (P=0.03). The concentration of circulating endotoxin on admission to the ICU was 0.199 EU ml^{-1} in the ketanserin group and 0.314 EU ml^{-1} in the placebo group (P<0.05).

The mean concentration of endotoxin in the prime fluid was 0.123 (0.039) EU ml^{-1} in the ketanserin group and 0.078 (0.032) EU ml^{-1} in the placebo group (ns).

COMPARISON OF OXYGEN CONSUMPTION AND OTHER CLINICAL VARIABLES

$\Delta\dot{V}o_2$ 2 h after admission to the ICU was significantly lower in patients treated with ketanserin than in placebo patients (P<0.001). Postoperative $\Delta\dot{V}o_2$ (AUC) was 44% lower in the ketanserin group than in the placebo group (P=0.03) (fig. 2).

Mean arterial pressure was lower in the ketanserin than in the placebo group (P=0.04 with two-way ANOVA for repeated measures); the group–time interaction was not significant (P>0.5) (table 2). There was no significant difference in the other haemodynamic variables; oxygen supply (table 2), use of dopamine and postoperative concentrations of lactate. Blood loss and the use of blood products were not significantly different between groups. Fluid balance during surgery was not different between groups, but there was a trend towards a more positive fluid balance in the ICU in the ketanserin group. This difference started 4 h after admission to the ICU and coincided with increased administration of fluids to patients treated with ketanserin in the period from 4 to 18 h after ICU admission (P=0.03). Times for tracheal extubation and discharge from the ICU were not significantly different between groups (table 3).

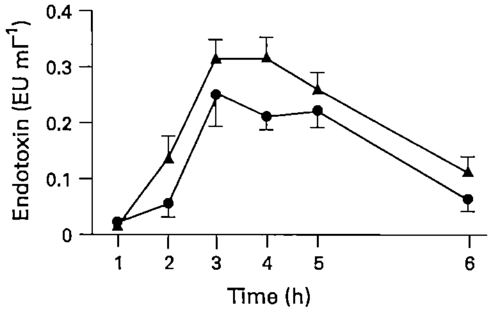

Figure 1 Plasma concentrations of endotoxin (mean, SEM) *vs* time for patients who received ketanserin (●) or placebo (▲) at the following times: baseline (after induction of anaesthesia and insertion of the pulmonary artery catheter) (1); 10 min after the start of CPB (2) and after termination of CPB (3); and in the ICU (30 min (4), 2 h (5) and 18 h (6) after admission). Circulating endotoxin (ANOVA) was significantly lower in ketanserin patients (P=0.04).

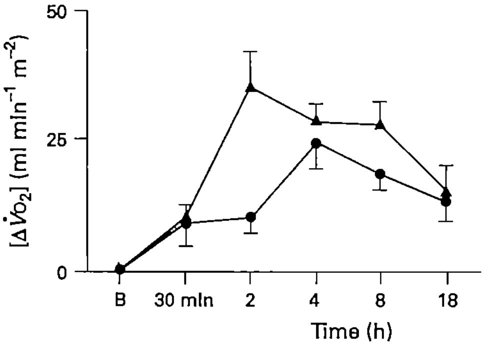

Figure 2 Increase in oxygen consumption ($\Delta\dot{V}o_2$) from baseline (B) (mean, SEM) for the ketanserin (●) and placebo (▲) groups 30 min and 2, 4, 8 and 18 h after admission to the ICU. Postoperative $\Delta\dot{V}o_2$ (AUC) was significantly lower in ketanserin patients (P=0.03).

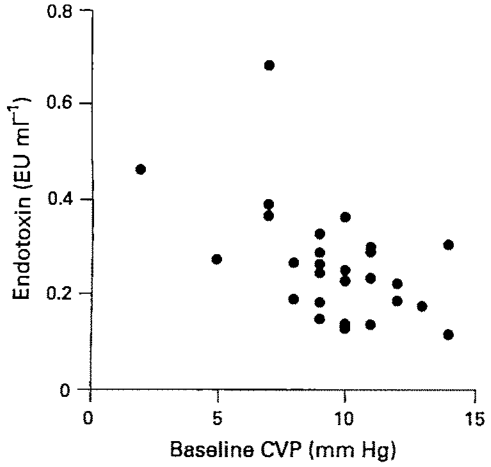

Figure 3 Relation between baseline central venous pressue (CVP) and the concentration of endotoxin on admission to the ICU (n=28, r=0.55, P=0.0036).

RELATION OF CIRCULATING ENDOTOXIN WITH OTHER VARIABLES

To investigate if haemodynamic variables could explain the variability of ET_{ICU}, these variables were used in a simple regression analysis, and then the significant factors were entered in a forward stepwise regression analysis. Baseline CVP, baseline PAOP and fluid balance during operation were significantly associated with ET_{ICU} (P<0.05). Of these, the relation between baseline CVP and ET_{ICU} was the most significant (fig. 3).

In the forward stepwise regression analysis, baseline CVP was entered first, fluid balance during operation and ketanserin treatment were entered next, and baseline PAOP was entered in the fourth step. After entering PAOP, CVP was removed from the model yielding a better fit after the other variables were entered. CVP and PAOP were interrelated. The final model is presented in table 4. ET_{ICU} was higher in patients with low baseline filling pressures, with a less positive fluid balance during operation in the placebo group. ET_{ICU} was not related to baseline CI or to duration of CPB. Endotoxin concentration 10 min after the start of CPB was not related to ET prime.

RELATION OF $\Delta\dot{V}O_2$ WITH OTHER VARIABLES

Apart from ketanserin, $\Delta\dot{V}O_2$ was related to ET_{ICU}. $\Delta\dot{V}O_2$ was not related to systemic oxygen supply, systemic vascular resistance, use of dopamine or concurrent temperature.

Table 3 Other clinical measurements (mean (SEM)). *Significant difference between groups. Extubation time and transfer from ICU were calculated from the patient's admission to the ICU

	Placebo group	Ketanserin group
Total blood loss (ml)	2160 (269)	2060 (269)
Fluid balance (operation) (ml)	3400 (243)	3777 (301)
Fluid balance (0–4 h ICU) (ml)	459 (248)	476 (302)
Fluid balance (4–18 h ICU) (ml)	1106 (387)	2176 (439)
Fluids (0–4 h ICU) (ml)	2991 (315)	3021 (251)
Fluids (4–18 h ICU) (ml)*	4608 (380)	6410 (714)
Extubation time (h)	20.4 (1)	22.8 (0.5)
Transfer from ICU (h)	24.8 (1.5)	25.9 (0.5)

Table 4 Determinants of the concentration of circulating endotoxin on the patient's admission to the ICU. The concentration of circulating endotoxin on ICU asmission (ET_{ICU} (EU ml^{-1}) can be expressed as a function of ketanserin treatment (1 = yes, 2 = no), fluid balance during operation (ml) and pulmonary artery occlusion pressure at baseline (mm Hg) in the following equation: $ET_{ICU} = 0.8-01$ (ketanserin treatment) $-(PAWP_{baseline})-0.067$ (fluid $balance_{operation}$). The F value describes the strength of the relation. $F \geq 4$ is considered statistically significant

Discussion

We have found that i.v. administration of ketanserin may reduce the degree of endotoxaemia during low-risk coronary bypass surgery, but does not prevent it. Ketanserin appeared to be more protective early after the onset of CPB than at the end. After the onset of CPB, tissue perfusion may decrease as a result of acute changes in vascular volume caused by haemodilution with a decrease in oncotic pressure[24], induction of hypothermia, extracorporeal circulation with non-pulsatile flow, and release of vasoactive substances such as angiotensin and noradrenaline[25 26]. Splanchnic vasoconstriction is one of the physiological compensation mechanisms maintaining blood flow to the heart and brain during such acute changes. However, subsequent splanchnic hypoperfusion may result in a loss of gut barrier function for intraluminal endotoxin and a decreased ability of the reticuloendothelial system to detoxify the permeated endotoxin.

The most plausible mechanism by which ketanserin reduces endotoxaemia is thought to be related to inhibition of vasoconstriction. This may lead to improvement in the microcirculation[17] and cardiac performance. However, this conclusion cannot be deduced directly from this study, as the splanchnic microcirculation was not measured. Nevertheless, our data give some indication. Patients with low baseline filling pressures and a less positive fluid balance during surgery had higher circulating endotoxin concentrations. The splanchnic vasoconstrictive response is thought to be more pronounced in patients with low vascular filling. While baseline filling pressures and fluid balance during operation were not significantly different between groups, ketanserin may have mitigated this response. That baseline filling pressures are important for ET_{ICU} and not baseline CI might be explained as follows. The major increase in circulating endotoxin occurred during CPB when the patient's heart is excluded from the circulation, and the heart–lung machine provides circulation, with pump flow standardized according to body surface area. Therefore, vascular filling and pump flow are the important determinants of circulation during CPB, and CI is irrelevant. After CPB, there was a trend towards a higher CI in the ketanserin group. This higher CI might also have contributed to a lower ET_{ICU} in patients treated with ketanserin, but may also have been an effect. Although our study design was not appropriate to explain the mechanism by which ketanserin reduced endotoxaemia, a combined strategy to reduce endotoxaemia may be advised. This strategy should aim at inhibition of vasoconstriction by the use of ketanserin and expansion of intravascular volume before, during and after CPB in the period that the patient is at risk for splanchnic vasoconstriction.

At the end of CPB, ketanserin appeared to be less effective. This might be attributed to the fact that maintenance of normovolaemia was not a goal of treatment during cardiopulmonary bypass. In addition, the use of the large prime fluid causing hypo-oncotic haemodilution may also have contributed to endotoxaemia[27]. At the end of CPB, other factors may also affect permeation of endotoxin into the systemic circulation, such as reperfusion of the ischaemic myocardium inducing distant tissue damage by circulating toxic mediators[28]. These might impair gut barrier function or detoxification of the permeated endotoxin by the RES, or both.

From the results of this study it also appears that treatment with i.v. ketanserin during low-risk coronary bypass surgery reduces $\Delta\dot{V}O_2$. In our study there was no evidence for a supply-limited $\dot{V}O_2$ in patients treated with ketanserin, as oxygen supply and lactate concentrations were not significantly different between groups. However, both ketanserin treatment and ET_{ICU} were associated with $\Delta\dot{V}O_2$. The effect of ketanserin on $\Delta\dot{V}O_2$ was probably related to its effect on endotoxaemia, but might also be the result of better tissue perfusion during operation with less depletion of cellular energy stores. The reduction in $\Delta\dot{V}O_2$ during treatment with ketanserin might be especially beneficial in patients with poor myocardial function, as the lower oxygen demand without impairment of myocardial performance improves oxygen balance.

All patients were discharged from the ICU on the first day after operation. However, there was a trend towards a longer duration of ventilatory support in the ketanserin patients. This effect coincided with administration of more fluids later in the ICU. In this study, ketanserin was administered in a standard dose until 18 h after operation, far beyond the period that the patient is at risk of compensatory vasoconstriction. After a longer infusion time, the α_1 adrenergic blocking effect of ketanserin increases and this may explain the lower arterial pressure and administration of more fluids later in the ICU. As it has been shown that ketanserin decreases the lower limit of autoregulation in the kidneys[29], sufficient organ perfusion is likely to be guaranteed at a lower arterial pressure while ketanserin is administered. Titration of ketanserin dose should preferably be based on circulation, and administration of ketanserin can generally be discontinued when the circulation has become stable.

From the preliminary results of this clinical study, we conclude that treatment with i.v. ketanserin, an inhibitor of vasoconstriction, may reduce the degree of endotoxaemia and postoperative hypermetabolism, but does not prevent their occurrence. Low vascular filling was also associated with endotoxaemia. Prevention of endotoxaemia is likely to require a combined strategy aiming at inhibition of vasoconstriction before and during operation using ketanserin and expansion of intravascular volume.

Influence of different volume therapy regimens on regulators of the circulation in the critically ill

J. Boldt, M. Mueller, T. Menges, M. Papsdorf and G. Hempelmann

Summary

Various vasoactive substances are involved in the regulation of the macro- and microcirculation. We have investigated if these regulators change during long-term volume therapy with human albumin (HA) or hydroxyethylstarch solution (HES) in trauma and sepsis patients. To maintain pulmonary capillary wedge pressure (PCWP) at 10–15 mm Hg, either 20% HA (HA-trauma, *n*=14; HA-sepsis, *n*=14) or 10% low-molecular weight HES solution (HES-trauma, *n*=14; HES-sepsis, *n*=14) were infused for 5 days, otherwise patient management did not differ between the two groups (trauma/sepsis). Mean arterial pressure (MAP), heart rate (HR), PCWP and cardiac index (CI) were monitored in all patients. Liver function was assessed using the monoethylglycinexylidide (MEGX) test, and gastric intramucosal pH (pH$_i$) was monitored by tonometry to assess splanchnic perfusion. Plasma concentrations of vasopressin, endothelin-1, adrenaline, noradrenaline, atrial natriuretic peptide and 6-keto-prostaglandin $F_{1\alpha}$ were measured from arterial blood samples. All measurements were carried out on the day of admission to the intensive care unit (trauma patients) or on diagnosis of sepsis, and daily over the next 5 days at 12:00. MAP, HR and PCWP did not differ between the corresponding subgroups (trauma/sepsis). CI increased significantly more in the HES than in the HA groups. pH$_i$ and MEGX plasma concentrations did not differ in the trauma patients throughout the study. Both were lower than normal in the sepsis groups and increased more markedly in the HES than in the albumin-treated patients ($P<0.05$). In the trauma patients, concentrations of all vasoactive regulators were very similar in both groups. In both sepsis groups, vasopressors (vasopressin, endothelin-1, noradrenaline and adrenaline) were significantly increased above normal at baseline and decreased more markedly in HES than in HA patients. Concentrations of atrial natriuretic peptide increased only in the HA patients (from 159 (SD 31) to 215 (38) pg ml^{-1} on day 2). Plasma concentrations of 6-keto-prostaglandin $F_{1\alpha}$ decreased significantly only in the HES sepsis patients (from 112 (25) to 47 (15) pg ml^{-1}). (*Br. J. Anaesth.* 1996;**77**:480–487)

Key words
Intensive care. Fluids, therapy. Fluids, i.v. Polypeptides, cytokines. Sympathetic nervous system, catecholamines.

There are various conditions such as shock, ischaemia, trauma and sepsis that exhibit flow alterations which are inadequate for tissue needs[1]. Various circulating vasoactive substances and inflammatory mediators are important in reducing perfusion in this situation. Activation of the sympathetic nervous system is a compensatory mechanism to maintain peripheral perfusion. Although this neurohumoral activation is beneficial at first, this mechanism becomes deleterious and may be involved in the poor outcome of the critically ill[2]. Recent evidence suggests that the endothelium functions not only as a passive barrier between circulating blood and tissue, but may also be involved in the regulation of microcirculatory blood flow by producing important regulators of vascular tone (e.g. prostaglandins, nitric oxide (NO), endothelins, angiotensin II)[3]. Thus regional regulation of blood flow is a balance between systemic (central) mechanisms (e.g. autonomic nervous system) and other circulating or locally active blood flow regulators.

One approach to improve perfusion in the critically ill is the use of adequate volume replacement. It is necessary not only to guarantee an adequate haemodynamic state but also to avoid microcirculatory abnormalities. Restoration of flow is an essential key for avoiding tissue ischaemia and subsequent development of multiple organ failure (MOF)[4]. Points of controversy in this area appear to be which type of solution is best suited to avoiding the sequelae of trauma or sepsis[5,6]. This controversy refers not only to the crystalloid/colloid debate, but has been widened in recent years to include a colloid/colloid debate as synthetic colloids (e.g. hydroxyethylstarch solutions) have proved to be of benefit for volume

therapy in this situation[7]. In spite of higher costs, human albumin solutions are still used widely in several centres. Most studies have compared only the short-term effects of volume infusion[8], and evaluation of the efficacy of various volume replacement regimens is not possible with this design. Serial data on the effects of long-term volume therapy with different solutions on regulators of the circulation in the critically ill are lacking. This study was designed to investigate if the type of volume replacement (human albumin *vs* hydroxyethylstarch) influences plasma concentrations of regulators of the circulation.

Patients and methods

After obtaining approval from the Ethics Study Board of the hospital and informed consent from closest relatives, we studied 56 patients from our surgical intensive care unit (ICU). Twenty-eight consecutive trauma patients with an injury severity score (ISS)[9] >15 points and 28 patients with sepsis secondary to major surgery (non-trauma, non-cardiovascular, non-neurosurgery) were prospectively included. Sepsis was defined using the guidelines of the American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference (ACCP/SCCM)[10], that is more than one of the following criteria: (1) temperature >38 °C or <36 °C; (2) heart rate <90 beat min^{-1}; (3) tachypnoea manifested by ventilatory frequency <20 bpm or Pa_{CO_2} <4.3 kPa; (4) alteration in white blood cell count (>12 000 ml^{-1}, <4000 ml^{-1}, >10% immature neutrophils). Patients with renal insufficiency (serum creatinine >2.0 mg dl^{-1}; blood urea nitrogen >150 mg dl^{-1}; urine output <20 ml h^{-1} in spite of diuretic therapy with frusemide), severe liver dysfunction or disseminated intravascular coagulation were excluded. All patients were haemodynamically stable (mean arterial pressure >70 mm Hg, cardiac index >2.00 litre min^{-1} m^{-1}) before inclusion in the study. The time between surgery and start of the study was more than 12 h. None of the patients was in septic shock before the beginning of the study.

All patients continuously received a mixture of fentanyl and midazolam, and all were receiving controlled mechanical ventilation. FI_{O_2} and ventilatory patterns were adjusted to maintain Pa_{O_2} at 13.33–20 kPa and Pa_{CO_2} at 5.0–6.4 kPa throughout the study.

Prospectively, patients were allocated randomly to one of the following groups: in group I, volume therapy was carried out using 10% low-molecular weight hydroxyethylstarch (HES) solution (mean molecular weight: 200 000 Da, degree of substitution 0.5 (HES-trauma, *n*=14; HES-sepsis, *n*=14); group II, 20% human albumin (HA) was infused for volume therapy (HA-trauma, *n*=14; HA-sepsis, *n*=14).

According to the design of the study, fluid was infused to maintain pulmonary capillary wedge pressure (PCWP) at 10–15 mm Hg. Banked blood cells (RBC) were transfused when haemoglobin (Hb) was <9 g dl^{-1}, fresh frozen plasma (FFP) was given only to maintain haemostasis (prothrombin time <50%; fibrinogen <2 g litre^{-1}) and platelet concentrations were infused when platelet count was <30×10^9 litre^{-1}. Crystalloids (Ringer's solution) were given to all patients to compensate for fluid loss by sweating, gastric tubes, extensive urine output and as a solvent for drugs (e.g. antibiotics).

Dopamine was given in a renal dose of 3 μg kg^{-1} min^{-1} to all patients. Adrenaline was given when mean arterial pressure (MAP) was <60 mm Hg and cardiac index (CI) was <2.25 litre min^{-1} m^{-2}. Noradrenaline was administered when MAP was <60 mm Hg and systemic vascular resistance (SVR) was <600 dyn s^{-1} cm^{-5} (target: MAP >70 mm Hg). All additional therapy (parenteral feeding, antibiotics, pharmacological support, ventilation) was performed according to our standard procedure of management of intensive care patients by physicians who were not involved in the study and who were blinded to the grouping of the patients (HA *vs* HES).

Heart rate (HR), MAP, pulmonary capillary wedge pressure (PCWP) and CI (by the thermodilution technique) were monitored in all patients.

Arterial blood samples were obtained from an indwelling arterial cannula and plasma was separated immediately and stored at −30 °C. Endothelin-1 (ET-1) was measured by radioimmunoassay (RIA; Biocode, Sclessin, Belgium)[11]. Sensitivity of the test kit is 0.5 pg ml^{-1}; cross reactivity with endothelin-1 is 100%, endothelin-2 34%, endothelin-3 64%, big-endothelin 2% and other vasoactive peptides (e.g. angiotensin I and II, bradykinin, atrial natriuretic peptide) <0.1%. Vasopressin (by RIA; Instar Corp., Stillwater, MN, USA[12]), atrial natriuretic peptide (ANP) (by RIA; Instar Corp.[13]), catecholamine plasma concentrations (adrenaline and noradrenaline by high-pressure liquid chromatography with combined electrochemical detection), and 6-ketoprostaglandin $F_{1\alpha}$ (the stable but inactive end-product of prostaglandin I_2 (prostacyclin), using a commercially available enzyme immunoassay kit (TiterZyme, PerSeptive Diagnostics, Cambridge, MA, USA))[14] were measured from plasma within 2 months after blood sampling. All data are means of duplicate measurements, and data were obtained by one investigator who was blinded to the patients (trauma/sepsis) and their grouping (HA/HES). When data differed by more than 10%, the measurement was repeated and the mean value calculated.

Gastric intramucosal pH (pH_i) was measured using a nasogastric tube (Tonometer, Tonometrics, Worcester, MA, USA). An equilibration time of 60 min was used, and pH_i was measured according to the guidelines of the manufacturer. Gastric pH_i was calculated using the Henderson–Hasselbalch equation[15].

Liver function was assessed using the monoethylglycinexylidide (MEGX) test. MEGX was measured from arterial blood samples by high-pressure liquid chromatography before and 15 min after lignocaine 1 mg kg^{-1} i.v.[16]. An MEGX plasma concentration of <50 ng ml^{-1} was taken as indicating abnormal liver function.

All measurements were carried out on the day of admission (traumatized patients) or on the day of sepsis diagnosis (baseline values) and continued for the following 5 days at 12:00.

All variables are expressed as mean (SD). Groups were compared using the Mann–Whitney *U* test. One- and two-way analysis of variance (ANOVA) with repeated measures (including Scheffé's test)

Results

Patients in the two subgroups (trauma/sepsis) were similar in characteristics and intensive care therapy (table 1). ISS, APACHE II score and outcome were similar in the corresponding groups. The number of patients who died during (early non-survivors) and after (late non-survivors) the study was comparable in the corresponding volume groups (trauma/sepsis) (table 1). All of these patients died from multiple organ dysfunction syndrome (MODS). Use of blood, FFP, amount of crystalloids and fluid balance did not differ between the groups (table 2). In both trauma and sepsis patients, significantly more HES than HA was infused during the study (table 2). HES costs approximately £9 per 500 ml whereas HA costs approximately £45 per 100 ml. Volume replacement with HA was significantly more costly than with HES (cumulative costs: HES-trauma, £77 (13); HES-sepsis, £70 (13); HA-trauma, £936 (156); HA-sepsis, £869 (200)). Catecholamine support was necessary more often and in higher doses in the sepsis compared with the trauma patients, but there were no differences between the two sepsis groups. Blood and urine electrolyte concentrations, haemoglobin, temperature and renal function did not differ significantly between the two corresponding groups.

MAP, HR, PCWP, CI and pulmonary function (Pa_{O_2}/FI_{O_2}) at baseline did not differ in the trauma and sepsis groups (table 3). CI increased significantly more in HES- than in HA-treated patients (table 3).

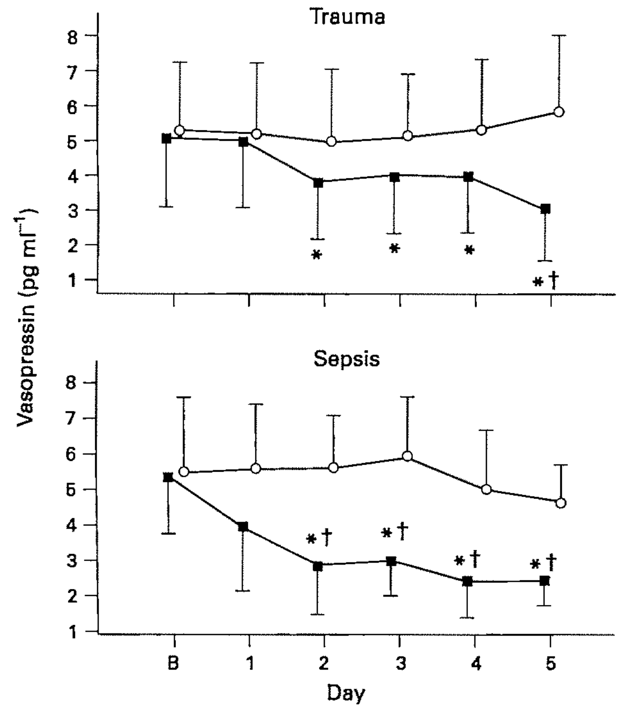

Figure 1 Changes in plasma concentrations of vasopressin (normal range <3.0 pg ml^{-1}) in the trauma and sepsis patients after administration of HES (■) or albumin (○). B=Baseline. †P<0.05 compared with baseline; *P<0.05 compared with corresponding volume group.

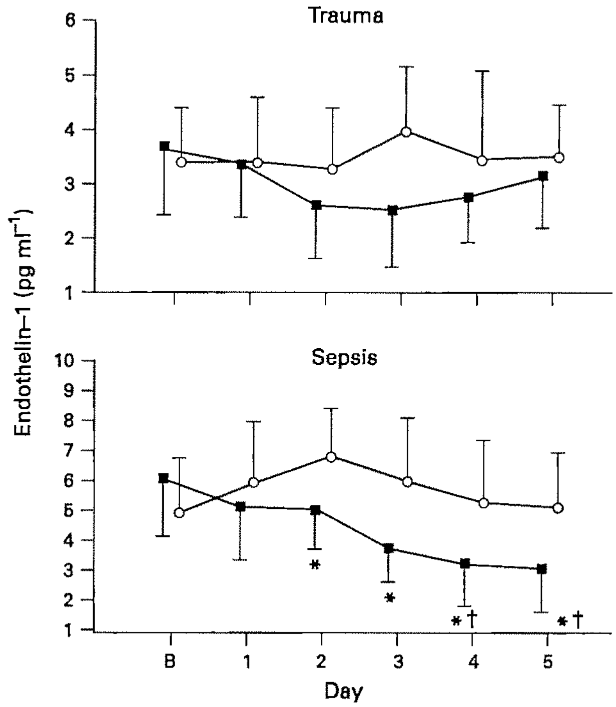

Figure 2 Changes in plasma concentrations of endothelin-1 (normal range <3 pg ml^{-1}) in the trauma and sepsis patients after administration of HES (■) or albumin (○). B=Baseline. †P<0.05 compared with baseline; *P<0.05 compared with corresponding volume group.

Pa_{O_2}/Fi_{O_2} increased in the trauma and sepsis groups in which HES was infused, whereas it was almost unchanged in the albumin-treated patients, being significantly different compared with the corresponding HES-group at the end of the study (table 3).

At baseline, plasma concentrations of MEGX were significantly lower in sepsis than in trauma patients (table 3). In the trauma patients, they remained almost unchanged and did not differ between the two groups. In the sepsis patients, plasma concentration of MEGX increased earlier in HES- than in HA-treated patients (table 3).

pH_i did not differ in the trauma patients throughout the study (table 3). In the sepsis patients it was

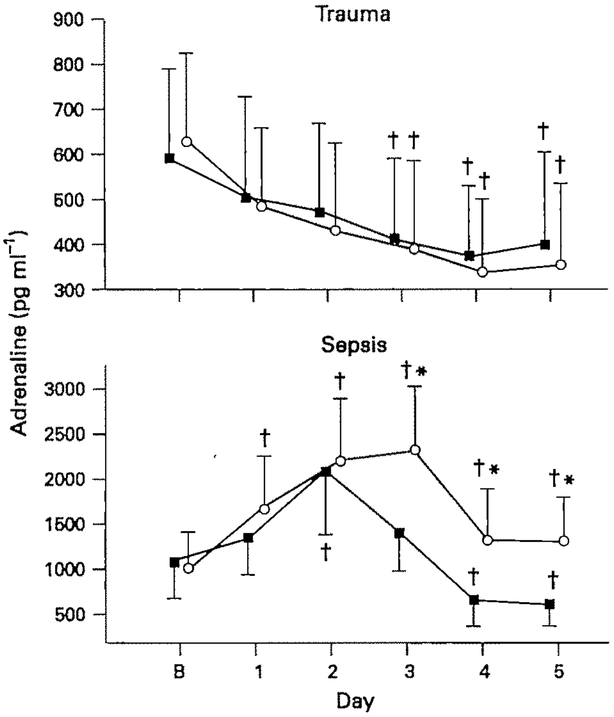

Figure 3 Changes in plasma concentrations of adrenaline (normal range 30–85 pg ml^{-1}) in the trauma and sepsis patients after administration of HES (■) or albumin (○). B=Baseline. †$P<0.05$ compared with baseline; *$P<0.05$ compared with corresponding volume group.

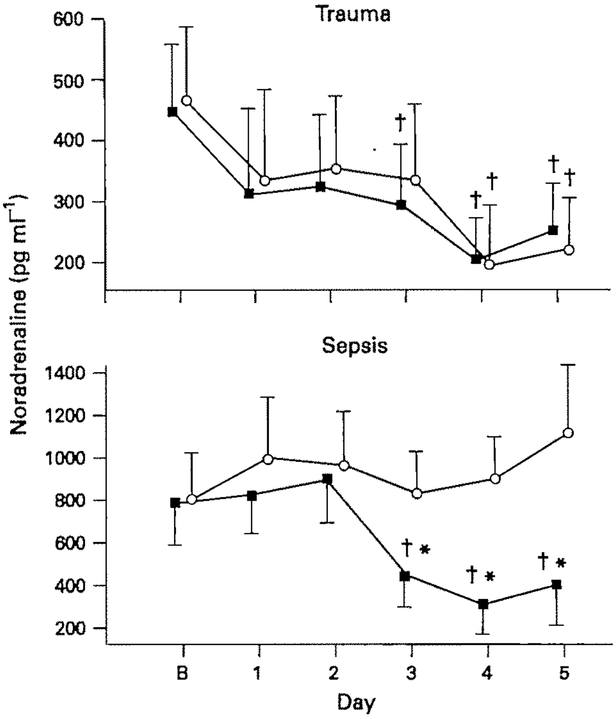

Figure 4 Changes in plasma concentrations of noradrenaline (normal range 180–250 pg ml^{-1}) in the trauma and sepsis patients after administration of HES (■) or albumin (○). B=Baseline. †$P<0.05$ compared with baseline; *$P<0.05$ compared with corresponding volume group.

similar at baseline (<7.30) and increased only in the HES group (to 7.48).

Vasopressin plasma concentrations were increased at baseline in all patients (>3.0 pg ml^{-1}) (fig. 1). Concentrations decreased to almost normal values in HES-treated patients but remained increased in both albumin groups. ET-1 plasma concentrations were within the normal range in trauma patients and did not differ between the two groups (fig. 2). In the sepsis patients, ET-1 plasma concentrations decreased in the HES group being significantly lower than in the albumin-treated patients at the end of the investigation.

Plasma concentrations of adrenaline and noradrenaline decreased similarly in all trauma patients

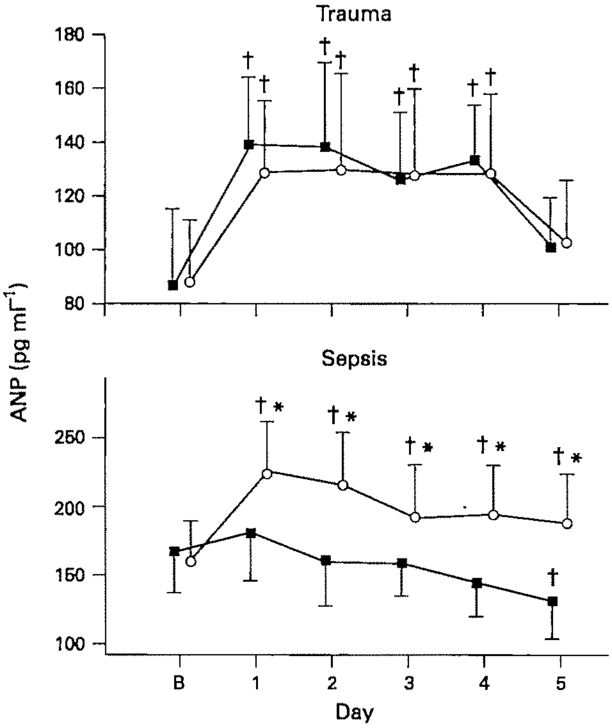

Figure 5 Changes in plasma concentrations of atrial natriuretic peptide (ANP) (normal values 20–100 pg ml^{-1}) in the trauma and sepsis patients after administration of HES (■) or albumin (○). B=Baseline. †$P<0.05$ compared with baseline; *$P<0.05$ compared with corresponding volume group.

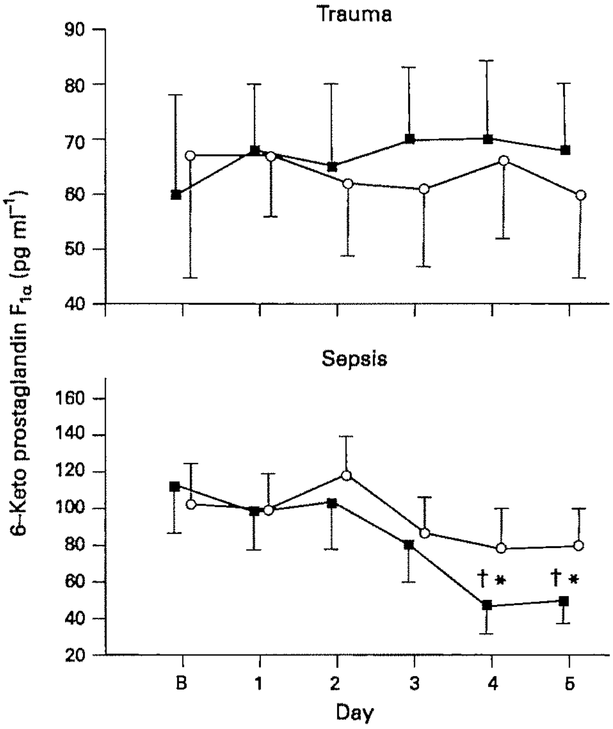

Figure 6 Changes in plasma concentrations of 6-keto-prostaglandin $F_{1\alpha}$ (normal range <30 pg ml^{-1}) in the trauma and sepsis patients after administration of HES (■) or albumin (○). B=Baseline. †$P<0.05$ compared with baseline; *$P<0.05$ compared with corresponding volume group.

($P<0.05$) (figs 3, 4). In the sepsis patients, concentrations decreased significantly only in the HES group until the end of the study. In the albumin group, adrenaline increased, whereas noradrenaline remained unchanged during the study. Atrial natriuretic factor increased similarly to greater than normal values in both sepsis groups and did not reach normal values at the end of the study (fig. 5). In the albumin group, plasma concentrations were increased at the start of the study and increased further (215.5 (38.9) pg ml^{-1} on day 2), whereas they were decreased in HES patients (131.3 (28.8) pg ml^{-1} on day 5). Plasma concentrations of 6-keto-prostaglandin $F_{1\alpha}$ did not differ in the trauma groups (fig. 6). In the sepsis patients, concentrations decreased more in the HES group (from 112 (25) to 47 (15) pg ml^{-1}) ($P<0.05$ *vs* HA-patients).

Discussion

Both trauma and sepsis may impair vasoregulation which is needed to control the distribution of cardiac output. Current evidence suggests that systemic and endothelial-derived mediators generated in critical illness may precipitate or sustain disturbances in tissue blood supply. Microcirculatory disturbances appear to be of major importance for the development of, and progression in the pathophysiology of shock or the evolution of MOF[4]. In this situation, volume infusion is known to be therapeutic. One important objective of fluid therapy is to restore or guarantee tissue perfusion. Whether one fluid is better than another may be a result of different experimental designs and end-points of volume therapy. To understand the effects of varying fluid management it is necessary not to limit the investigation to a specific number of hours after single volume infusion. Thus we studied the effects of two different volume therapy regimens over a period of 5 days.

In our sepsis patients, plasma concentrations of important regulators of the macro- and microcirculation were significantly more altered than in our trauma groups. Vasopressin, ET1, adrenaline and noradrenaline plasma concentrations exceeded the normal range at baseline. The increased concentrations of these potent vasoconstrictors may cause microcirculatory alterations, inadequate perfusion and ultimately tissue damage. This compensatory activation of the vasopressor systems is beneficial at first, but may become deleterious. It may result in splanchnic vasoconstriction, although there is a marked increase in the need for oxygen delivery in this situation[17]. In this study, pH_i differed between our sepsis (<7.30) and trauma (>7.35) patients, indicating alteration in splanchnic perfusion in sepsis[18]. Also the MEGX test was reduced below the normal range (<50 ng ml^{-1}) in our sepsis patients, indicating altered hepatic function, possibly because of perfusion deficits. The increased plasma concentrations of potent systemic and local vasodilators (ANP and 6-keto-prostaglandin $F_{1\alpha}$) in our sepsis patients may be regarded as a compensatory reaction to activation of the vasopressor systems.

ET-1 represents an extremely potent vasoconstrictor, which may play an important role in (regional) blood flow regulation[19]. ET-1 is released by pathophysiological states that are characterized by limitation of cardiac output or hypotension. Moreover, endotoxin directly stimulates ET-1 release *in vivo* and *in vitro*[20]. In sepsis patients, the greatest severity of disease paralleled the highest concentration of ET-1[21]. One problem with measurement of ET-1 from plasma samples is that it does not represent the actual local concentration, but appears to be a "spill over" of endothelin released by the endothelium.

The sympathetic nervous system is activated in the critically ill[22]. The increased plasma concentrations of catecholamines in this study reflected this activation. The higher plasma concentrations in our sepsis patients may also be related to the higher catecholamine support in these patients. However, inotropic support (adrenaline) and vasopressor therapy (noradrenaline) did not differ in our sepsis groups and thus cannot explain the differences between the two volume groups. ANP plays an important role in the regulation of arterial pressure and volume homeostasis. Plasma concentrations of ANP were reported to be increased significantly from normal in sepsis patients, particularly in combination with acute respiratory failure[23]. Nakae and colleagues[24] showed that 6-keto-prostaglandin $F_{1\alpha}$ was higher in sepsis patients who died than in those who survived, and it may serve as a marker of illness severity.

It has been shown from animal and human studies that adrenaline stimulates ANP secretion[25], by which negative effects on the (micro-) circulation of adrenaline may be compensated. ET-1 may stimulate the release of catecholamines and renin[26], thus possibly contributing to vasconstriction and reduced blood flow at the microcirculatory level. In contrast, ET increased circulating ANP in dogs and ANP acts as a potent inhibitor of ET synthesis. Thus ANP may function as a negative feedback regulator of ET[5] and the vasoconstrictive actions of endothelin are opposed by this vasodilator[27]. Also, prostaglandin synthesis was shown to be increased by adrenaline[28], by which counter regulatory vasodilatation may be induced.

In our trauma patients, the choice of volume therapy did not influence either the measured regulators of the circulation, pH_i or the MEGX test. This implies that volume therapy with 20% HA in these patients can be replaced easily by HES. In our sepsis patients, however, long-term volume therapy for 5 days with hydroxethylstarch solution resulted in a more beneficial influence overall on these regulators than infusion of albumin. pH_i and the MEGX test improved also more markedly in the HES than in the HA group. As monitoring of pH_i has been shown to be an excellent indicator of changes in splanchnic perfusion[15 18], improved splanchnic perfusion may be assumed in HES patients. We used the MEGX test in this study to assess hepatic function because it was demonstrated in animal experiments that this test is a suitable tool for clinical evaluation and therapeutic interventions after hypovolaemic shock[16]. The increase in MEGX plasma concentrations in our sepsis patients treated with HES solution indicated compensation of possible hepatic perfusion deficits. Overall, HES-treated patients also showed better oxygenation than HA-treated patients. This may result from either improved microcirculation in the pulmonary circulation or from less shift of fluid from the intravascular to the interstitial space resulting in less extravascular lung water (EVLW).

The reasons for these differences between the two volume regimens can only be speculative at present; although fluid balance and PCWP did not differ significantly between the corresponding groups throughout the study, higher preload with subsequent improved systemic perfusion (increased CI) in the HES groups cannot be excluded as a reason for the reduction in circulating vasopressors. Beneficial rheological effects secondary to the HES solution may have improved the microcirculation and tissue perfusion and may thus have resulted in less activation of vasopressor systems. Direct effects on endothelial cells may also have played a role; 10% pentastarch (a comparable low-molecular weight HES preparation) may have influenced directly endothelial function, for example by beneficially altering endothelial cell integrity by oxygen free radical scavenging or by stabilizing fragile cell membranes[29]. In an experimental setting, Schmand and colleagues[30] found that in a group of animals which had received HES solution for volume replacement, circulating interleukin-6 (IL-6) concentrations were normalized. This is of great interest as IL-6 may be detrimental to host immune function and thus may also be involved in (micro-) circulatory abnormalities.

Changes in pulmonary function, pH$_i$ and liver function (assessed by the MEGX test) were influenced more beneficially in those patients in whom HES was infused in comparison with HA-treated patients. Survival rate during the study and thereafter was similar in the two groups. Effective fluid therapy appears to be the mainstay of managing the critically ill; however, it was not the aim of this study to clarify if the choice of fluid has an impact on patient outcome. Large studies with considerable numbers of patients must be undertaken to fully evaluate the influence of volume regimen on outcome.

Potency and time course of action of rocuronium during desflurane and isoflurane anaesthesia

N. KUMAR, R. K. MIRAKHUR, M. J. J. SYMINGTON AND G. J. MCCARTHY

Summary

We have studied the potency and onset and duration of action of rocuronium in patients anaesthetized with 1 MAC of desflurane or isoflurane (in 66% nitrous oxide). Potency was estimated using the single bolus dose technique. Neuromuscular block was measured by stimulation of the ulnar nerve and recording the force of contraction of the adductor pollicis muscle. The ED_{50} and ED_{95} of rocuronium were estimated as 138 (95% confidence limits 117–162) μg kg^{-1} and 281 (241–328) μg kg^{-1}, and 126 (105–151) μg kg^{-1} and 283 (236–339) μg kg^{-1} during desflurane and isoflurane anaesthesia, respectively. The mean times to onset of maximum block after rocuronium 0.6 mg kg^{-1} were 1.0 (SD 0.10) min and 1.1 (0.15) min, respectively, during anaesthesia with desflurane and isoflurane. The respective times to recovery of T1 (the first response in the train-of-four (TOF) stimulation) to 25% and 90% were 36 (8.3) min and 54 (15.4) min during desflurane anaesthesia and 31 (8.2) min and 45 (12.7) min during isoflurane anaesthesia. The times to recovery of the TOF ratio to 0.7 were 66 (13.4) min and 52 (16.3) min and the 25–75% recovery indices 14 (5.3) min and 10 (3.2) min, respectively, in the desflurane and isoflurane groups. There were no differences in the estimated potency or onset of action of rocuronium during desflurane and isoflurane anaesthesia. However, duration of action tended to be longer during desflurane anaesthesia although only the differences in times to TOF ratio of 0.7 and the recovery indices were close to being significantly different (P=0.0503 and 0.0560). (*Br. J. Anaesth.* 1996;**77**:488–491)

Key words

Neuromuscular block, rocuronium. Anaesthetics volatile, desflurane. Anaesthetics volatile, isoflurane. Neuromuscular block, measurement of response. Potency, anaesthetic, ED_{50}.

Desflurane is a new volatile agent with a low blood-gas solubility giving it the properties of rapid uptake and elimination[1]. Rocuronium is a newer aminosteroid non-depolarizing neuromuscular blocker with a rapid onset and intermediate duration of action[2 3]. Although there are some reports of interaction of neuromuscular blockers with desflurane[4–6], this is not known for rocuronium. Most of these studies have involved studying the effects of only single doses of neuromuscular blockers. This study was undertaken to compare the potency and time course of action of rocuronium during anaesthesia with desflurane or isoflurane.

Patients and methods

We studied 68 patients, aged 18–65 yr, ASA I or II, with their written informed consent and approval of the Research Ethics Committee. Exclusion criteria were body weight greater or less than 30% of ideal for height and patients receiving medication known to interact with neuromuscular blocking drugs.

After premedication with temazepam 10–20 mg, anaesthesia was induced with fentanyl 2 μg kg^{-1} and propofol 2–3 mg kg^{-1}, and maintained with either isoflurane or desflurane and 66% nitrous oxide in oxygen, based on a computer-generated randomization scheme. Ventilation of the lungs was assisted to maintain normocapnia and skin temperature over the adductor pollicis was maintained greater than 32 °C. End-tidal concentration of volatile agent was monitored using the Ohmeda 5250 respiratory gas monitor and stabilized at 1 MAC (adjusted for age and concomitant use of nitrous oxide; 4% and 2.8% desflurane, and 0.56% and 0.5% isoflurane for those aged 18–30 yr and 31–65 yr, respectively)[7 8].

Heart rate, arterial pressure and oxygen saturation were monitored in a standard way. The ulnar nerve was stimulated transcutaneously at the wrist with supramaximal stimuli of 0.2 ms duration in a single twitch mode at 0.1 Hz for potency estimation and in a train-of-four (TOF) mode at 2 Hz every 12 s for the onset and duration of action part of the study. The resultant force of contraction of the adductor pollicis muscle was recorded using a force displacement transducer and neuromuscular function analyser (Myograph 2000, Biometer Ltd, Denmark). Baseline neuromuscular responses were allowed to stabilize at the same time as the end-tidal concentration of the volatile agent was being stabilized over a period of about 10 min.

We studied 48 patients for estimation of potency using the single bolus technique, described in previous studies and preferred for neuromuscular block-

ers with intermediate duration of action[9 10]. Twelve patients each (six for desflurane and six for isoflurane) were allocated randomly to receive rocuronium 75, 150, 225 or 300 µg kg^{-1}. Maximum block attained with each dose was recorded and the study terminated. Subsequently, anaesthesia was carried out as appropriate for surgical needs. Twitch height data were subjected to arc-sine transformation[11]. Dose–response curves were constructed using least squares regression analysis and subjected to analysis of covariance. ED_{50} and ED_{95} (doses required to produce 50% and 95% depression of twitch response, respectively) were estimated from the results.

A separate group of 20 patients (10 each in the desflurane and isoflurane groups) anaesthetized in the same way as above was studied to measure the onset and duration of action of rocuronium 0.6 mg kg^{-1}. The variables recorded were onset time (time from drug administration to maximum effect), and times to recovery of T1 to 25% and 90% of control, and of the TOF ratio to 0.7. The results of this part of the study were analysed using the *t* test. $P<0.05$ was considered significant.

Results

The groups were comparable in age, weight, height and sex distribution (table 1). Mean maximum twitch depression attained with each dose of rocuronium is given in table 2; mean values ranged from 14% and 25% with desflurane and isoflurane, respectively, with a dose of rocuronium 75 µg kg^{-1}, to 97% and 99% with the 300-µg kg^{-1} dose. The degree of block was dose-related but the difference between groups for each of the doses was not significant.

The dose–response curves (fig. 1) did not differ in their slopes or intercepts. The calculated ED_{50} and ED_{95} values are given in table 3. These were similar and almost identical: 138 (95% confidence intervals 117–162) µg kg^{-1} and 126 (105–151) µg kg^{-1}, and 281 (241–328) and 283 (236–339) µg kg^{-1}, respectively, during desflurane and isoflurane anaesthesia.

The times for onset and duration of action of rocuronium 0.6 mg kg^{-1} are given in table 4. Onset times were 1 and 1.1 min in the desflurane and isoflurane groups, respectively (ns). Times to 25% recovery of T1 were 36 and 31 min, to T1 of 90% 54 and 45 min, and to TOF ratio of 0.7, 66 and 52 min in the desflurane and isoflurane groups, respectively. The 25–75% recovery indices were 14 and 10 min, respectively, in the desflurane and isoflurane groups. Although recovery times to all end-points were longer in the desflurane group, only the times for TOF ratios to reach 0.7 and T1 25–75% were close to being significantly different (P=0.0503 and 0.0560, respectively).

ED_{95} (µg kg^{-1})	281 (241-328)	283 (236-339)

Discussion

We found no significant difference in the apparent potency of rocuronium during anaesthesia with 1 MAC of desflurane or isoflurane. There are no previous reports of potency estimation of rocuronium during desflurane anaesthesia but the ED_{95} of

rocuronium during isoflurane anaesthesia in this study was similar to that reported by previous workers[12–14] and was only marginally lower than values obtained during nitrous oxide–opioid anaesthesia[15 16].

Onset times after rocuronium 600 µg kg^{-1} were similar in both groups. These were consistent with previously published results in the absence of volatile anaesthetics using the TOF mode of stimulation[3 17] but were faster than the time of 89 s reported by Cooper and colleagues using the single twitch (at 0.1 Hz) mode of stimulation[18]. As volatile agents need to diffuse into the muscle compartments and as penetration is slow, they are unlikely to influence the onset of action of neuromuscular blockers. Our patients were exposed to the inhalation agents for 10 min before administration of rocuronium and during this time tissue concentrations would be much lower than the end-tidal concentration and therefore unlikely to affect onset of action (see below). The more likely reason for similar onset times with or without volatile anaesthetics may be the use of the TOF mode of stimulation. It has been shown previously that onset time for intermediate duration neuromuscular blocking drugs is faster using a TOF mode of stimulation[18–20].

The clinical duration of action and recovery index of rocuronium during isoflurane–nitrous oxide anaesthesia were consistent with other published studies[14 15]. Recovery times to all end-points (including recovery index) were longer with desflurane although only the times to a TOF ratio of 0.7 and the recovery index were close to being significantly different. Volatile agents require approximately 30–45 min to equilibrate between alveolar, blood and muscle compartments and are therefore less likely to affect the onset of block. This was demonstrated in the study of Cannon and colleagues who showed that it took approximately 45 min to attain steady state block after infusion of vecuronium, even with the use of volatile anaesthetics[21]. It is likely therefore that the principal effects are on recovery of block. The blood–muscle partition coefficient of desflurane is 2.02 compared with 2.92 for isoflurane[22]. Therefore, equilibration between muscle and end-tidal concentration may have been more complete for desflurane than for isoflurane. This might have increased the comparative differences between the muscle partial pressures of anaesthetic and accounted for the increased duration of action and recovery index seen in the desflurane group. Desflurane has also been postulated to have a depressant effect at the neuromuscular junction both pre- and post-junctionally[4]. The duration of action of rocuronium during desflurane anaesthesia may therefore be longer than during isoflurane anaesthesia. This was an exploratory study based on the hypothesis that there would be no difference between the groups and a larger study may show significant differences in the duration of action of rocuronium during anaesthesia with desflurane and isoflurane.

The results of this study differed from previous results with atracurium and mivacurium which showed little difference between desflurane and isoflurane[5 23]. The difference may be because of the unique metabolic pathways of these two latter blockers. In contrast, others have shown that 1 MAC of desflurane and isoflurane had a similar effect on the neuromuscular effects of vecuronium[6]. However, they used a Datex Relaxograph to monitor neuromuscular block. This instrument is known to yield somewhat different results from those obtained using mechanomyography, as used in this study[24]. In addition, these authors measured recovery to only 25% of control values. However, our results are in agreement with those of Wright and colleagues who observed that desflurane produced greater potentiation of the effects of vecuronium compared with isoflurane[25].

In summary, this study has demonstrated no difference in the estimated potency of rocuronium during anaesthesia with 1 MAC of desflurane or isoflurane. The effects of rocuronium 0.6 mg kg^{-1} were, however, longer during anaesthesia with desflurane.

Neuromuscular blocking action of suxamethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine

N. W. FLEMING, S. MACRES, J. F. ANTOGNINI AND J. VENGCO

Summary

The reported effects of edrophonium on a subsequent dose of suxamethonium are variable and the effects of pyridostigmine have not been evaluated extensively. We have studied this interaction in patients anaesthetized with propofol and sufentanil. After recovery from an initial bolus (1 mg kg^{-1}) of suxamethonium, vecuronium was infused to produce 75% block. After 30 min, the infusion was discontinued and saline 5 ml, edrophonium 0.75 mg kg^{-1}, pyridostigmine 0.24 mg kg^{-1} or neostigmine 0.05 mg kg^{-1} was given. Fifteen minutes later the mean durations of a second bolus of suxamethonium were: 10.5 (SD 3.9) min (saline), 10.9 (3.7) min (edrophonium), 18.7 (5.4) min (pyridostigmine) and 23.8 (7.4) min (neostigmine). Corresponding plasma cholinesterase activities (percentage of baseline) were: 91 (18), 87 (9), 21 (10) and 52 (26). When both treatment groups and individual patients were compared, the changes in duration of action did not correlate with changes in cholinesterase activity. These data suggest that other mechanisms in addition to cholinesterase inhibition may contribute to this drug interaction. (*Br. J. Anaesth.* 1996;**77**:492–495)

Key words

Neuromuscular block, suxamethonium. Antagonists neuromuscular block, edrophonium. Antagonists neuromuscular block, neostigmine. Antagonists neuromuscular block, pyridostigmine. Enzymes, cholinesterase.

At the end of a surgical procedure there is occasional need for urgent short-term neuromuscular block to retrieve a misplaced gauze sponge or relieve severe laryngospasm. Suxamethonium may be used because of its rapid onset and short duration of action. However, prior administration of a cholinesterase inhibitor to antagonize non-depolarizing neuromuscular block may prolong the duration of a subsequent dose of suxamethonium[1]. This interaction has been demonstrated consistently with pyridostigmine and neostigmine[2 3], but studies with edrophonium have produced variable results ranging from no prolongation[4] to slight prolongation[5] or increases comparable with those produced by pyridostigmine and neostigmine[6].

Because of these inconsistencies, and the absence of a single study comparing edrophonium, pyridostigmine and neostigmine in humans, we have investigated the interactions between suxamethonium and each of these cholinesterase inhibitors in patients anaesthetized for elective surgery.

Patients and methods

After obtaining approval from our Human Subjects Review Committee, written informed consent was obtained from patients undergoing elective operations with an anticipated duration of more than 3 h. Patients were excluded if they had any known neuromuscular disease, had experienced prolonged immobilization or bed rest, or were receiving any medications known to interfere with neuromuscular function. Patients were premedicated with midazolam (up to 0.03 mg kg^{-1}) i.v. Standard intraoperative monitors were attached, an antecubital vein was cannulated, a blood sample obtained for measurement of baseline plasma cholinesterase activity, surface stimulating electrodes placed over the ulnar nerve at the wrist, and the forearm fixed securely in a mechanomyogram holder. The thumb was attached to a force transducer (Model FT-10, Grass Instruments, West Warwick, RI, USA) and the resting tension adjusted to approximately 200 *g*. After preoxygenation, general anaesthesia was induced with propofol 1.0–2.5 mg kg^{-1} and sufentanil 0.25–1.0 μg kg^{-1}. The lungs were ventilated with oxygen or an oxygen–air mixture and general anaesthesia was maintained with infusions of propofol 50–250 μg kg^{-1} min^{-1} and sufentanil 0.004–0.025 μg kg^{-1} min^{-1}, adjusted as indicated clinically.

Neuromuscular function was assessed using a stimulator (Model S48, Grass Instruments) triggering a battery-operated nerve stimulator (Digi Stim II, Neuro Technology, Houston, TX, USA) and a computer-assisted data acquisition and analysis system written in the Asyst programming language. The ulnar nerve was stimulated every 2 s (single pulse, 0.1 ms duration, delivered current 60–75 mA). The analogue signal from the transducer was amplified (Model C-150 DC amplifier, Astro-Med, Inc., West Warwick, RI, USA) and digitized (100 points at 333 Hz) using an analogue-to-digital conversion board (Model 2801, Data Translations, Inc., Marlboro, MA, USA). Resting tension and peak contractile tension were calculated online. Each twitch, and

NEAL W. FLEMING*, MD, PHD, STEPHEN MACRES, MD, JOSEPH F. ANTOGNINI, MD, JOEL VENGCO, Department of Anesthesiology, University of California, Davis, CA, USA. Accepted for publication: June 17, 1996.

*Address for correspondence: University of California, Davis, Department of Anesthesiology, TB 170, Davis, CA 95616-8634, USA.

the trend in peak tension over time, were displayed on the computer monitor.

After induction of anaesthesia, manual, controlled ventilation was continued for approximately 10 min to allow stabilization of the contractile response. Suxamethonium 1.0 mg kg^{-1} in normal saline 10 ml was infused into the hub of the antecubital catheter at a rate of 1 ml s^{-1} with the carrier solution flowing at 250 ml h^{-1}. After the onset of complete neuromuscular block, the trachea was intubated. After complete recovery from suxamethonium, as demonstrated by stable contractile tension for at least 5 min, a loading dose of vecuronium was given followed by an infusion titrated to maintain approximately 75% neuromuscular block. Thirty minutes after the loading dose of vecuronium, the infusion was discontinued and glycopyrronium 7 µg kg^{-1} was administered. Thirty seconds later, patients received a 5-ml i.v. injection containing saline, edrophonium 0.75 mg kg^{-1}, pyridostigmine 0.24 mg kg^{-1} or neostigmine 0.05 mg kg^{-1}. Fifteen minutes later, a second blood sample was obtained for measurement of serum cholinesterase activity and a second bolus of suxamethonium 1.0 mg kg^{-1} in 10 ml was injected, as described previously. A fifth group of patients also received edrophonium 0.75 mg kg^{-1}, but blood sampling and administration of suxamethonium occurred after 5 instead of 15 min.

For each suxamethonium bolus, onset time (start of injection to maximum block), recovery index (time for recovery from 25% to 75% of the final maximal twitch) and duration (start of injection to return to 90% of the final twitch) were determined.

Blood samples were centrifuged after collection. Serum was aspirated and stored at −70 °C for subsequent analysis. Serum cholinesterase activity was measured by a modification of the assay described originally by Ellman and colleagues[7] (Physicians Clinical Laboratory, Inc., Sacramento, CA, USA).

Comparisons of patient characteristics or baseline neuromuscular data were made using either the Kruskal–Wallis test (non-parametric data) or the Student–Neuman–Keul's test (parametric data). Analysis of the response to suxamethonium was made with either a paired *t* test for within-group comparisons or Dunnett's test, using saline treatment as the control response for comparisons between groups. In all cases, $P \leq 0.05$ was considered statistically significant. All values are expressed as mean (SD).

Results

We studied 50 patients (28 females, 22 males), mean age 51 (range 22 to 79) yr, mean weight 75 (2.6) kg. Eight patients were ASA I, 27 ASA II and 15 ASA III. Patients were assigned sequentially to one of five treatment groups: saline, edrophonium (5 min), edrophonium, pyridostigmine or neostigmine. There were no differences between the 10 patients in each group in terms of sex, age, weight or ASA classification.

The mean initial contractile response was 574 (91) g and was stable throughout the study. The final contractile response was 101 (16) % of the initial twitch height. The first bolus of suxamethonium had a mean onset time of 59 (15) s, duration of 13.7 (4.2) min and a recovery index of 2.6 (1.3) min. Infusion of vecuronium decreased the contractile response to 26 (7) % of the initial baseline response and required a mean total dose of 2.8 (1.0) mg. There were no differences between the groups in initial contractile response, onset, duration or recovery index for the first bolus of suxamethonium (table 1). Neuromuscular block produced by vecuronium was comparable in all groups with the exception of the edrophonium (5 min) group (80 (6) % *vs* 70 (6) % for the saline group). Correspondingly, the total dose of vecuronium administered to this group was higher (3.1 (1.1) mg *vs* 2.6 (1.6) mg).

The effects of treatment on the response to the second dose of suxamethonium are summarized in table 1. Onset time increased in all five groups (range 131–196% of control onset times). Duration of action was shorter in patients who received saline or edrophonium and prolonged in patients who received pyridostigmine (35% increase) or neostigmine (78% increase). The effects of neostigmine were significantly greater than those of pyridostigmine. Recovery index followed a similar pattern, with slightly shorter times in patients who received saline or edrophonium and prolonged times in patients who received pyridostigmine or neostigmine.

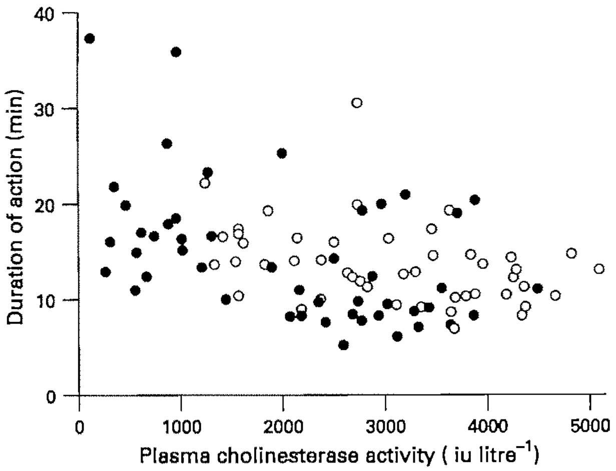

Figure 1 Relationship between plasma cholinesterase activity and duration of action produced by suxamethonium (all groups combined). Data points are for before (○) and after (●) drug treatment.

Baseline plasma cholinesterase activity ranged from 1229 to 5007 iu litre^{-1} (normal range 1000–3500 iu litre^{-1}). These values were comparable between treatment groups (table 1, fig. 1). Lower pre-drug cholinesterase activity correlated with a longer duration of action of suxamethonium. This relationship was best described by an exponential curve, consistent with previous reports[8]. Cholinesterase activity was not significantly altered by saline administration, but decreased after drug treatment in the other four groups. Post-treatment measurements were 93–4461 iu litre^{-1}. Statistically significant decreases in activity occurred after treatment with cholinesterase inhibitors but the magnitude varied widely; edrophonium (5 min) −26 (17) %; edrophonium −13 (8) %; pyridostigmine −79 (10) %; neostigmine −48 (26) %. The changes after pyridostigmine and neostigmine differed significantly from the saline control group (−9 (18) %) and from each other.

Discussion

Based on previous case reports and theoretical concerns, Sunew and Hicks studied the effects of pyridostigmine and neostigmine on the duration of subsequently administered suxamethonium[2]. Both drugs prolonged the duration of neuromuscular block. Pyridostigmine increased the mean duration of a 1-mg kg^{-1} dose to 24 min (182% of baseline) while neostigmine increased the duration to 35 min (315% of baseline). Our data confirmed this interaction. Both cholinesterase inhibitors prolonged the duration of action, and the effects of neostigmine (178% of baseline) were greater than those of pyridostigmine (135% of baseline). The smaller increases reported here probably resulted from the greater time between anticholinesterase and suxamethonium administration (15 min *vs* 5 min) and the effects of residual vecuronium on nicotinic cholinergic receptors.

Interactions between edrophonium and suxamethonium have also been evaluated previously. Mirakhur examined the effects of edrophonium on plasma cholinesterase activity in 15 patients[9]. From the lack of inhibition he inferred that edrophonium would be unlikely to prolong the effects of suxamethonium and subsequently confirmed this in patients undergoing elective surgical procedures with halothane–nitrous oxide–oxygen general anaesthesia[4]. In contrast, Sohn, Cronnelly and Sharma examined the interactions between suxamethonium and edrophonium in six surgical patients and demonstrated a transient decrease in plasma cholinesterase activity and a 60% increase in the duration of action of suxamethonium[5]. These patients also received general anaesthesia with halothane–nitrous oxide–oxygen but pancuronium, which is a significant plasma cholinesterase inhibitor[10], was used as a maintenance neuromuscular blocking agent. Patients in our study received propofol–sufentanil–oxygen as a maintenance anaesthetic which does not potentiate the actions of neuromuscular blocking drugs, and vecuronium, which does not inhibit plasma cholinesterase to any clinically significant extent[10], was used for maintenance of neuromuscular block. Our results are comparable with those of Mirakhur who demonstrated that prior treatment with edrophonium did not increase the duration of subsequently administered suxamethonium[9].

Our previous evaluation of the interactions between cholinesterase inhibitors and suxamethonium used a rat model to limit confounding variables such as volatile anaesthetic gases and anaesthetic adjuncts which inhibit plasma cholinesterase activity[6]. These studies demonstrated that all three inhibitors produced a similar (27–38%) increase in the duration of suxamethonium. However, caution is warranted when extrapolating these animal data directly to clinical practice. Studies in isolated rat muscle tissues or whole animals are used frequently to predict responses in humans, but there are quantitative differences between species[11]. Drug interactions involving metabolism by plasma cholinesterase and inhibition by anticholinesterases increase sources of variability. There are differences with regard to enzyme form and concentrations between species[12]. However, the sensitivities of the acetylcholinesterase and butyrylcholinesterase enzymes to inhibitors are similar in humans and rats[13 14]. If the pharmacokinetics and pharmacodynamics of both neuromuscular blocking agents and reversal agents were characterized fully in both species and drug administration procedures adjusted accordingly, responses in the rat model might more directly predict responses in humans. Ultimately, confirmation in a clinical setting is still required, as emphasized by the contrast between the results reported here and previous animal studies[6].

By concurrently measuring the effect of each cholinesterase inhibitor on both enzyme activity and suxamethonium duration, these studies suggest that the increased duration of action is not solely the result of inhibition of plasma cholinesterase. Edrophonium has either no inhibition[9], or a minimal, transient effect on plasma cholinesterase[5]. Neostigmine and pyridostigmine produce similar maximal inhibitory responses, but the effects of pyridostigmine are slightly prolonged[15 16]. Measurements of plasma cholinesterase activity in this study (15 min after drug administration) were consistent with this pattern of slower recovery from pyridostigmine. In contrast, neostigmine has a significantly greater effect on suxamethonium duration. Cholinesterase inhibitors have many non-cholinergic mediated actions[1]. The lack of correlation between enzyme inhibition and prolongation of suxamethonium block suggests that these or other mechanisms may also need to be considered when evaluating this drug interaction.

Both practical and theoretical conclusions can be drawn from these studies. It is not possible to know in advance which patients may require urgent paralysis after they have received a cholinesterase inhibitor. However, if suxamethonium is required, even a dose of 1 mg kg^{-1} will not have a prohibitively long duration of action, particularly if edrophonium is the reversal agent. This is true even if edrophonium is given only 5 min earlier. In the event of an extremely long duration of paralysis (>45 min) after suxamethonium, other contributing factors such as decreased plasma cholinesterase activity, atypical plasma enzyme or additional drug interactions should be considered. In addition, with the introduction of other anaesthetic adjuncts dependent on plasma cholinesterase for metabolism, such as esmolol, mivacurium and remifentanil, studies of interactions with the commonly used cholinesterase inhibitors must consider the potential for both cholinergic and non-cholinergic mediated interactions. A current example of this is the potential for a paradoxical response when a cholinesterase inhibitor is used to antagonize mivacurium neuromuscular block[17]. A similar evaluation of this drug interaction might be revealing.

Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium?

M. J. BAURAIN, F. HOTON, A. A. D'HOLLANDER AND F. R. CANTRAINE

Summary

To test if recovery of neuromuscular transmission is complete after the use of neostigmine under standardized conditions, we have measured adductor pollicis mechanical activity in response to 0.1 Hz (twitch height), train-of-four (TOF) and 100 Hz (RF 100 Hz) ulnar nerve stimulations. We studied 56 adult anaesthetized (thiopentone, fentanyl, nitrous oxide in oxygen) patients, allocated randomly to one of four groups (n=14) to receive rocuronium (group Roc), vecuronium (group Vec), atracurium (group Atr) or pancuronium (group Pan). Recovery of neuromuscular transmission was studied for 15 min after neostigmine 40 μg kg^{-1} was given at 25% recovery of twitch height. Fifteen minutes after antagonism, the TOF ratio was 0.91 (SEM 0.01), 0.88 (0.02) and 0.92 (0.01) (ns), and RF 100 Hz was 0.78 (0.01), 0.79 (0.02) and 0.78 (0.01) (ns) respectively, in patients in groups Roc, Vec and Atr, respectively. In patients in group Pan, TOF ratio and RF 100 Hz were only 0.76 (0.01) and 0.33 (0.04) respectively (P<0.01, one-way analysis of variance, Duncan's multiple classification range tests). In contrast with pancuronium, antagonism of rocuronium-, vecuronium- and atracurium-induced neuromuscular blocks produced a similar high degree of recovery of neuromuscular transmission. (*Br. J. Anaesth.* 1996;**77**:496–499)

Key words

Neuromuscular block, rocuronium. Neuromuscular block, vecuronium. Neuromuscular block, atracurium. Neuromuscular block, pancuronium. Antagonists neuromuscular block, neostigmine. Measurement techniques, neuromuscular block. Neuromuscular block, measurement of response.

Recently, Eriksson and colleagues showed in awake volunteers receiving vecuronium to stabilize the TOF ratio at 0.7, that while the ventilatory response to hypercapnia was normal, reflex hyperventilation induced by hypoxaemia was depressed. This test returned to normal when the TOF ratio returned to 0.9[1 2]. These observations cast doubt on the often proposed 0.7 TOF ratio as a "gold standard" to guarantee a safe clinical situation and also raised interest in the 0.9 TOF ratio as a new end-point for defining adequate recovery of neuromuscular transmission.

In normal patients receiving medium duration neuromuscular blocking agents (rocuronium[3–7], vecuronium, atracurium) a TOF ratio of 0.7 is currently obtained after administration of neostigmine given at a twitch height of 10–25%, but even for vecuronium, data related to a TOF ratio of 0.9 are still scarce[8–12].

In addition to the 2 Hz TOF stimulation pattern, the use of high stimulation rates, especially 100 Hz tetanic stimulation, to quantify recovery of neuromuscular transmission may be desirable because of the TOF ratio limitations for detection of residual neuromuscular block in many clinical situations[8–12]. In normal awake patients also, firing rates of approximately 100 Hz are often observed in different muscle types[13].

The purpose of this study was to assess the level of recovery of neuromuscular transmission 15 min after administration of neostigmine 40 μg kg^{-1} with atropine 15 μg kg^{-1} in patients receiving rocuronium, vecuronium, atracurium and pancuronium.

Patients and methods

After obtaining approval from the hospital Ethics Committee for Human Research and written informed consent, we studied 56 young, healthy adult patients, ASA I and II, undergoing elective lower limb surgery. None had clinical or routine biochemical evidence of hepatic or renal damage. All were devoid of neuromuscular disease and drugs that are known to interfere with neuromuscular transmission.

Patients received lormetazepam 0.2 mg kg^{-1} orally, 1 h before anaesthesia, which was induced with thiopentone 3–5 mg kg^{-1} i.v. After loss of consciousness, ventilation was controlled manually (with 50% nitrous oxide in oxygen). The trachea was intubated after i.v. administration of one of the four neuromuscular blockers. Thereafter, ventilation was controlled mechanically (open circuit, 65% nitrous oxide in oxygen) and adjusted to produce an end-tidal carbon dioxide partial pressure of 4.4 (0.3) kPa. For maintenance of anaesthesia, patients received fentanyl 5 μg

kg^{-1} and dehydrobenzperidol 100 μg kg^{-1} i.v., followed by bolus doses of fentanyl 2 μg kg^{-1} if there was clinical evidence of inadequate analgesia. Heat loss from the body surface and the arms was controlled by the use of a water warming mattress (autoregulation on 37 °C rectal temperature) and surgical sheets (monitored hypothenar temperature greater than 35 °C).

To measure isometric contraction of the adductor pollicis, a force displacement transducer (UC3 cell Statham TM), fitted with tension attenuator (ULE-20, Statham TM) and incorporated in a hand grip, was preloaded to 100 *g* and secured with adhesive tape onto the patient's left hand. Mechanical activity of the adductor pollicis was induced by square wave pulses of 0.2 ms duration at supramaximal intensity, delivered at 0.1 Hz from an Organon Teknika Digit-Stim III TM stimulator, via two paediatric surface electrodes placed near the ulnar nerve at the wrist. The resulting analogue signals were amplified and recorded. Skin thenar temperature was measured with a surface electrothermometer (YSI 409B TM).

The 56 patients were allocated randomly to one of four groups of 14 patients each to receive rocuronium (group Roc), vecuronium (group Vec), atracurium (group Atr) or pancuronium (group Pan). After a 5-min recording of control twitch height, 100 Hz, 5-s duration was assessed and control RF 100 Hz was measured during thiopentone–fentanyl–nitrous oxide in oxygen anaesthesia, but in the absence of neuromuscular blocker. When twitch height had regained its control value, rocuronium 600 μg kg^{-1}, vecuronium 100 μg kg^{-1}, atracurium 500 μg kg^{-1} or pancuronium 80 μg kg^{-1} was given i.v. Thereafter, to achieve a neuromuscular block of about 1 h, when twitch height had spontaneously regained 25% of control, patients received two additional doses of rocuronium 120 μg kg^{-1} (group Roc), vecuronium 20 μg kg^{-1} (group Vec), atracurium 100 μg kg^{-1} (group Atr), while in group Pan, patients received only an initial dose of pancuronium 80 μg kg^{-1}.

The 56 randomized patients received atropine 15 μg kg^{-1} mixed with neostigmine 40 μg kg^{-1} at the end of the surgical procedure, exactly when twitch height had spontaneously regained 25% of control. Thereafter, twitch height (every 10 s) and TOF ratio (2 Hz, every 3 min) were measured for 15 min in the four groups. Immediately after the TOF ratio at 15 min, 100 Hz tetanic stimulation, 5-s duration, was assessed. Residual force after 100 Hz tetanic stimulation (RF 100 Hz) was calculated as the ratio between tension at the end of the 5-s stimulation period and maximum response registered. Statistical analysis of the data was performed using one-way analysis of variance[14]. In case of significant differences observed by ANOVA, Duncan's multiple classification range tests were performed to indicate the best recovery scores.

Table 1 Patients characteristics (mean (SEM) [range]). Clinical duration of block = time elapsed from maximum block achieved after the initial dose of neuromuscular blocker to administration of neostigmine

Group	Age (yr)	Weight (kg)	Height (cm)	Clinical duration of block (min)
Roc	38 [20–56]	75 (3)	176 (2)	68 (5) [43–86]
Vec	39 [18–58]	70 (3)	170 (2)	67 (6) [42–96]
Atr	35 [18–57]	76 (4)	174 (2)	70 (6) [44–100]
Pan	37 [27–47]	73 (3)	174 (3)	68 (5) [45–130]

Results

There were no significant differences between patients in the four groups in terms of their characteristics (table 1). Mean age of all patients was 37 (range 18–58) yr, mean weight 73 (SEM 2) (53–108) kg and mean height 174 (1) (154–194) cm (n=56) (table 1). Mean clinical duration of neuromuscular block (time elapsed from maximum block achieved after the initial dose of neuromuscular blocker to administration of neostigmine) was 69 (SEM 3) min for all patients (n=56), and 68 (5) (range 43–86) min, 67 (6) (42–96) min, 70 (6) (44–100) min and 68 (6) (45–130) min in patients in groups Roc, Vec, Atr and Pan, respectively (table 1). Control RF 100 Hz during thiopentone–nitrous oxide in oxygen anaesthesia under normothermal conditions (cutaneous hypothenar temperature greater than 35 °C), but in the absence of neuromuscular blockers, was 0.9 (0.003) (0.85–0.95) (n=56).

At the time of antagonism, when twitch height had regained 25% of its control value, mean TOF ratio was 0.07 (0.003) for all patients (range 0.02–0.14) and there were no significant differences between the four groups (fig. 1). Evolution of the TOF ratios were similar in patients who received rocuronium 840 μg kg^{-1}, vecuronium 140 μg kg^{-1} and atracurium 700 μg kg^{-1}, except that the TOF ratio was significantly higher (0.68 (0.03); $P<0.05$) 3 min after neostigmine 40 μg kg^{-1} in patients who received vecuronium compared with those who received rocuronium (0.57 (0.03)) and atracurium (0.56 (0.03)). Fifteen minutes after administration of neostigmine, TOF ratios were 0.91 (0.01) (range 0.81–0.95), 0.88 (0.02) (0.71–0.99) and 0.92 (0.01) (0.87–0.95) in groups Roc, Vec and Atr, respectively (fig. 1). In con-

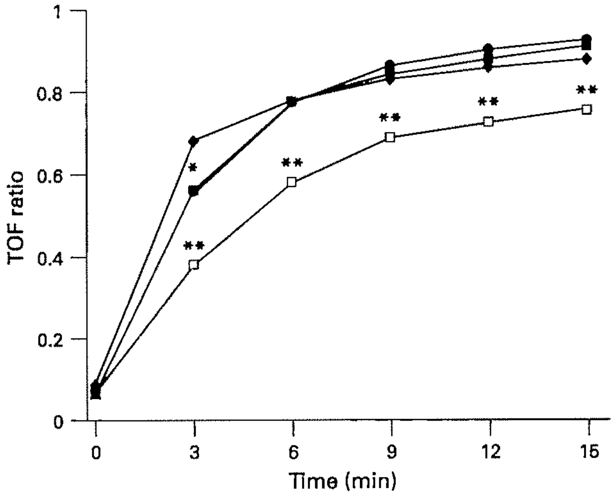

Figure 1 Evolution of the train-of-four (TOF) ratio (mean) recorded at 3-min intervals after administration of neostigmine 40 μg kg^{-1} when twitch height had returned to 25% of its initial value in groups Roc (■), Vec (♦), Atr (●) and Pan (□). *$P<0.05$, one-way analysis of variance and Duncan multiple classification range tests (group Vec *vs* groups Roc and Atr). **$P<0.01$, one-way analysis of variance and Duncan multiple classification range tests (group Pan *vs* groups Vec, Roc, Atr).

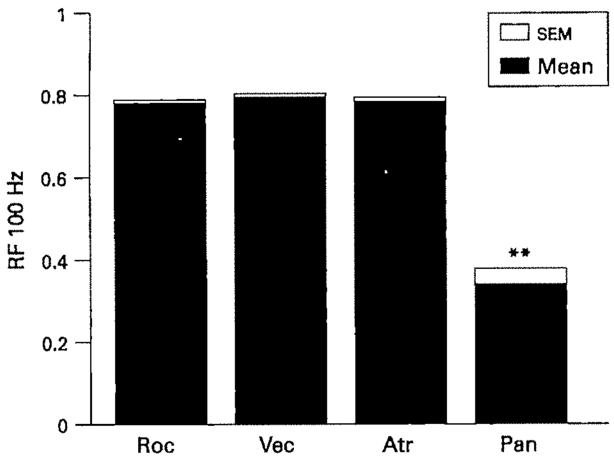

Figure 2 Values for residual force (RF) after 100 Hz tetanic stimulation (RF 100 Hz) recorded 15 min after administration of neostigmine 40 μg kg^{-1} when twitch height had regained 25% of its initial value (mean, SEM). **$P<0.01$, one-way analysis of variance, Duncan multiple classification range tests (group Pan *vs* groups Roc, Vec and Atr).

trast, during the 15-min period after administration of atropine–neostigmine, TOF ratios were always lower ($P<0.01$) in patients who received pancuronium 80 μg kg^{-1} (fig. 1). At 15 min, the TOF ratio was 0.76 (0.01) (0.67–0.86) (fig.1). Fifteen minutes after administration of neostigmine, mean values for RF 100 Hz were similar in groups Roc, Vec and Atr: 0.78 (0.01) (0.71–0.85), 0.79 (0.02) (0.60–0.95) and 0.78 (0.01) (0.65–0.85), respectively. These values were much higher ($P<0.01$) than the RF 100 Hz of 0.33 (0.04) (0.09–0.65) measured in group Pan (fig. 2).

Discussion

Our results have confirmed previous data indicating that rocuronium, in common with vecuronium and atracurium, can be antagonized easily to an end-point of a TOF ratio of 0.7 when neostigmine 40 μg kg^{-1} is given at 25% recovery of control twitch height[9-12]. But the "gold standard" of these authors (a TOF ratio of 0.7) does not imply complete recovery of neuromuscular transmission. Moreover, Eriksson and colleagues showed recently that the ventilatory response to hypoxaemia was depressed if the TOF ratio was reduced to 0.7 by vecuronium in awake volunteers, and that it returned to normal when the TOF ratio was 0.9[12]. These results suggest that a TOF ratio of 0.9 may be considered as a new end-point for defining adequate recovery of neuromuscular transmission. In patients who received rocuronium, our data indicated that such a high (0.9) TOF ratio may be observed 15 min after administration of neostigmine 40 μg kg^{-1} when twitch height has regained 25% of its initial value, in common with patients who received vecuronium and atracurium. In contrast, under the same conditions, a TOF ratio of only approximately 0.75 was observed in patients who received pancuronium.

RF 100 Hz mean values ranged from 0.8 to 0.9, associated with a TOF ratio of 0.9, and were also observed previously to antagonize vecuronium-induced block, 15 min after administration of neostigmine 40 μg kg^{-1} at 25–50% twitch height[8 9 11 12]. Mean values in patients who received rocuronium were as high (about 0.8) as in patients who received vecuronium and atracurium. In contrast with patients who received neuromuscular blockers of intermediate duration of action, the mean value for RF 100 Hz in patients in group Pan was only approximately 0.3, confirming the previously reported very high sensitivity of measured RF 100 Hz[8-12]. The use of RF 100 Hz is important also because a small, but statistically significant and clinically important 0.15 TOF ratio difference is amplified by a factor of 3–4 for the compound investigated in this study. Moreover, our data were obtained in the absence of halogenated agents, which are known to potentiate neuromuscular blockers and impair antagonism of non-depolarizing neuromuscular blockers by anticholinesterases[15-19] by various mechanisms[20 21]. In the past, the response to 100 Hz tetanic stimulation was also observed by Kopman, Epstein and Flashburg in halothane anaesthetized patients[22]. Pancuronium-induced block was antagonized when the TOF ratio was in excess of 0.1 with 5-mg increments of edrophonium until the TOF ratio exceeded 0.7. At a mean TOF ratio of 0.79, the mean value of the response to 100 Hz, 2 s tetanic stimulation, was very weak (0.28), indicating incomplete recovery of neuromuscular transmission when poor reversal conditions co-exist (long-acting neuromuscular blockers and sustained concentrations of halogenated agents).

When recovery of neuromuscular transmission was assessed by measuring the TOF ratio, neostigmine 36–50 μg kg^{-1}, given at 10% twitch height, produced a mean TOF ratio of approximately 0.7–0.8 after a 20–30-min period in fentanyl–nitrous oxide in oxygen anaesthetized patients and a TOF ratio of approximately 0.6 in enflurane–or halothene–nitrous oxide in oxygen anaesthetized patients[15 23]. In contrast, in a previous study in humans, vecuronium and pancuronium were considered to be antagonized effectively and equally by neostigmine because the duration of the effect of neostigmine on twitch height recovery was not different[24]. However, when assessing recovery of neuromuscular transmission, monitoring twitch height appears to be an insensitive test. Twitch height has little or no discriminating ability for the influence of pre-reversal twitch heights or edrophonium and neostigmine dose, or both, mainly because apparent antagonism by these measures is so complete[10 11]. Whalley, Lewis and Bedocs showed also that equipotent doses of atracurium, compared with pancuronium, were not associated with a shorter time to complete recovery from neuromuscular block induced by pancuronium[25]. In this study, all patients received an initial dose of pancuronium 0.1 mg kg^{-1}; no patient received only atracurium and complete recovery was defined by a TOF ratio of 0.7.

In patients receiving short-acting neuromuscular blockers such as mivacurium, neostigmine, given under the same clinical conditions, also accelerated recovery of the TOF ratio to 0.9. However, unlike the patients in this study who received medium-acting neuromuscular blockers, all patients obtained a TOF ratio of 0.9 within 15 min of administration of neostigmine, compared with 50% of patients during spontaneous recovery of mivacurium-induced block[26]. The use of short-acting neuromuscular blockers such as mivacurium should probably make adequate or even complete antagonism an easier problem to solve in many patients.

Chronic carbamazepine therapy does not influence mivacurium-induced neuromuscular block

A. SPACEK, F. X. NEIGER, C. K. SPISS AND H. G. KRESS

Summary

Patients receiving anticonvulsant drugs chronically are relatively resistant to some non-depolarizing neuromuscular blocking drugs. We investigated the influence of chronic carbamazepine therapy on neuromuscular block induced by mivacurium in 20 otherwise healthy individuals undergoing neurosurgical operations, 10 of whom were receiving chronic treatment with carbamazepine and the other 10 served as controls. The median duration of carbamazepine therapy was 22 weeks (range 4–182 weeks). After premedication with oral diazepam, anaesthesia was induced with fentanyl and thiopentone and maintained with 0.5% isoflurane and nitrous oxide in oxygen. The ulnar nerve was stimulated and the evoked electromyogram recorded using a Datex NMT monitor. Mivacurium 0.15 mg kg^{-1} ($2\times ED_{95}$) was given as a bolus i.v. Based on the response to the first of four stimuli, lag time, onset-time, times to recovery to 10%, 25%, 50% and 75% of baseline responses and recovery index (RI 25–75%) did not differ between the two groups. We conclude that mivacurium-induced neuromuscular block was not influenced by preceding chronic carbamazepine therapy. (*Br. J. Anaesth.* 1996;**77**:500–502)

Key words

Anticonvulsants. Neuromuscular block, mivacurium. Neuromuscular block, measurement of response.

Patients receiving chronic carbamazepine therapy show a relative resistance to the neuromuscular effects of vecuronium[1 2], pancuronium[3], doxacurium[4] and pipecuronium[5]. Resistance to vecuronium was manifested as an increased ED_{50}[1]. For the other neuromuscular blockers and also vecuronium, resistance was documented either by increased hourly requirements for maintenance of a constant neuromuscular block or by a shorter duration of action[2–5]. Recovery time was decreased by 65% after an i.v. bolus dose ($2\times ED_{95}$) of pancuronium[3].

Mivacurium chloride is a new short-acting non-depolarizing neuromuscular blocking agent. Enzymatic hydrolysis catalysed by plasma cholinesterase is the primary metabolic pathway and distinguishes mivacurium from all other non-depolarizing neuromuscular blockers[6 7]. The distinct degradation pathway of mivacurium stimulated us to investigate the interaction between carbamazepine and mivacurium in neurosurgical patients. A report on a similar topic appeared recently after we had concluded our experiments[8].

Patients and methods

After obtaining approval from the Institutional Ethics Committee at the University Hospital of Vienna and written informed consent, we studied 20 patients, ASA I–III, undergoing various neurosurgical procedures. All patients were free of cardiac, renal, pulmonary, hepatic and neuromuscular diseases. Individuals receiving medications thought to potentially affect neuromuscular transmission were excluded, as were those undergoing deliberate hypotension during operation. Patients with psychiatric diseases, those with a recent history of alcohol or drug abuse, and those with known or suspected reduced activity of plasma cholinesterase or with an atypical form of the enzyme were also excluded. Plasma cholinesterase was measured and found to be within the normal range in all subjects. No further characterization of the enzyme was performed. Ten patients (group I) were receiving continuous carbamazepine therapy for seizure disorders for at least 4 weeks. Plasma concentrations of carbamazepine, measured by radioimmunoassay, were determined before surgery and were within the therapeutic range (15–40 μmol $litre^{-1}$). Control patients (group II) received no anticonvulsants.

All patients were premedicated with oral diazepam 10 mg, 1 h before surgery. Anaesthesia was induced with fentanyl 3–4 μg kg^{-1} and thiopentone 4–6 mg kg^{-1}, and maintained with 0.5% inspired isoflurane and 70% nitrous oxide in oxygen, and supplementary doses of fentanyl. After tracheal intubation, the lungs were ventilated mechanically to maintain end-tidal carbon dioxide partial pressure at 4.0–4.4 kPa. Oesophageal temperature was maintained greater than 36 °C with convective heating (Bair Hugger). Routine patient monitoring included continuous ECG, invasive arterial pressure, pulse oximetry, end-tidal capnography and oesophageal temperature probe.

Neuromuscular transmission was monitored with the Datex Neuromuscular Transmission Monitor

ANNA SPACEK, MD, HANS G. KRESS, MD, Department of Anaesthesia and General Intensive Care B, University of Vienna, Währinger Gürtel 18-20, A-1090 Vienna, Austria. FRANZ X. NEIGER, MD, CHRISTIAN K. SPISS, MD, Department of Anaesthesia and General Intensive Care A, University of Vienna, Austria. Accepted for publication: June 17, 1996.

NMT measuring the evoked electromyographic response (EMG) of the abductor digiti minimi muscle to supramaximal stimulation of the ulnar nerve at the wrist. The NMT delivered trains-of-four supramaximal square wave impulses (100 µs width) at 2 Hz. The trains were repeated every 20 s. The heights of the EMG responses to the first stimuli in the train (as percentage of baseline) were recorded by a printer connected to the monitor. To minimize movement-induced artefacts, the patient's hand was secured carefully to a padded board and the hand kept warm. The system was calibrated for each patient after induction of anaesthesia but before administration of mivacurium. The control EMG was recorded for a 3-min period and a stable baseline was obtained in each patient. Thereafter, a bolus dose of mivacurium 0.15 mg kg^{-1} (2×ED$_{95}$) was given i.v. The time required for the first response to decrease noticeably below the control level (lag time), time to disappearance of all responses (onset time), and times for T1 to recover to 10%, 25%, 50% and 75% of baseline were measured in all patients. Recovery index (RI) was calculated as the time required for the responses to the first stimuli to recover from 25% to 75% of baseline.

Comparisons were made between the carbamazepine and control groups using the two tailed Student's *t* test for independent samples and the nominal 5% level of statistical significance. In addition, a comprehensive exploratory statistical analysis of the data was performed. A sample size of 10 patients per treatment group can be justified by the subsequent rationale: setting the nominal alpha risk (two-sided) to 5% and defining the clinically relevant difference between the means of both groups as exceeding 1.3-fold of the standard deviation, yields a power of 80% with a sample size of 10 patients per treatment group.

Results

Patient data were similar in the control and carbamazepine groups (table 1). The shortest period of carbamazepine treatment was 4 weeks, the longest 182 weeks (median 22 weeks). Daily doses ranged from 300 to 1200 mg. Mean preoperative blood concentrations of carbamazepine were 27.4 (SD 9.9) µmol litre^{-1}.

The EMG response to mivacurium in both groups is shown in table 2. The EMG response to the first stimulation in the train was decreased by at least 95% in all patients. The times required for the response to recover to baseline were not significantly different between the control patients and those receiving chronic carbamazepine therapy.

Discussion

We have demonstrated that mivacurium-induced neuromuscular block was unaffected by chronic carbamazepine therapy. Although all measured variables of recovery were slightly shorter in the carbamazepine-treated group compared with the control group, the differences were not statistically significant. We conclude that chronic treatment with carbamazepine has no effect on neuromuscular block produced by mivacurium. Similar findings were reported recently for patients receiving chronic treatment with carbamazepine and other antiepileptic drugs[8]. In this respect mivacurium differs from vecuronium, pancuronium, doxacurium and pipecuronium[2-5], as the duration of action of these drugs was diminished by more than 40% in patients treated with carbamazepine.

Table 1 Patient data (mean (SD or range) or number). No significant differences between groups

	Carbamazepine (n=10)	Control (n=10)
Age (yr)	49.9 (19–70)	41.0 (18–68)
Weight (kg)	75.8 (13.3)	70.0 (11.0)
Sex (F/M)	4/6	5/5

Table 2 Lag time, onset, recovery times and recovery index (mean (SD) min) after a bolus dose of mivacurium 0.15 mg kg^{-1} (2×ED$_{95}$). No significant differences between groups

	Carbamazepine (n=10)	Control (n=10)
Lag time	0.7 (0.3)	0.8 (0.3)
Onset	3.6 (1.2)	3.9 (1.2)
10% recovery	12.7 (6.5)	13.0 (6.7)
25% recovery	16.2 (7.3)	16.9 (7.0)
50% recovery	19.5 (7.7)	21.6 (8.6)
75% recovery	24.9 (9.3)	26.3 (9.8)
Recovery index	8.7 (3.7)	9.3 (4.0)

The reasons why carbamazepine treatment reduces the potency and duration of action of some non-depolarizing neuromuscular blockers while not influencing others is still unclear. Both pharmacokinetic and pharmacodynamic explanations have been proposed. The pharmacodynamic explanation is based on the assumption that treatment with anticonvulsants decreases the affinity of the acetylcholine receptor for neuromuscular blockers or increases the number of receptors on muscle fibres[9-11]. This explanation could account for the increased ED$_{50}$ of vecuronium[1] and, at least in part, for the shorter duration of neuromuscular block. Our study was not designed to test the potency of mivacurium in patients receiving carbamazepine therapy and, hence, the possible effect of carbamazepine on the interaction of mivacurium with receptors remains open.

The pharmacokinetic explanation for the shortened duration of action of vecuronium in patients receiving carbamazepine therapy is supported strongly by the finding of Alloul and coworkers[12]. These authors reported that systemic clearance is markedly higher in treated than in control patients. The faster elimination of vecuronium could account for the shorter duration of action. As vecuronium concentrations at the site of action required for half-maximal neuromuscular block were similar in the control and treated patients (EC$_{50}$ of 151.1 (SEM 19.2) and 125.0 (11.2) ng ml^{-1}, respectively), the authors could not substantiate the hypothesis that treatment with carbamazepine lowers the affinity of the receptors for vecuronium. Increased systemic clearance of vecuronium induced by carbamazepine may be attributed to more rapid hepatic uptake and metabolism of vecuronium. As hepatic uptake and metabolism are irrelevant for mivacurium, neither its rate of degradation nor its duration of action would be expected to be altered by treatment with carbamazepine.

The action of atracurium was also reported not to be affected by chronic anticonvulsant therapy[13-15], although there is one contradictory report[16]. We suggest that the common denominator for the different findings with mivacurium and atracurium is that their distinct degradation pathway is not influenced by carbamazepine.

Although the pharmacokinetic explanation in terms of enhanced elimination of some but not other neuromuscular blockers by carbamazepine appears plausible, pharmacodynamic mechanisms may also be involved. To elucidate these mechanisms in more detail, further pharmacokinetic, pharmacodynamic and electrophysiological studies are needed. In clinical practice, however, mivacurium may be preferred in patients receiving chronic anticonvulsant therapy when a brief but predictable duration of neuromuscular block is required or neuromuscular monitoring is unavailable.

LABORATORY INVESTIGATIONS

Thiobarbiturates suppress depolarization-induced contraction of vascular smooth muscle without suppression of calcium influx

R. KITAMURA, M. KAKUYAMA, K. NAKAMURA, I. MIYAWAKI AND K. MORI

Summary

We have studied the effects of barbiturates on vascular smooth muscle tension and cytosolic calcium concentrations ([Ca^{2+}]$_i$) in endothelium-denuded rat aortic rings, preloaded with fluo-3. Changes in [Ca^{2+}]$_i$ were estimated by the fluorescence intensity of the calcium-bound form of fluo-3. In aortic rings under basal conditions, thiobarbiturates (thiopentone and thiamylal 100–300 µmol litre^{-1}) increased [Ca^{2+}]$_i$, concomitantly with an increase in tension, although oxybarbiturates (pentobarbitone and secobarbitone up to 300 µmol litre^{-1}) had no effect. Thiopentone (300 µmol litre^{1})-induced increases in tension and fluorescence intensity were mean 25.1 (SD 3.2) % and 55.0 (6.0) %, respectively, of those induced by KCl 30 mmol litre^{-1} (n=8, each). In KCl (30 mmol litre^{-1})-precontracted aortic rings, thiopentone decreased tension without reduction of [Ca^{2+}]$_i$, whereas pentobarbitone decreased tension and [Ca^{2+}]$_i$. KCl (30 mmol litre^{-1})-induced contraction was suppressed by pretreatment with all barbiturates (100–300 µmol litre^{-1}); thiopentone 300 µmol litre^{-1} suppressed contraction to 64.8 (2.5) % (n=6) and pentobarbitone 300 µmol litre^{-1} to 57.5 (2.2) % (n=9). However, the increase in [Ca^{2+}]$_i$ was suppressed by oxybarbiturates (pentobarbitone 300 µmol litre^{-1} to 77.9 (5.2) %; n=9), but not altered by thiobarbiturates. These results suggest that thiobarbiturates and oxybarbiturates affect vascular smooth muscle differently and that the affected site in thiobarbiturate-induced vasodilatation is distal to regulation of [Ca^{2+}]$_i$. (*Br. J. Anaesth.* 1996;**77**:503–507)

Key words

Muscle vascular, responses. Anaesthetics i.v., thiopentone. Anaesthetics i.v., thiamylal. Hypnotics barbiturate, pentobarbitone. Hypnotics barbiturate, secobarbitone. Ions, calcium.

Thiobarbiturates have been used for induction of general anaesthesia and also for brain protection in cerebral ischaemia. Although the reduction in arterial pressure after i.v. injection of thiobarbiturates may be caused mainly by suppression of sympathetic tone and cardiac contractility, barbiturates have been shown to exert direct effects on vascular smooth muscle of various origins[1–9]. Previous authors have suggested that the direct vascular effect of pentobarbitone is a result of its Ca^{2+} channel blocking action[10]. Except for our previous reports[11–13], however, there have been no investigations of the mechanism of thiobarbiturate-induced vasodilatation. In this study, we used a fluorescent indicator of cytosolic calcium concentration ([Ca^{2+}]$_i$) to determine the effect of barbiturates on [Ca^{2+}]$_i$ under basal conditions and on depolarization-induced calcium influx. We demonstrated different effects of oxybarbiturates and thiobarbiturates on [Ca^{2+}]$_i$ and calcium-contraction coupling in vascular smooth muscle.

Materials and methods

The study was approved by the Kyoto University Animal Use Committee. We studied 20 male Wistar rats (250–350 g) anaesthetized with pentobarbitone 50 mg kg^{-1} i.p. and killed by exsanguination from the common carotid arteries. The descending part of the thoracic aorta was isolated from each rat and dissected into 8–10 rings (2-mm wide). The rings were rinsed and bathed in Krebs' bicarbonate solution at 25 °C for more than 20 min until used. The rings were then bathed in Krebs' bicarbonate solution containing fluo 3-AM 10 µmol litre^{-1} [14] and 0.02% vol/vol Cremophor EL for 0.5–1 h at 25 °C. Cremophor EL is a non-cytotoxic detergent which was added to increase the solubility of fluo 3-AM[15]. After rinsing, the endothelium was removed from the luminal surface by rubbing with cotton sticks in order to exclude the influence of endothelial [Ca^{2+}]$_i$ on fluorescence intensity. The vascular rings were then mounted under a resting tension of 1 g weight, in Krebs' bicarbonate solution, maintained at 37 °C, and aerated with a mixture of 5% carbon dioxide in oxygen. They were then contracted with phenylephrine 0.1 µmol litre^{-1} and exposed to acetylcholine 10 µmol litre^{-1} which induced less than 10% of the phenylephrine-induced precontraction in all rings used[16].

Isometric tension and fluorescence intensity were recorded continuously using an Amplifier Case 7903 force-displacement transducer (San-ei, Tokyo, Japan) and a CAF-110 fluorometer (Japan Spectroscopic, Tokyo, Japan)[17]. The arterial rings were illuminated with a 75-W xenon lamp at an excitation wavelength of 490 nm, and the emitted fluorescence at 540 nm was considered to be an indicator of

Correspondence to R. K.

$[Ca^{2+}]_i$[14]. In our preliminary study, thiopentone 300 μmol litre^{-1} decreased the transmittance of light at wavelengths of 340 nm and 380 nm to 91.8% and 94.0%, respectively, and thiamylal to 86.5% and 96.3%. However, transmittance of 490 nm light was not significantly altered by the barbiturates tested (up to 1 mmol litre^{-1}).

In the relaxation study, vascular rings were precontracted with KCl 30 mmol litre^{-1}. When the tension and fluorescence intensity had stabilized after KCl exposure, the rings were exposed to cumulative concentrations of thiopentone or pentobarbitone (30–300 μmol litre^{-1}). The time-control was run in an identical manner but without exposure to barbiturates. The stabilized tension and fluorescence intensity after exposure to each barbiturate concentration were expressed as percentages, taking the levels before exposure to KCl as 0% and those after exposure and just before the start of barbiturate exposure as 100%.

In the contraction study, all rings were first exposed to KCl 30 mmol litre^{-1} for 5 min and then washed out. The change induced by this first exposure to KCl was taken as 100%, and the changes in tension and fluorescence intensity in the following study were expressed as values relative to this. The rings were then exposed to one of the barbiturates for 10 min or, after 5 min of pretreatment with a barbiturate, exposed to KCl 30 mmol litre^{-1} again for another 5 min. The barbiturates used were thiopentone, thiamylal, pentobarbitone and secobarbitone (30–300 μmol litre^{-1}). After washout, the rings were exposed to KCl 30 mmol litre^{-1} as a post-barbiturate control. The time-control was run in an identical manner but without barbiturates.

Krebs' bicarbonate solution contained (mmol litre^{-1}): NaCl 127.5, $NaHCO_3$ 15.5, glucose 10.0, KCl 4.6, KH_2PO_4 1.2, $MgSO_4$ 1.2 and $CaCl_2$ 2.5. Drugs used were fluo 3-AM (Dojindo Laboratories, Kumamoto, Japan), Cremophor EL (Sigma, St Louis, MO, USA), L-phenylephrine hydrochloride (Sigma), acetylcholine (Daiichi Pharmaceutical Co., Tokyo, Japan), sodium thiopentone (Tanabe Pharmaceutical, Osaka, Japan), sodium thiamylal (Kyorin Pharmaceutical, Tokyo, Japan), sodium secobarbitone (Yoshitomi Pharmaceutical, Osaka, Japan) and sodium pentobarbitone (Nacalai Tesque, Kyoto, Japan). Data in the relaxation study were analysed by Student's *t* test for unpaired data. All other data were analysed using analysis of variance and Scheffe's test. Differences were considered significant at $P<0.05$.

In the relaxation study, vascular rings were exposed to KCl 30 mmol litre^{-1} twice, and cumulative concentrations of thiopentone or pentobarbitone. The order of the experiments for the two barbiturates was randomized. In the contraction study, after the first exposure to KCl and washout, the rings were exposed to one of the barbiturates for 10 min, or exposed to KCl again for another 5 min after 5 min of pretreatment with a barbiturate. The time-controls were run in an identical manner, but without barbiturates.

Results

KCl-precontracted aortic rings were relaxed by thiopentone and pentobarbitone 100–300 μmol litre^{-1} in a concentration-dependent manner ($P<0.05$–0.01) (figs 1, 2). $[Ca^{2+}]_i$, as measured by fluorescence intensity, was decreased by pentobarbitone 300 μmol litre^{-1} ($P<0.05$), but not by thiopentone (figs 1, 2). Mean thiopentone- and pentobarbitone 300 μmol litre^{-1}-induced reductions in tension were 59.4 (SD 2.8) % and 40.7 (4.4) %, respectively, and pentobarbitone 300 μmol litre^{-1}-induced reduction in $[Ca^{2+}]_i$ was −31.2 (17.0) % (n=4, each).

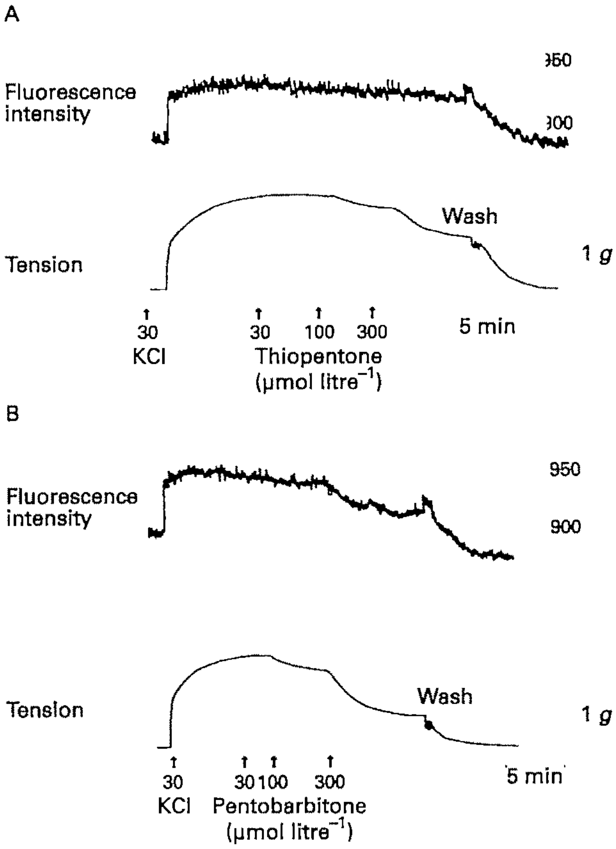

Figure 1 Representative recordings of fluorescence intensity (as an indicator of $[Ca^{2+}]_i$) and tension in rat aortic rings, which had been precontracted with KCl 30 mmol litre^{-1} and then exposed to thiopentone (A) or pentobarbitone (B) in cumulative concentrations (30–300 μmol litre^{-1}).

The tension and fluorescence intensity of aortic rings under basal conditions were increased by 10 min exposure to thiopentone and thiamylal 100–300 μmol litre^{-1} (figs 3, 4), but not to pentobarbitone or secobarbitone (up to 300 μmol litre^{-1}). The increase in tension and fluorescience intensity induced by thiopentone 300 μmol litre^{-1} was 25.1 (3.2) % and 55.0 (6.0) % of KCl 30 mmol litre^{-1}-induced changes, respectively, and those for thiamylal 300 μmol litre^{-1} were 29.1 (8.9) % and 48.5 (5.5) %, respectively.

Although the addition of KCl 30 mmol litre^{-1} to barbiturate-treated rings increased their tension and fluorescence intensity, the total increase in tension induced by KCl and barbiturates was less than in the barbiturate-untreated controls ($P<0.05$–0.01) (fig. 4). The changes in tension in the presence of thiopentone, thiamylal, pentobarbitone and secobarbitone 300 μmol litre^{-1} were 64.8 (2.5) % (n=6), 70.8 (4.2) % (n=6), 57.5 (2.2) % (n=9) and 36.6 (3.4) % (n=6), respectively.

KCl-induced increase in fluorescence intensity was decreased by pentobarbitone and secobarbitone 300 μmol litre^{-1} to 77.9 (5.2) % (n=9) and 67.3 (8.7) % (n=6), respectively ($P<0.05$). In contrast, the total

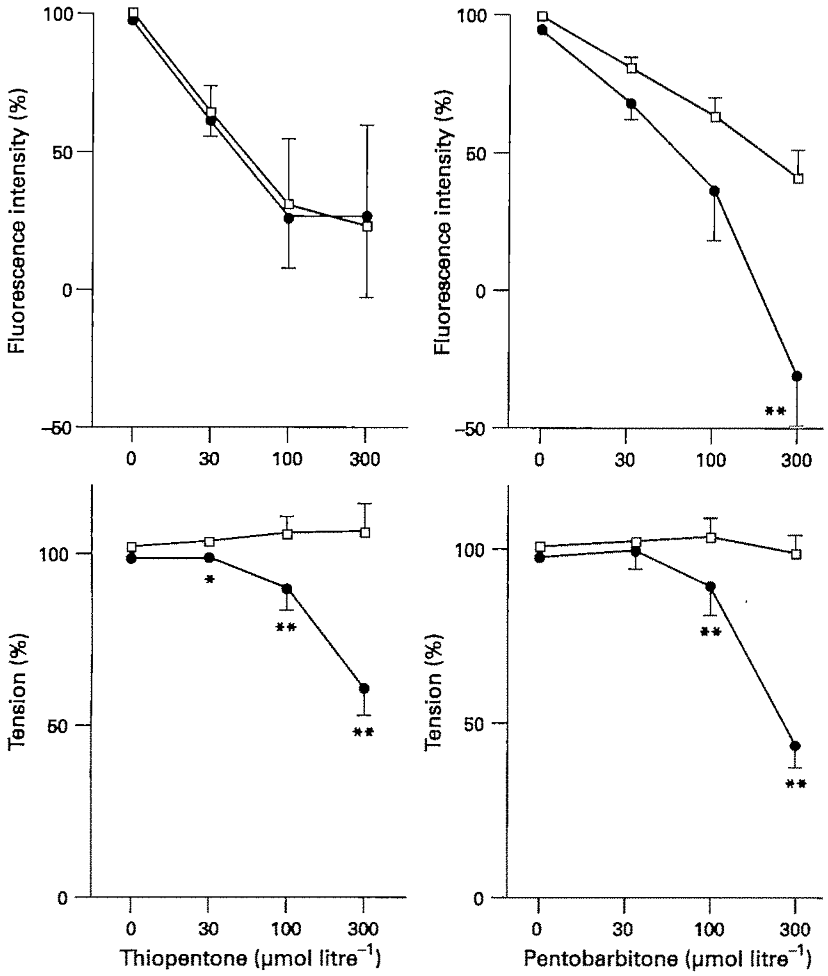

Figure 2 Changes in fluorescence intensity and tension of aortic rings precontracted with KCl 30 mmol litre^{-1}. □=Without barbiturates; ●=exposed to thiopentone or pentobarbitone at cumulative concentrations (30–300 µmol litre^{-1}). Levels before exposure to KCl 30 mmol litre^{-1} were taken as 0% and those just before exposure to barbiturates as 100%. n=4, each. *P<0.05, **P<0.01 compared with untreated control.

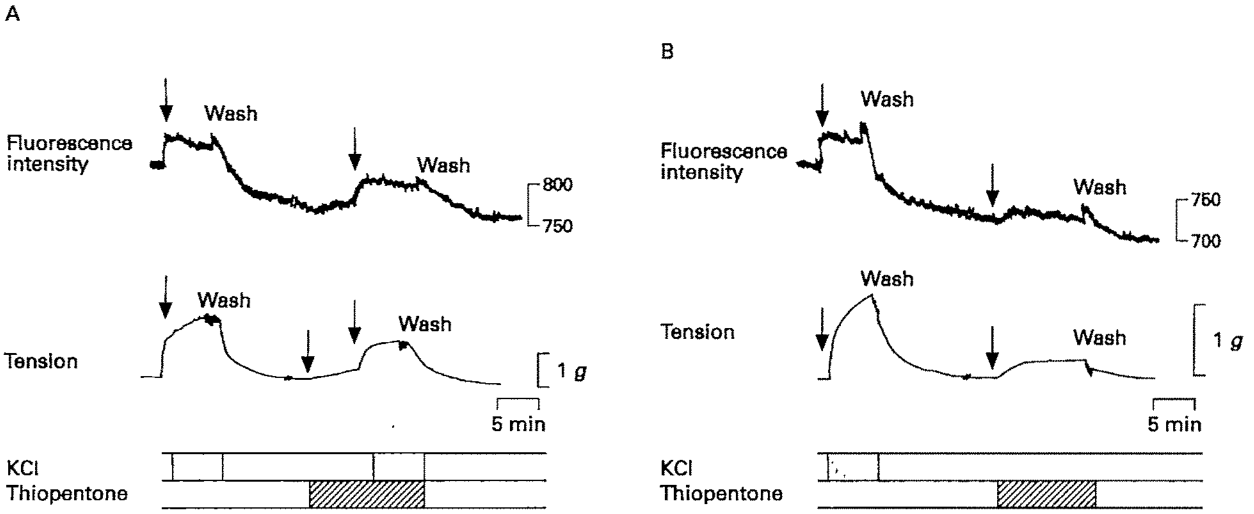

Figure 3 Representative recordings of fluorescence intensity and tension of aortic rings exposed twice to KCl 30 mmol litre^{-1} in the absence (first exposure) and presence of thiopentone 100 µmol litre^{-1} (second exposure) (A). Recordings of rings exposed to thiopentone but not to KCl are also shown (B).

increase in fluorescence intensity in rings treated with up to 300 µmol litre^{-1} of thiopentone or thiamylal was not significantly different from controls. Changes in tension and fluorescence intensity induced by the post-barbiturate and KCl-exposure were not significantly different from the pre-barbiturate control values (data not shown), indicating that the effects of the barbiturates were reversible.

Discussion

One might criticize the fact that we used pentobarbitone anaesthesia before exsanguination of rats, arguing that pentobarbitone injected i.p. would have affected the result. However, our *in vitro* results suggested that this was unlikely, because the vascular effects of barbiturates at up to 300 µmol litre^{-1} added to the bathing solution were abolished completely

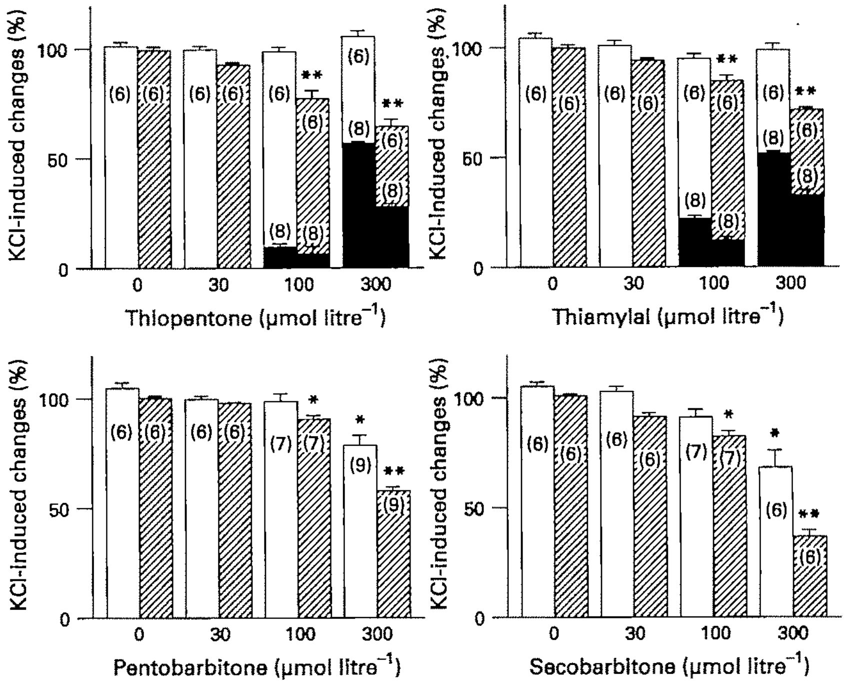

Figure 4 Changes in fluorescence intensity (open bars) and tension (hatched bars) induced by KCl 30 mmol litre^{-1} and barbiturates 30–300 μmol litre^{-1}. Solid bars=changes induced by barbiturates alone. Changes induced by the first KCl-exposure in the absence of barbiturates (pre-barbiturate controls) were taken as 100%. Values in parentheses indicate the number of rings studied. *$P<0.05$, **$P<0.01$ compared with values without barbiturates (time-controls).

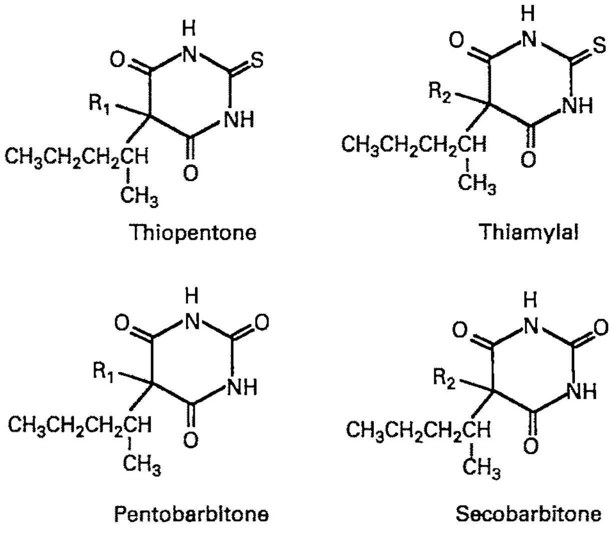
after washout and the anaesthetic concentration of pentobarbitone was less than 300 μmol litre^{-1}. Also, in preliminary studies we used rats anaesthetized with both ketamine and pentobarbitone and the results obtained were similar.

Our previous studies demonstrated that thiobarbiturates, but not oxybarbiturates, exerted vasoconstrictive effects on rat aortae and canine peripheral arteries under basal conditions[7–9]. This study confirmed these findings and further demonstrated that the thiobarbiturate-induced contractions in aortic rings under basal conditions were associated with increased $[Ca^{2+}]_i$.

In contrast, in KCl-precontracted aortic rings, the thiopentone-induced decrease in tension was not associated with a reduction in $[Ca^{2+}]_i$. Moreover, although the KCl-induced contraction was smaller in thiobarbiturate-treated than in untreated rings, the KCl-induced increase in $[Ca^{2+}]_i$ did not differ between the two treatments.

Previous studies by Sanchez-Ferrer and colleagues[6] and ourselves[11–13] have shown that thiobarbiturates suppressed contractions induced by an influx of extracellular Ca^{2+} and also those caused by the release of Ca^{2+} from intracellular stores in vascular smooth muscle, including those mediated by inositol triphosphate (IP3) and calcium-induced calcium release (CICR). These results suggest two possibilities; either thiobarbiturates suppress Ca^{2+} mobilization by non-specific means or they affect some site distal to the regulation of $[Ca^{2+}]_i$. The former possibility was clearly not supported by the present finding that thiobarbiturates, at concentrations of up to 300 μmol litre^{-1}, did not decrease $[Ca^{2+}]_i$ in the presence of high K. Furthermore, the latter possibility was supported by previous reports showing that thiobarbiturates suppressed Ca^{2+}-induced contractions of chemically skinned muscle fibres from canine mesenteric artery[11 12].



Thiopentone

Thiamylal

Pentobarbitone

Secobarbitone

Figure 5 Chemical structures of thiopentone, thiamylal, pentobarbitone and secobarbitone. R1= $-CH_2CH_3$; R2=- $CH_2CH{=}CH_2$.

In contrast with the thiobarbiturates, relaxation induced by pentobarbitone was accompanied by a decrease in $[Ca^{2+}]_i$. In oxybarbiturate-pretreated rings, KCl-induced changes in $[Ca^{2+}]_i$ were smaller than in control rings. These findings concur with those of previous authors[10] and ourselves using these compounds[12 13]. Therefore we speculate that oxybarbiturates suppress depolarization-induced calcium influx, although the possibility that they also affect some site distal to calcium mobilization cannot be excluded.

Except for substitution of an oxygen atom for sulphur on the second carbon atom, thiopentone has the same chemical structure as pentobarbitone, and thiamylal the same as secobarbitone (fig. 5). Thus we postulate that thiobarbiturates and oxybarbiturates, at concentrations of up to 300 μmol litre^{-1}, have different effects on smooth muscle from rat aorta; only thiobarbiturates increased $[\mathrm{Ca}^{2+}]_i$ to constrict rat aorta under basal conditions, whereas only oxybarbiturates decreased $[\mathrm{Ca}^{2+}]_i$ in KCl-contracted rat aorta. In addition to their effects on $[\mathrm{Ca}^{2+}]_i$, thiobarbiturates seemed to affect some site distal to the regulation of $[\mathrm{Ca}^{2+}]_i$, such as calmodulin, the phosphorylation or dephosphorylation process of myosin light chain (MLC), or the contractile machinery itself.

The peak plasma concentration of thiobarbiturates after induction of anaesthesia is 100–300 μmol litre^{-1}, and as more than 85% is bound to plasma proteins, the concentration of the unbound form is less than 50 μmol litre^{-1} [18,19]. Therefore, the effective concentrations of thiobarbiturates in this study were not much higher than those that are found clinically.

In summary, we found that thiobarbiturates relaxed vascular smooth muscle isolated from rat aorta independently of $[\mathrm{Ca}^{2+}]_i$, while oxybarbiturates reduced both tension and $[\mathrm{Ca}^{2+}]_i$. In regulating vascular smooth muscle tone, thiobarbiturates seemed to affect sites distal to the regulation of $[\mathrm{Ca}^{2+}]_i$.

Comparative actions of propofol and thiopentone on cell membranes of isolated guineapig ventricular myocytes

F. SAKAI, M. HIRAOKA AND K. AMAHA

Summary

We have examined the effects of propofol and thiopentone on membrane potentials and currents of isolated guineapig ventricular myocytes using the whole-cell patch-clamp technique. After current clamping, propofol at concentrations greater than 0.5 μmol litre^{-1} shortened the plateau and action potential duration (APD) ($P<0.05$). Thiopentone 10 μmol litre^{-1} prolonged APD ($P<0.05$), whereas concentrations of 50 μmol litre^{-1} or higher decreased plateau height ($P<0.05$) and resting membrane potential (RMP) ($P<0.05$) with abbreviation of the prolonged APD. With voltage clamping, propofol 1 μmol litre^{-1} decreased the L-type Ca^{2+} current ($I_{Ca.L}$) to 88.4% of control ($P<0.01$) without affecting the delayed rectifier K$^+$ current (I_K) and propofol 10 μmol litre^{-1} decreased $I_{Ca.L}$ and I_K to 75.0% ($P<0.01$) and 78.4% ($P<0.01$), respectively, with no effect on the inward rectifier K$^+$ current (I_{K1}). Thiopentone 10 μmol litre^{-1} decreased $I_{Ca.L}$ to 88.5% ($P<0.01$) and I_K to 78.3% ($P<0.05$), while thiopentone 100 μmol litre^{-1} depressed $I_{Ca.L}$ to 82.8% ($P<0.01$), I_K to 27.0% ($P<0.01$) and I_{K1} to 67.3% ($P<0.05$). These results indicated that propofol, at concentrations greater than those that are clinically relevant, shortened APD mainly by suppression of $I_{Ca.L}$, and the biphasic effects on APD by thiopentone were caused by depression of I_K, and concomitant suppression of $I_{Ca.L}$ and I_{K1} at higher concentrations. The distinct cardiodepressant effects of propofol and thiopentone may be, at least in part, attributed to different actions on membrane Ca^{2+} and K$^+$ currents. (*Br. J. Anaesth.* 1996;**77**:508–516)

Key words

Anaesthetics i.v., propofol. Anaesthetics i.v., thiopentone. Heart, myocytes. Ions, calcium. Ions, potassium. Ions, ion channels. Heart, isolated preparation. Guineapig.

Propofol is a useful anaesthetic as an induction and maintenance hypnotic agent because of its rapid onset, short duration of action and rapid elimination[1]; its disadvantages include depression of systemic arterial pressure or heart rate, or both[2]. Several studies have demonstrated that propofol directly suppresses myocardial contractility evaluated by tension development in multicellular preparations[3-6]. Thiopentone also has been known to depress cardiac contractility[4,6-9] and to have both arrhythmogenic and antiarrhythmic actions[10].

It remains controversial as to which is the more potent negative inotropic and pro- or antiarrhythmic drug, because previous studies *in vitro* have focused mainly on trans-sarcolemmal Ca^{2+} influx and sarcoplasmic reticulum function[3,5,9,11]. In single ventricular myocytes, propofol at relatively high concentrations has been shown to shorten action potential duration (APD)[5] and suppress delayed rectifier K$^+$ currents (I_K)[12] and L-type calcium currents ($I_{Ca.L}$)[5,13] without affecting the inward rectifier K$^+$ current (I_{K1})[12]. In contrast, thiopentone has been shown to induce prolongation of APD in multicellular preparations[4,6,8,14], and to suppress $I_{Ca.L}$[15], I_K and I_{K1}[16] in single myocytes, suggesting that propofol and thiopentone have different actions on membrane currents.

Because I_{K1} and I_K together with $I_{Ca.L}$ regulate APD by determining repolarization of action potentials, modification of any one of these currents could alter contractile function and refractory period. Knowledge of the precise actions of propofol and thiopentone on repolarizing currents at therapeutic concentrations should aid understanding of their inotropic and chronotropic effects. Therefore, we assessed the comparative actions of propofol and thiopentone on membrane currents forming the repolarization phase of action potentials of isolated guineapig ventricular myocytes.

Materials and methods

The experimental procedure was approved by the Animal Care and Use Committee of Tokyo Medical and Dental University. Single ventricular myocytes were isolated from guineapig hearts by enzymatic dissociation, as described previously[17]. Briefly, animals weighing 300–400 g were anaesthetized with sodium pentobarbitone 40–50 mg kg^{-1} i.p. after heparinization (300 u. kg^{-1} i.v.). The chest was opened during artificial ventilation and the aorta was cannulated *in situ* and then perfused with Tyrode's solution before the heart was dissected out. Using a Langendorff apparatus, the heart was perfused retrogradely at 37 °C with low-Ca^{2+} (30 μmol litre^{-1}) Tyrode's solution, followed by perfusion with 0.04% collagenase (type 1, Sigma Chemical Co., St Louis, MO, USA) dissolved in low-Ca^{2+} Tyrode's solution

for about 20 min. Single cells were obtained by gentle agitation of small pieces of ventricular tissue in a beaker containing the high-K^+, low-Cl solution (KB medium[16]) and stored at 4 °C. The preparations were transferred to a recording chamber filled with bath solution (normal Tyrode), which was placed on the stage of an inverted phasecontrast microscope (Diaphot TMD, Nikon, Tokyo, Japan). A single isolated cell with a smooth surface and clear striations was selected for electrical measurements. Electrophysiological experiments were performed within 12 h of cell isolation.

Test solutions of propofol (2,6-diisopropylphenol; Zeneca, Macclesfield, UK) were obtained by adding appropriate amounts of an aqueous emulsion (1% (w/v) propofol in 10% (w/v) soya bean oil, 1.2% (w/v) egg phosphatide and 2.25% (w/v) glycerol) to normal Tyrode's solution. Thiopentone (5-ethyl-5(1-methyl butyl)2-thiobarbiturate; Tanabe Pharmaceut Co., Osaka, Japan) was prepared freshly before every experiment. This agent was also diluted in normal Tyrode's solution to obtain the final concentrations indicated in the text. All anaesthetic concentrations in this study, therefore, are expressed as free concentrations in aqueous solution.

The composition of normal Tyrode's solution used in cell dissociation and the bath solution was (mmol litre^{-1}): NaCl 144, NaH_2PO_4 0.33, KCl 4.0, $CaCl_2$ 1.8, $MgCl_2$ 0.53, glucose 5.5 and HEPES 5.0, and the pH was adjusted to 7.3–7.4 by adding NaOH. The high-K^+, low-Cl solution had the following composition (mmol litre^{-1}): K-glutamate 70, taurine 15, KCl 30, KH_2PO_4 10, $MgCl_2$ 0.5, glucose 11, EGTA 0.5 and HEPES 10, and the pH was adjusted to 7.4 by adding KOH. The composition of the pipette solution used in recording action potentials and membrane currents was (mmol litre^{-1}): KCl 130, K_2ATP 5.0, creatine phosphate 5.0, EGTA 0.2 and HEPES 5.0, and the pH was adjusted to 7.2 with KOH. For isolation of $I_{Ca.L}$, the pipette solution replacing internal K^+ with Cs^+ and a TEA-rich external solution for Na^+ were used. The TEA-rich solution contained (mmol litre^{-1}): TEA-Cl 154.0, $CaCl_2$ 2.0, $MgCl_2$ 2.0, glucose 10.0 and HEPES 10.0, and the pH was adjusted to 7.4 with TEA-OH. The pipette solution contained (mmol litre^{-1}): CsCl 110.0, TEA-Cl 20.0, $CaCl_2$ 0.068, $MgCl_2$ 4.0, BAPTA 5.0, HEPES 10.0, K_2ATP 5.0 and cAMP 3.0, and the pH was adjusted to 7.2 with CsOH.

The whole-cell variation of the patch-clamp technique was used to record action potentials and membrane currents using an amplifier (Axopatch 1C, Axon Instruments, Foster City, CA, USA) and low-pass filtered at 10 kHz. Action potentials and membrane currents were recorded under whole-cell current-clamp and voltage-clamp modes, respectively. Acquisition and analysis of the data, and generation of the stimulus procedure, were performed with the pCLAMP software package (version 5.5.1; Axon Instruments). The temperature of the perfusion chamber was maintained at 35–36 °C. At the beginning and end of each experiment, the junction potentials between the pipette and bath solutions were checked and if differences in the two values were more than 2 mV, membrane potential was corrected accordingly. The resistance of the pipette filled with standard pipette solution was 2–4 MΩ. Test solution was applied to the bath solution at concentrations indicated in the text for 5–10 min of the observation. The washout data were observed 15 min after removal of the drug from the bath solution. Some depression of membrane currents after administration of drug may result from "rundown", and therefore data were excluded if washing with control solution did not yield recovery to at least 80% of control.

To examine the kinetics of $I_{Ca.L}$ produced by the drug, the time course of development was assessed by a curve-fitting procedure using a simple non-linear least-squares algorithm on a personal computer (IBM-AT). The formula for the curve fitting used in this study is:

$I_{Ca.L}=A_1\exp(-bC_1)+A_2\exp(-bC_2)+A_3\exp(-bC_3)+A$

where b=pulse number or time, and C_1, C_2 and C_3=onset rates. Applicability of either one, two or three exponential functions was always examined using the F test.

All values are expressed as mean (SEM). Statistical significance of a drug treatment was determined by paired or unpaired Student's t test; $P<0.05$ was considered significant, except in the F test where $P<0.01$ was significant.

Results

EFFECTS OF PROPOFOL AND THIOPENTONE ON ACTION POTENTIALS

Propofol 0.1 μmol litre^{-1} had no effect on action potential variables (n=4, fig. 1A). Propofol shortened APD at 90% repolarization (APD_{90}) at concentrations of 0.5 μmol litre^{-1} or greater ($P<0.05$). At concentrations of 1 μmol litre^{-1} or higher, propofol shortened APD at 20% repolarization (APD_{20}) ($P<0.05$). Propofol changed neither action potential amplitude (APA) nor resting membrane potential (RMP) (fig. 1A, table 1). Administration of the vehicle alone (0.002% Intralipid; Otsuka Pharmaceutical Co., Tokyo, Japan), in an amount equal to that contained in propofol 10 μmol litre^{-1}, did not significantly affect action potential variables (n=5, data not shown).

Administration of thiopentone 1 μmol litre^{-1} had little effect on APD_{20} or APD_{90}. Thiopentone 10 μmol litre^{-1} induced prolongation of APD_{90} (n=5, $P<0.05$) without change in APD_{20} (table 1). At 50 and 100 μmol litre^{-1}, thiopentone caused a decrease in RMP ($P<0.05$) and shortened APD_{20} ($P<0.05$). The prolonged APD_{90} was abbreviated by thiopentone 50 and 100 μmol litre^{-1}; values were almost the same as those of the control (fig. 1B, table 1).

EFFECTS OF PROPOFOL AND THIOPENTONE ON MEMBRANE CURRENTS

Figure 2 shows the changes in current–voltage relationships (A) and current traces (B) induced by the two agents. At concentrations of 1 μmol litre^{-1} or higher, propofol had almost no observable effects on the late current at potentials negative to −30 mV, which reversed its polarity at about −90 mV. Propofol decreased the late current at voltages positive to −30 mV. These results suggest that propofol reduced I_K but had no detectable effect on I_{K1}. In addition, propofol depressed the initial peak inward current on depolarization from −30 mV without change in its reversal potential.

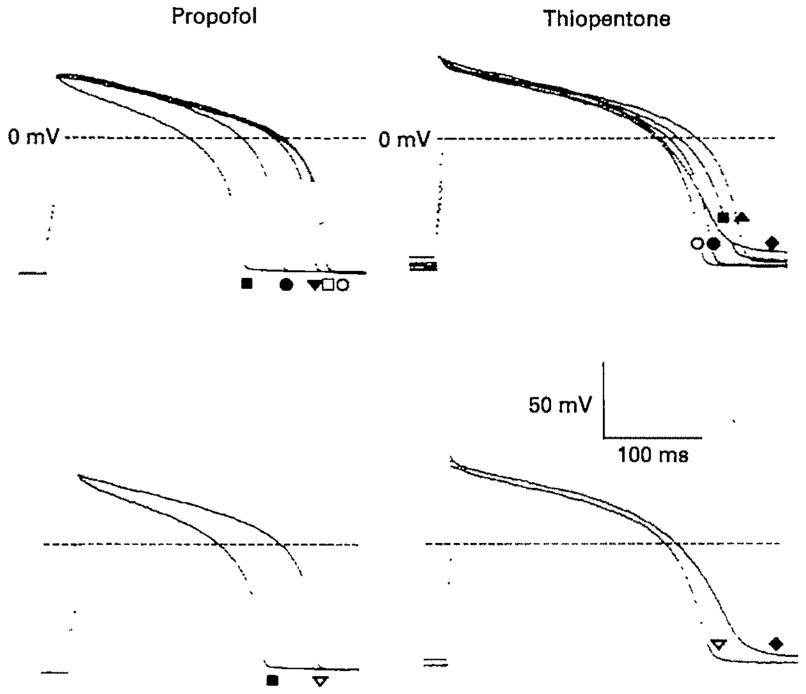

Figure 1 Effects of propofol and thiopentone on action potentials. Action potentials were elicited by applying rectangular pulses with a 5-ms duration at a frequency of 0.2 Hz to ventricular myocytes, 5–6 min after achieving the whole-cell current-clamp and their configurations became stable. Propofol and thiopentone were then applied to the bath solution at concentrations of 0.1 (□), 0.5 (▼), 1 (●), 10 (▲) and 50 (■) μmol litre^{-1} and 1 (●), 10 (▲), 50 (■) and 100 (◆) μmol litre^{-1} in a successive manner, respectively. O= Control. ▽= Washout of drug. Action potentials were recorded from a single preparation.

Table 1 Effects of propofol and thiopentone on variables of the action potential in guineapig ventricular myocytes (mean (SEM)). At concentrations of 10 μmol litre^{-1} or higher, thiopentone suppressed the late current at all voltages tested, suggesting that thiopentone depresses both I_{K1} and I_K. Thiopentone decreased the late current at test pulses to −110 mV to 89.2 (1.9) % (10 μmol litre^{-1}; ns *vs* control as 100%), 82.7 (5.5) % (50 μmol

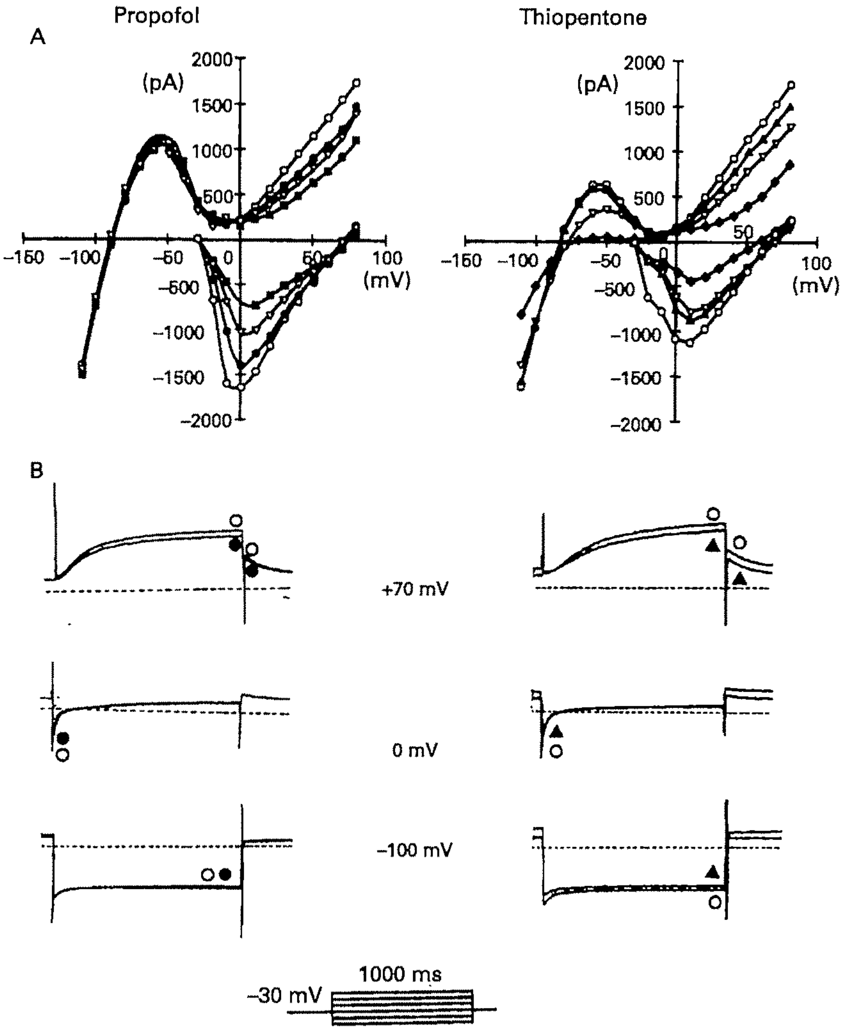

Figure 2 Effects of propofol and thiopentone on membrane currents. (A) Current–voltage relationship. Membrane currents were elicited by depolarizing or hyperpolarizing voltage steps from the holding potential of −30 mV for 1000 ms at 0.1 Hz. The late current was measured by the current level at the end of test pulses. The peak inward current was measured as the difference between the initial peak inward current on depolarizing and the control holding current level. O=Control. ●= Drug 1 μmol litre^{-1}; ▲=drug 10 μmol litre^{-1}; ■=drug 50 μmol litre^{-1}; ◆=drug 100 μmol litre^{-1}; ∇=washout. (B) Current traces in the absence (O) and presence of propofol 1 μmol litre^{-1} (●) or thiopentone 10 μmol litre^{-1} (▲) were superimposed at each voltage step (mV).

litre^{-1}; $P<0.05$) and 67.3 (8.0) % (100 μmol litre^{-1}; $P<0.05$) ($n=5$). After washout of thiopentone 100 μmol litre^{-1}, the current recovered to 89.1 (3.1) % of control ($n=5$; $P<0.05$ *vs* 100 μmol litre^{-1}). The late current positive to −30 mV was decreased by the drug. Thiopentone also suppressed the initial peak current on depolarization from −30 mV.

EFFECTS OF PROPOFOL AND THIOPENTONE ON $I_{Ca.L}$

Propofol and thiopentone decreased the initial peak inward current on depolarization (fig. 2), suggesting suppression of $I_{Ca.L}$. Therefore, we examined the effects of these agents on isolated $I_{Ca.L}$ (fig. 3). The amplitude of $I_{Ca.L}$ was decreased to 88.4 (1.8) % by propofol 1 μmol litre^{-1} ($n=5$; $P<0.01$ *vs* control as 100%) and 75.0 (5.3) % at propofol 10 μmol litre^{-1} ($n=5$; $P<0.01$) at a frequency of 0.2 Hz. The currents recovered to 87.8 (2.8) % ($P<0.05$ *vs* 10 μmol litre^{-1}) after washout of propofol 10 μmol litre^{-1}. Administration of thiopentone 10 and 100 μmol litre^{-1} decreased $I_{Ca.L}$ to 88.5 (1.2) % ($n=5$; $P<0.01$ *vs* control as 100%) and 82.8 (1.6) % ($n=5$; $P<0.01$), respectively. After washout of thiopentone 100 μmol litre^{-1}, the current recovered to 89.7 (2.4) % of control ($P<0.01$ *vs* 100 μmol litre^{-1}) (fig.3A).

Use-dependent block of $I_{Ca.L}$ by propofol and thiopentone was examined by applying 11 depolarizing pulses at 0.2 Hz or 50 pulses at 1 Hz (fig.3B). In the absence of drug (control), the currents at the 11th (0.2 Hz) or 50th (1 Hz) pulse were decreased by 6% or less of the first pulse of $I_{Ca.L}$. Thus steady-state $I_{Ca.L}$ was 94% or the higher of the current as the first pulse. In the presence of propofol 1 μmol litre^{-1}, $I_{Ca.L}$ at the 11th pulse at 0.2 Hz was decreased to 91.8 (1.0) % of the current at the first pulse ($P<0.01$; $n=4$). The current at the 50th pulse at 1 Hz was decreased to 60.0 (4.9) % ($P<0.05$; $n=4$). In the presence of thiopentone 10 μmol litre^{-1}, $I_{Ca.L}$ at the 11th pulse at 0.2 Hz was suppressed to 90.0 (2.0) % of the first pulse ($P<0.05$; $n=4$) and the current at the 50th at 1 Hz was 68.0 (5.3) % of the first pulse ($P<0.05$; $n=4$). Therefore, both drugs produced use-dependent block of $I_{Ca.L}$.

EFFECTS OF PROPOFOL AND THIOPENTONE ON THE KINETICS OF $I_{Ca.L}$

The inactivation time course of $I_{Ca.L}$ was analysed using the current evoked by depolarization to +10 mV at 0.2 Hz with the voltage procedure similar to figure 3B. The time course of the current was well fit-

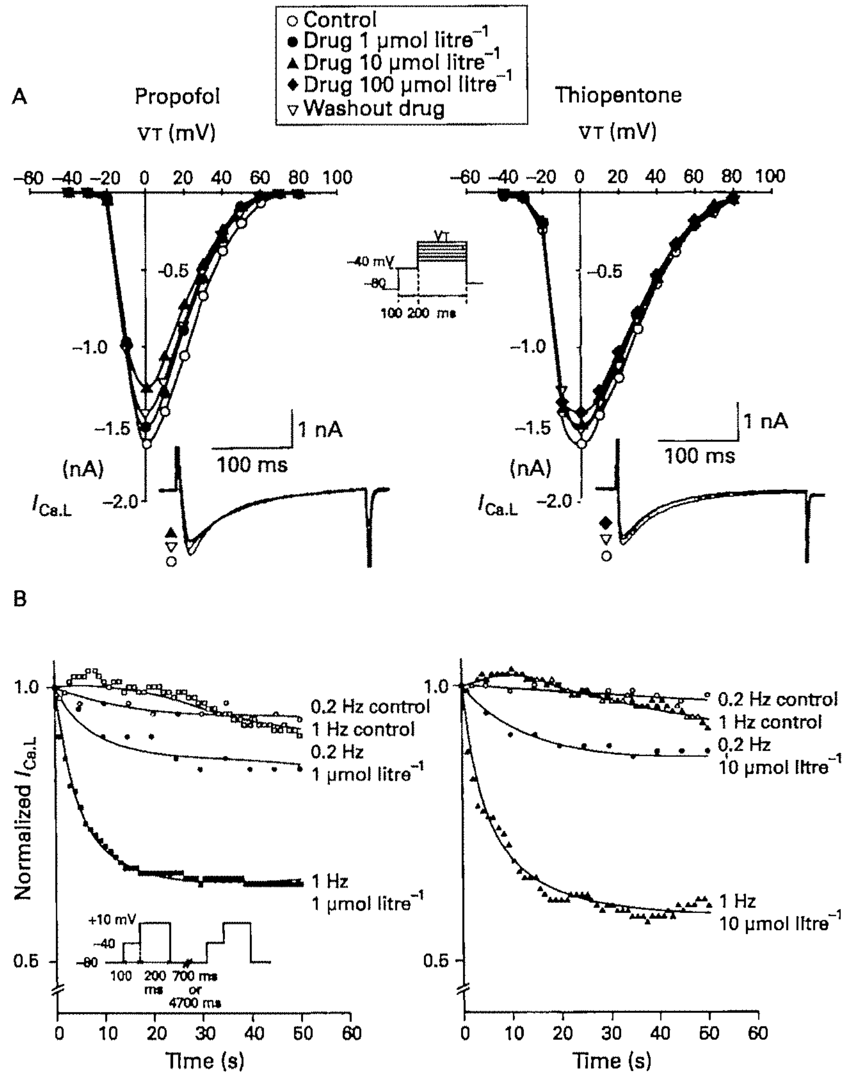

Figure 3 Effects of propofol and thiopentone on $I_{Ca.L}$. (A) Current–voltage relationship. $I_{Ca.L}$ were activated by stepping to different depolarized levels in 10-mV increments for 200 ms after the conditioning pulse to −40 mV for 100 ms from the holding potential of −80 mV to inactivate the fast Na^+ and T-type Ca^{2+} currents. The current traces of $I_{Ca.L}$ (inset) were evoked at test potential to 0 mV. (B) Use-dependent block of $I_{Ca.L}$ was examined by applying test pulses at 0.2 Hz or 1.0 Hz for periods of 50 s. $I_{Ca.L}$ evoked by the test pulse consisted of 200ms depolarizing pulses to +10 mV preceded by 100-ms depolarizations to −40 mV from a holding potential of −80 mV. The current amplitudes were normalized to the current amplitude of the first pulse.

ted to the sum of two exponentials with the fast (τ fast; 9.0 (1.8) ms) and slow (τ slow; 64.0 (4.8) ms) time constants in the control (n=7). Administration of propofol 1 and 10 µmol litre^{-1} increased τ fast to 10.1 (1.8) ms (P<0.05) and 12.6 (2.0) ms (P<0.01), respectively, with no change in τ slow. In contrast, thiopentone 10 and 100 µmol litre^{-1} decreased τ slow from 66.4 (3.6) ms in the control (n=12) to 57.1 (3.4) ms (P<0.01) and 49.0 (3.6) ms (P<0.01), respectively, without affecting τ fast. Washout of thiopentone reversed τ slow to 60.6 (5.1) ms (P<0.01 *vs* thiopentone 100 µmol litre^{-1}).

Effects of the drugs on steady-state inactivation and activation processes of $I_{Ca.L}$ were evaluated. Steady-state inactivation curves (f_∞) were drawn by least-square fitting to the empirical Boltzmann equation to the mean values from each group of data:

$$f_\infty=1/(1+\exp((Vm-Vh)/s))$$

where Vm=pre-pulse potential, Vh=membrane voltage at which $I_{Ca.L}$ is half maximal, and s=slope factor. Under control conditions, Vh and s were −19.4 (0.2) mV and 5.7 (0.2) mV, respectively (n=5). These values did not change significantly during administrations of drugs (fig. 4A).

Steady-state activation curves (d_∞) were drawn by fitting the Boltzmann equation to data points of the mean values:

$$d_\infty=1-1/(1+\exp((Vm-Vh)/s))$$

where Vm=membrane voltage, Vh=voltage, where the current amplitude is half maximal, and s=slope factor. Control values of Vh and s were -8.2 (0.4) mV and 8.9 (0.4) mV, respectively (n=5). Neither anaesthetic had any effect on these variables (fig. 4B).

We investigated the effects of propofol and thiopentone on recovery from inactivation of $I_{Ca.L}$ using a double pulse design. Under control conditions the recovery process was well fitted to a single exponential with a time constant of 84.6 (16.4) ms. In the presence of propofol 1 µmol litre^{-1}, the time constant increased to 142.4 (22.9) ms (P<0.05; n=7). Similarly, thiopentone 10 µmol litre^{-1} increased it from a control value of 77.4 (22.6) ms to 106.1 (24.3) ms (P<0.05; n=5)(fig. 4C).

EFFECTS OF PROPOFOL AND THIOPENTONE ON THE DELAYED RECTIFIER K^+ CURRENT

The drug effects on I_K were estimated by measuring

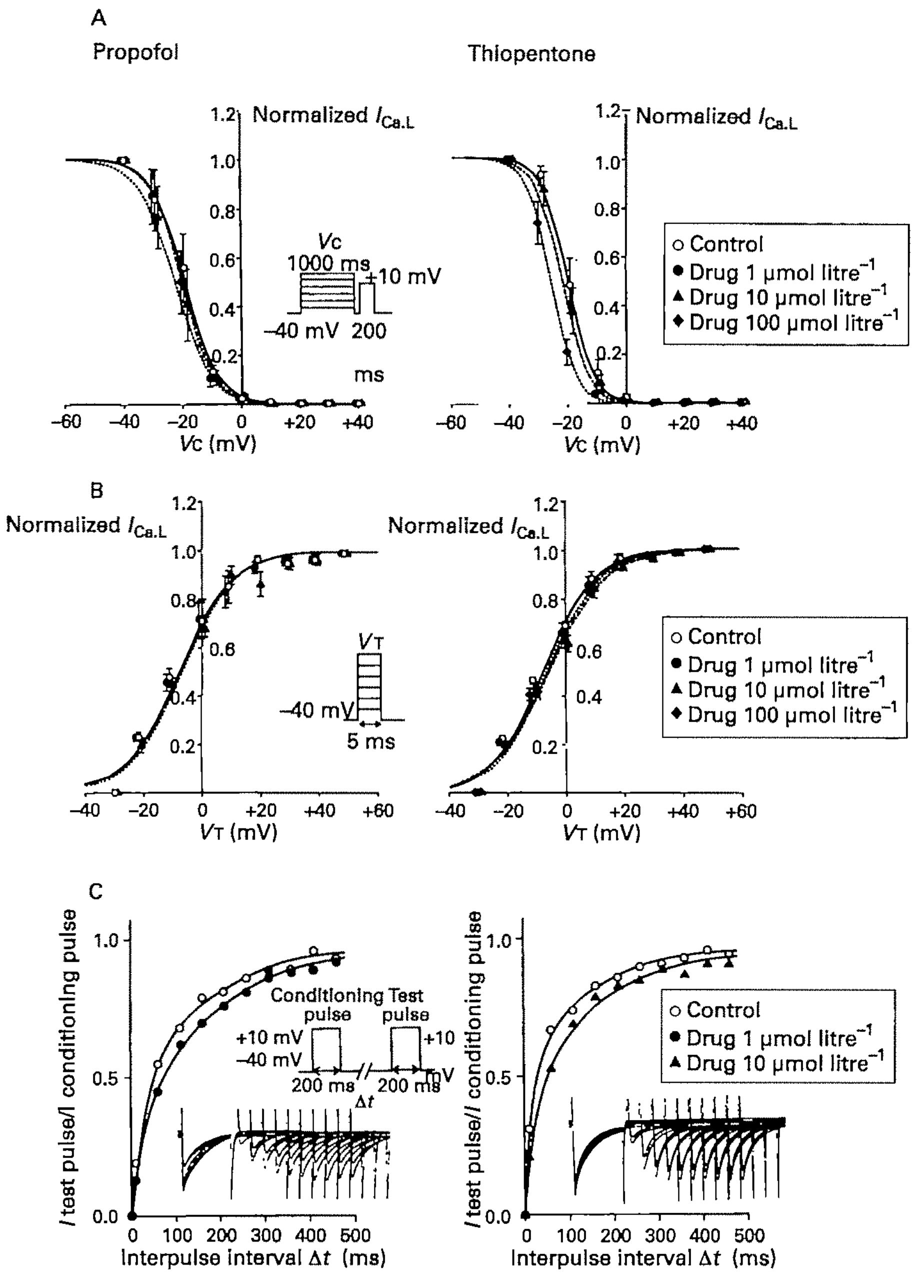

Figure 4 Effects of propofol and thiopentone on changes in the kinetics of $I_{Ca.L}$. (A) Steady-state inactivation of $I_{Ca.L}$ was assessed by applying conditioning pre-pulses for 1000 ms in 10-mV increments from −30 mV, followed by 200 ms test pulses to +10 mV preceded by a 4-ms return to the holding potential of −40 mV, and normalized $I_{Ca.L}$ was plotted as function of pre-pulse voltage. (B) Steady-state activation of $I_{Ca.L}$ was measured by the inward tail current elicited by depolarizing test pulses of 5 ms duration from a holding potential of −40 mV to +50 mV by 10-mV increment. (C) Effects of propofol and thiopentone on recovery from inactivation of $I_{Ca.L}$. The current amplitude evoked by test pulses to +10 mV for 200 ms was elicited after various diastolic intervals ranging from 10 to 1500 ms at −40 mV, following the conditioning pulse for 200 ms to +10 mV.

the tail current of I_K ($I_{K.tail}$) on repolarization to −30 mV. Steady-state activation of $I_{K.tail}$ and the drug effects are shown in figure 5 (inset). During administration of propofol 1 μmol litre^{-1}, $I_{K.tail}$ did not change from control, but propofol 10 μmol litre^{-1} significantly suppressed the current. $I_{K.tail}$ at test pulses to +80 mV was decreased to 78.4 (4.0)% of control ($P<0.01$; $n=6$) in the presence of propofol 10 μmol litre^{-1}. Administration of thiopentone 10 and 100 μmol litre^{-1} significantly decreased $I_{K.tail}$ at test pulses to +80 mV to 78.3 (6.9) % ($P<0.05$ *vs* control as 100%; $n=4$) and 27.0 (4.2) % ($P<0.01$; $n=4$), respectively. After drug washout, $I_{K.tail}$ recovered to 91.7 (3.2) % ($P<0.05$ *vs* propofol 50 μmol litre^{-1}; $n=6$) and 84.6 (4.4) % ($P<0.05$ *vs* thiopentone 100 μmol litre^{-1}; $n=4$), respectively. The normalized activation curves of $I_{K.tail}$ were fitted to the Boltzmann equation (fig. 5). *Vh* was 20.3 (0.2) mV and *s* was 15.6 (0.2) mV in the control ($n=11$). These values remained almost unchanged during administration of drug ($n=11$ for propofol and $n=5$ for thiopentone), except for a slight negative shift by thiopentone 100 μmol litre^{-1}.

Discussion

We have demonstrated that at concentrations of 0.5 μmol litre^{-1} or higher, propofol shortened APD without affecting RMP, and thiopentone had a biphasic effect on APD. Thiopentone 10 μmol litre^{-1} pro-

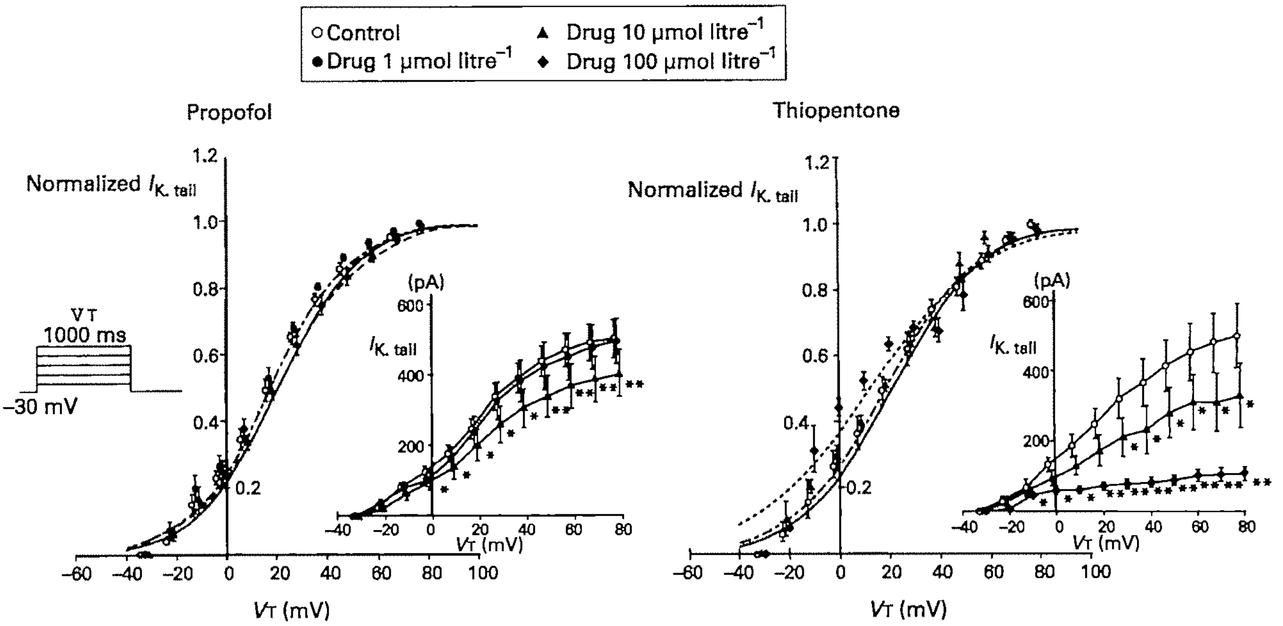

Figure 5 Effects of propofol and thiopentone on activation of I_K. Activation of I_K was initiated using the voltage procedure shown in the inset at the left. I_K was assessed by the tail current amplitude ($I_{K.tail}$). Steady-state activation of $I_{K.tail}$ is plotted on the right side for both propofol and thiopentone. The normalized $I_{K.tail}$ curves were least-square fits of a Boltzmann equation to the mean values of each data group. *$P<0.05$ *vs* control, **$P<0.01$ *vs* control.

longed APD while concentrations higher than 50 μmol litre⁻¹ decreased RMP and abbreviated the prolonged APD to the control level. Propofol at concentration greater than 1 μmol litre⁻¹ suppressed mainly $I_{Ca.L}$ with minimal changes in I_K without affecting I_{K1}. In contrast, thiopentone 10 μmol litre⁻¹ predominantly suppressed I_K with mild suppression of $I_{Ca.L}$ and minimal effects on I_{K1}. At concentrations of 50 μmol litre⁻¹ or higher, thiopentone profoundly depressed $I_{Ca.L}$, I_K and I_{K1}. These results at high concentrations are generally in agreement with previous reports[4 6 9 12 16].

Because the main currents underlying the plateau and repolarization phases of action potentials in guineapig ventricular myocytes are $I_{Ca.L}$, I_K and I_{K1}[19], changes in action potentials can be ascribed mainly to the different potencies of the drugs against these membrane currents. Although at high concentrations propofol suppressed both $I_{Ca.L}$ and I_K[3 12], the main target channel of the drug at lower concentrations has not been clarified. Anaesthetic EC_{50} concentrations of propofol and thiopentone required for lack of response to a painful stimulus are 0.4 μmol litre⁻¹ and 25 μmol litre⁻¹ in free aqueous phases, respectively[20]. The low concentrations used in the our experiments (propofol 1 μmol litre⁻¹ and thiopentone 10 μmol litre⁻¹) correspond approximately to the therapeutic concentrations of the two agents. Our data clearly demonstrated that propofol, at clinically relevant concentrations, predominantly suppressed $I_{Ca.L}$ with minimal or no action on I_K, while thiopentone, at clinically relevant concentrations, was found to exert a preferential action on I_K rather than $I_{Ca.L}$ and I_{K1}.

Barbiturates such as pentobarbitone and thiopentone most likely affect similar parts of the $GABA_A$ receptor, therefore, a confounding effect of a previous pentobarbitone anaesthetic may affect the *in vitro* results of subsequent thiopentone exposure. To the best of our knowledge, however, there has been no report describing the existence of $GABA_A$ receptors in heart tissue. In addition, the effects of pentobarbitone on the cell membrane are not expected to affect the outcome of this study in view of the extensive washing and equilibration periods, including the cell isolation procedures, before the experiments were performed.

The most distinct difference in the membrane actions of the two i.v. anaesthetics was suppression of K^+ currents. Propofol exerted minimal suppression of I_K at low concentrations (1 μmol litre⁻¹) when $I_{Ca.L}$ was depressed, but had no effect on I_{K1}, even at high concentrations (50 μmol litre⁻¹). In contrast, thiopentone significantly suppressed I_K at low concentrations (10 μmol litre⁻¹) with a mild effect on $I_{Ca.L}$, and at high concentrations exhibited strong suppression on I_K with moderate effects on I_{K1}. Concentration-dependent depression of I_{K1} by thiopentone at concentrations greater than 10 μmol litre⁻¹ was also reported in frog atrial and guineapig ventricular myocytes[16]. These may contribute to the different effects of propofol and thiopentone on APD.

Recent studies have highlighted the existence of at least two components of I_K: fast activating I_K ($I_{K.r}$) and slow activating I_K ($I_{K.s}$)[21]. Although we did not examine selective inhibition of the two components of I_K, it is conceivable that propofol and thiopentone have a predominant blocking action on $I_{K.s}$ because of the pulse design (1000 ms depolarization) used and dominant $I_{K.s}$ in guineapig ventricular myocytes[21]. Suppression of I_{K1} induces depolarization of RMP and prolongation of APD. While the latter action may exert prevention of re-entrant arrhythmias because of the long refractory period, similar to class III antiarrhythmic agents, the former induces serious effects on arrhythmogenesis. A decrease in RMP inactivates the fast sodium current ($I_{Na.fast}$) to cause slowing of cardiac impulses. This may facilitate development of re-entry and produce abnormal automaticity. Additionally, depolarization of RMP may account for the negative inotropic effect because it promotes inactivation of $I_{Ca.L}$ under certain conditions. Therefore, thiopentone may be more responsible for the proarrhythmic and negative inotropic actions in ischaemic heart[22].

Three i.v. anaesthetics, ketamine 100 µmol litre^{-1}, methohexitone 100 µmol litre^{-1} and propofol 28 µmol litre^{-1}, have been shown to have different actions on I_{K1} and I_K[12]. Ketamine, thiopentone, etomidate, propofol and midazolam at relatively high concentrations were shown to depress the transient outward K$^+$ current (I_{to}) in canine ventricular myocytes[15 23]. Our study demonstrated that propofol and thiopentone had different selectivity of effects on two voltage-dependent K$^+$ currents. This evidence suggest that i.v. anaesthetics have specific site(s) of actions on the cardiac cell membrane, such as individual ion channels[24] or the lipid environment of the channel, or both, to exert their effects[13], rather than a generalized membrane effect.

Both anaesthetics not only suppressed $I_{Ca.L}$ but also affected current kinetics in a slightly different manner. Although the values of $I_{Ca.L}$ measured included components of "rundown", propofol and thiopentone at clinically relevant concentrations suppressed the peak amplitudes of $I_{Ca.L}$. These results indicate that propofol and thiopentone at anaesthetizing concentrations depress cardiac contractility, at least partly as a result of abbreviation of Ca^{2+}-influx through the sarcolemma. Compared with an equipotent dose of propofol, the decrease in the amount of Ca^{2+} influx produced by thiopentone may be smaller than that produced by propofol in each action potential because of prolonged APD in the former. This observation is compatible with reports that the cardiodepressant effects of propofol are more pronounced and more prolonged than those of equipotent doses of thiopentone when given as a single bolus[25]. This explanation, however, conflicts with most of the previous studies that showed that propofol had little or no effect on cardiac contractility[6 26 27], or was less potent than thiopentone[4 6].

There may be additional factors involved in the modification of Ca^{2+} influx and cardiac contractility by these drugs. During excitation–contraction coupling, Ca^{2+} release from the sarcoplasmic reticulum and trans-sarcolemmal Ca^{2+} entry are two main sources for the Ca^{2+} supply, but the contribution of each component may differ in various species (higher dependence on sarcoplasmic reticulum Ca^{2+}-release in the order of rat>dog, cat>human>guineapig, rabbit>frog ventricle)[28]. Thiopentone[9 11] but not propofol[3 5] has been reported to impair sarcoplasmic reticulum function. In addition, propofol was shown to reduce the second inward current during action potential plateau or depolarizing pulses at positive voltages which was carried presumably by the Na$^+$–Ca^{2+} exchange mechanism[3]. Reduction of this inward current could also be partly attributed to the negative inotropic effect of propofol.

In summary, we found that propofol suppressed mainly $I_{Ca.L}$ with minimal depression of I_K and little or no change in I_{K1}, while thiopentone, at clinically relevant concentrations, demonstrated predominant block of I_K rather than $I_{Ca.L}$ and I_{K1}. The distinct suppressive effects on cardiac function of propofol and thiopentone may result, at least in part, from the different actions on membrane currents forming the repolarization phase of action potentials.

Dose–response curve for anaesthetics based on the Monod–Wyman–Changeux model

T. IWAI, H. KIHARA, K. IMAIAND AND M. UCHIDA

Summary

We have analysed the dose–response curve for halothane and isoflurane according to the Monod–Wyman–Changeux (MWC) model. This model describes the nature of the physiological data reported by Wakamori, Ikemoto and Akaike for inhibitory Cl currents induced by GABA or glycine in dissociated rat brain neurones and by Herrington and colleagues for Ca^{2+} currents in clonal pituitary cells. With some assumptions on the difference in response to anaesthetics between patients, the model is applicable *in vivo*, and it also describes well the human dose–response curve for isoflurane reported by Mather, Raftery and Prys-Roberts. However, the steeply sigmoidal dose–response curve in humans for halothane presented by deJong and Eger is difficult to understand with the same model, because it gives rise to unrealistic MWC variables. (*Br. J. Anaesth.* 1996;**77**:517–521)

Key words

Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane. Model, mathematical.

The mechanism of action of anaesthetics is still controversial. Because the potencies of volatile anaesthetics increase in proportion to their solubility in oil, it has been proposed that general anaesthetics act by disturbing the structure or dynamic properties of the lipid–bilayer portions of nerve membranes. Such perturbations, however, were found to be extremely small at concentrations used clinically. In contrast, physiological studies indicate that specific interactions occur with membrane proteins, such as receptors and ligand-gated ion channels, and these receptors have been proposed as sites of anaesthetic action[1,2]. For example, the γ-aminobutyric acid (GABA) receptor is very sensitive to most volatile anaesthetics; inhalation agents, halothane and enflurane, at surgical concentrations, markedly enhanced inhibitory currents induced by GABA, causing a shift in the dose–response curve (response of current to GABA concentration) to lower GABA concentrations[3]. Moss, Franks and Lieb demonstrated that the activity of a soluble lipid-free enzyme, firefly luciferase, was inhibited by a range of anaesthetics at concentrations close to their respective EC_{50} values[4]. Some agents with optical isomers show stereoselectivity[5]. This suggests that anaesthetics may act by binding directly to proteins.

Changeux has reviewed the most thorough study on the nicotinic acetylcholine receptor, and demonstrated the allosteric nature of ligand-gated ion channels[6]. The dose–response curve determined experimentally suggests binding of anaesthetic molecules to a receptor protein molecule. In this article, we have analysed the behaviour of anaesthetics in the framework of the Monod–Wyman–Changeux (MWC) model[7], which has been used successfully to understand the behaviour of allosteric protein molecules[8–10]. We refer to the electrophysiological data reported by Wakamori, Ikemoto and Akaike[3] and by Herrington and colleagues[11] to see how well the MWC model works. We then analyse the data on anaesthetic potency for humans presented by deJong and Eger[12] and by Mather, Raftery and Prys-Roberts[13] on the basis of the MWC model.

Methods

IN VITRO DOSE–RESPONSE

According to the MWC model[7], we assume that a receptor protein molecule has two different conformations, R and T, each of which contains r binding sites for a ligand X; the sites are similar and independent. The whole system is assumed to be in equilibrium. The R form is termed anaesthetic-sensitive, because anaesthetic molecules (the ligand) bind more readily to the R form of the receptor molecule than to the T form. The binding equilibrium constant K_T for a site on the T-form molecules is usually much smaller than that for the R-form molecules, K_R, so that the ratio c $(=K_T/K_R)$ is much smaller than unity. However, in the absence of anaesthetic ($[X]=0$), most of the receptor molecules are in the T form; the equilibrium constant for the $R \rightleftharpoons T$ transition, $L(=[T]/[R])$, is usually much greater than unity. Hence there is near-zero response at low concentrations of ligand. As the concentration of ligand increases, the ligand binds mainly to the R-form molecules giving combined molecules RX, RX_2, RX_3, as one, two and three of the receptor sites on the R-form molecules become occupied with ligand X. In addition, there are some TX, TX_2, TX_3, molecules, and the numbers of the RX_i molecules is

Correspondence to H. K.

equal to that of the TX_i molecules (i =0, 1, 2,..., r) at the ligand concentration giving 50% response. Eventually, at high concentrations of X, almost all the receptor molecules are in the RX_i form and the response is maximal. At all concentrations of X, the response, expressed as a fraction Z of the maximum, is considered to be equal to the amount of RX_i molecules as a fraction of the total RX_i and TX_i molecules. The MWC formulation (appendix) gives the fractional response Z as follows:

$$Z = \frac{(1+K_Rx)^r}{(1+K_Rx)^r+L(1+cK_Rx)^r} \qquad (1)$$

where x=ligand concentration at receptor sites: x =[X]. The MWC variables of the equilibrium process, K_R, c, L and the number of sites r, should be determined from reasonable fitting to the experimental dose–response data.

In practice, we determined those variables using the Hill approximation. The experimental dose–response curve is conventionally expressed by:

$$y = \frac{x^n}{x_m^n+x^n} \qquad (2)$$

where n=the Hill coefficient and is a measure of cooperativity (n >1 is the condition of cooperativity). When n is large, the curve shows high cooperativity and is steep in shape. Constant x_m is the x value at a half-maximal point (y=50%). The Hill coefficient n can be determined from the Hill plot, $\ln[y/(1-y)]$ *vs* $\ln x$, in which the slope at $x=x_m$ gives the n value. Starting from those values estimated graphically, we determined the Hill variables, n and x_m, using the least-square fitting of equation (2) to the data points.

According to Colosimo, Brunori and Wyman[14], if the experimental dose–response curve is symmetrical with respect to the half-maximal point $x=x_m$, it follows that:

$$L=c^{-1/2} \text{ (symmetrical condition)} \qquad (3)$$

and

$$K_Rx_m = c^{-1/2} \text{ and } n = \frac{1-c}{(1+\sqrt{c})^2}r \qquad (4)$$

We assumed some integer for r (larger than the Hill coefficient n) at first and then obtained other variables from equations (3) and (4). We attempted to determine the final r value for which the MWC curve, $Z=Z(x)$, fits best to the experimental one through trials with different r values.

IN VIVO DOSE–RESPONSE

The basis of a clinical dose–response curve is essentially different from that of an *in vitro*, dose–response curve, because the clinical curve is based on statistics of the logit or probit model. Thus we cannot apply the MWC model to the *in vivo* case by itself. We assume, however, that some log-normal distribution of the *in vivo* curve, instead of a delta function, against anaesthetic concentration is caused by the difference between individual patients in threshold concentrations required for not responding to surgical incision. First, we assume that all individuals have the same receptor molecules in sufficient concentrations to respond. Second, we assume that such thresholds are determined by fractions of active combined molecules RX_i to the total TX_i and RX_i molecules. In other words, we assume that anaesthetic-sensitive patients do not respond to surgical incision even at low fractions, while non-sensitive patients still respond at high fractions. Using this assumption the dose–response curve derived from our MWC model is consistent with statistics of the univariate binary model. Third, we assume that the anaesthetic concentration is the same as the ligand concentration at receptor sites. Based on these assumptions we apply the MWC model to analyse *in vivo* and *in vitro* dose–response data. We consider that the fractional response Z in equation (1) is the percentage of patients not responding to anaesthetics and x is the anaesthetic concentration.

Results

IN VITRO DOSE–RESPONSE

As an example of a ligand–receptor system, we referred to the electrophysiological results of Wakamori, Ikemoto and Akaike in dissociated CNS neurones of the rat[3], and examined the MWC model in the following cases: normalized response of the Cl^- current evoked by GABA 3×10^{-6} mol litre^{-1} and glycine 2×10^{-5} mol litre^{-1} as a function of halothane concentration x. We determined the Hill variables as follows: n=1.8 and x_m=0.21 mmol litre^{-1} for GABA; n=1.9 and x_m=0.37 mmol litre^{-1} for glycine. These half-maximal concentrations are comparable with clinical concentrations; MAC of halothane is 0.75%atm, which gives a concentration of 0.24 mmol litre^{-1} in the water phase at 37 °C. We then evaluated the three variables in the MWC model using equations (3) and (4) for several r values for GABA (fig. 1) and for glycine (fig. 2). In both cases, the MWC curves described well the sigmoidal nature of the experimental dose–response curves, but we could not definitively determine the r values. As seen in reference[9], more data points are necessary to determine exactly the number of sites r. Among those MWC curves, that for r=2 agreed with its respective Hill curve, and the error sum of squares was smaller for r=2 than for the others in both cases. From these we set r=2 for both cases, and the MWC variables for r =2 and the related Hill variables are listed in table 1.

We also examined the MWC model for the effect of halothane on the high-threshold component Ca^{2+} current of clonal (GH_3) pituitary cells reported by Herrington and colleagues[11], as an example of ion channels. The Hill variables were determined as n=1.6 and x_m=0.84 mmol litre^{-1}. It is noted that the half-maximal concentration x_m is three or four times larger than the clinical concentration. Figure 3 shows our MWC curves for various r values and their data points. Here we also failed to determine definitively the r value, but the cooperative nature of the experimental curve was expressed well by the MWC model and the Hill approximation. As seen in figure 3, the MWC curve for r=2 is close to the Hill curve, and the error sum of squares is smaller than for the others. For the same reasons as mentioned above, we set r=2, and the MWC variables are listed in table 1.

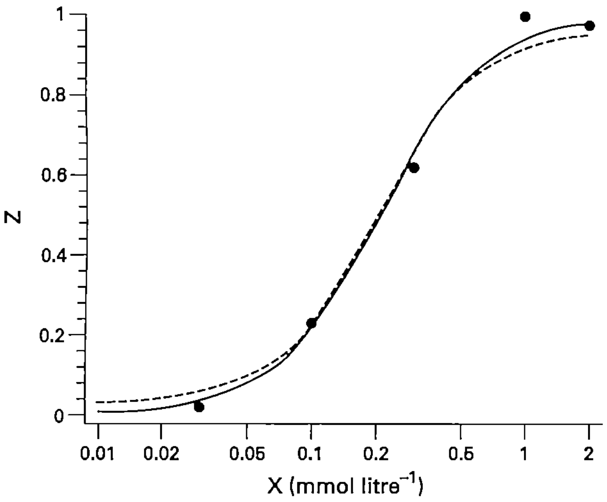

Figure 1 Response relationship of GABA-induced Cl⁻ current to halothane concentration. The solid curve was obtained from the MWC calculation for r=2; the curve of the Hill approximation, n=1.8 and x_m=0.21 mmol litre^{-1}, is on the same solid curve. The broken curves are those for r=4, 8 and 10, which agree with each other within the limit of errors. Data points were read from[3]; the response was normalized to the peak current induced by GABA 3×10^{-6} mmol litre^{-1} alone.

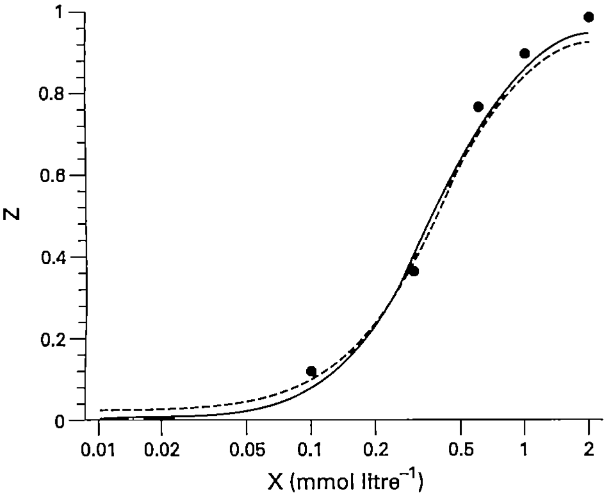

Figure 2 Response relationship of glycine-induced Cl⁻ current to halothane concentration. The solid curve was obtained from the MWC calculation for r=2; the curve obtained from the Hill approximation, n=1.9 and x_m =0.37 mmol litre^{-1}, is on the same one. The broken curves are those for r=4, 8 and 10, which agree with each other within the limit of errors. Data points were read from[3]; response was normalized to the peak current induced by glycine 2×10^{-5} mmol litre^{-1} alone.

IN VIVO DOSE–RESPONSE

Anaesthetic dose–response data in humans were reported by deJong and Eger for halothane[12], and by Mather, Raftery and Prys-Roberts for isoflurane[13]. For halothane, figure 4 shows the Hill curves for various n values, where x_m=0.75 %atm =0.24 mmol litre^{-1}, together with the data points[12]. The least-square fitting of equation (2) gave x_m=0.24 mmol litre^{-1} and n=27, which is much larger than n<2 for the *in vitro* results mentioned above. In this case, it was not possible to determine the number of binding sites and it is only possible to note that the r value is an integer more than 27 (see equation (4)). Our trials for r=28, 30 and 40 gave MWC curves which agreed with each other and with the Hill curve for n=27. The MWC variables for r=30 are listed in table 1 as an example. Notice that the L value is of the order of magnitude of 10^{38} which is unrealistically large.

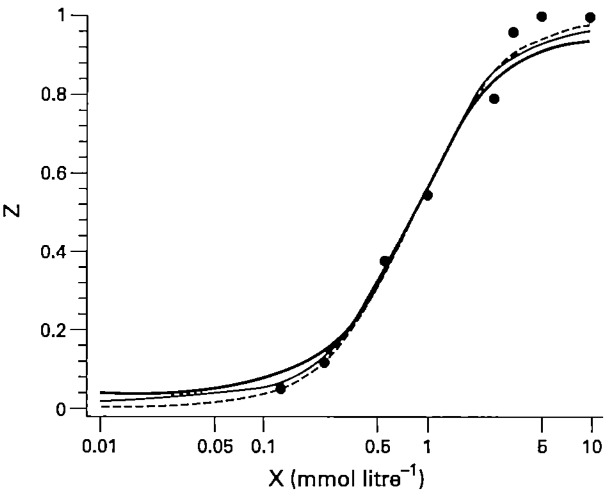

Figure 3 Concentration dependence of block of Ca^{2+} current by halothane. The solid single curve was obtained from the MWC calculation for r=2, the solid heavy curve for r=4, 8 and 10 and the broken curve is the Hill approximation: n=1.6 and x_m=0.84 mmol litre^{-1}. Data points were read from[11].

Table 1 Hill variables n and x_m, and MWC variables K_R, K_T, c and L, and the number of binding sites r. A was determined from[3] for GABA-induced Cl⁻ current (fig. 1); B from[3] for glycine-induced Cl⁻ current (fig. 2); C from[11] for Ca^{2+} current (fig. 3); D from[12] for humans (fig. 4); and E from[14] for humans (fig. 5). A to D halothane, E = isoflurane

	n	r	x_m (mmol litre^{-1})	K_R (mmol litre^{-1})	K_T (mmol litre^{-1})	c	L
A	1.8	2	0.21	90	0.25	2.8×10^{-3}	360
B	1.9	2	0.37	105	0.069	6.6×10^{-1}	1520
C	1.6	2	0.84	11	0.13	1.2×10^{-2}	81
D	27	30	0.24 %atm	79 (%atm)$^{-1}$	0.22 (%atm)$^{-1}$	2.8×10^{-3}	2.3×10^{38}
E	3.6	4	1.03	18	0.052	2.8×10^{-3}	1.3×10^{5}

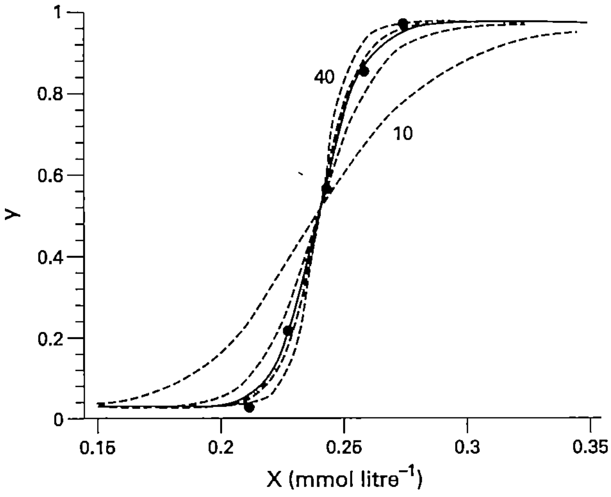

Figure 4 Anaesthetic potency of halothane in humans. All curves are obtained from the Hill approximation. The solid curve is for n=27 and agrees with the MWC curve for r=30; the four broken curves are for n=10, 20, 30 and 40 in order of steepness, of which the n values of 10 and 40 are indicated. x_m=0.24 mmol litre^{-1}=0.75 %atm. Data points were referred to[12].

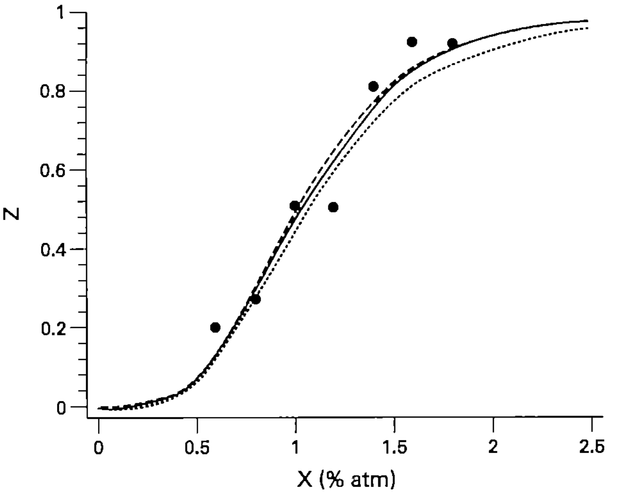

Figure 5 Anaesthetic potency of isoflurane in humans. The solid curve was obtained from the MWC calculation for r=4; the Hill approximation, n=3.6 and x_m=1.03%atm, is on the same solid curve. The broken curves (- - - and ⋯) are for r=8 and r=12, respectively. Data points were referred to[13].

In contrast, the *in vivo* dose–response curve exhibited a much lesser slope for isoflurane. A least-square fitting of the data points[13] to equation (2) gave the Hill variables as n=3.6 and x_m=1.03 %atm. Figure 5 shows the data points and our MWC curve for three r values. The MWC curve for r=4 gave the smallest error sum of squares among the trials with various r values. The MWC variables for r=4 and the Hill variables are listed in table 1.

Discussion

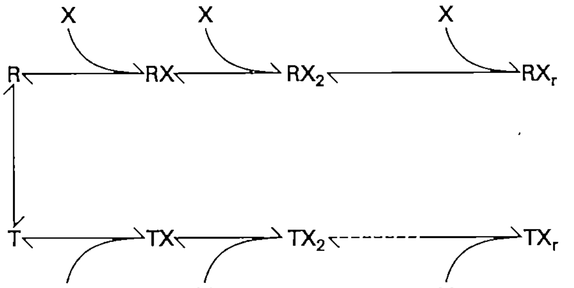
The MWC model describes the nature of the dose–response curve in the electrophysiological experiments for halothane, although the number of binding sites r cannot be determined strictly as yet. If we assume that the fractional response is the percentage of patients not responding to anaesthetics, the MWC model also describes the sigmoidal nature of the clinical dose–response curve for isoflurane. In contrast, the human dose–response curve for halothane is difficult to understand on the basis of the MWC model because of the extremely large value of L.

Mather, Raftery and Prys-Roberts[13] suggested that the steepness of the human dose–response curve obtained by deJong and Eger[12] was apparently enhanced because their sampling method tended to exclude low and high concentrations. For example, the Hill coefficient n, which is a measure of steepness, can be estimated to be 3.6[13] or 8.4[12] for isoflurane. If we assume that such a difference is true proportionally for another anaesthetic, the n value would be reduced from 27 to approximately 10 for halothane. However, it seems that the *in vivo* curve is steeper than the *in vitro* curve.

Our *in vivo* dose–response curve must be governed by the statistics of a univariate binary model on our assumptions. However, its distribution may not agree with the log-normal distribution. In order to check the difference between our distribution and log-normal distribution, we estimated EC_{50} and EC_{95} values for isoflurane from our curve. The values obtained were 1.03%atm and 2.36%atm, respectively, which are in agreement with those of Mather, Raftery and Prys-Roberts (EC_{50}=1.00%atm and EC_{95}=2.16%atm)[13].

Appendix

As mentioned in the text, the MWC model assumes that a receptor molecule has two conformations, R and T, and each form contains r binding sites for a ligand X. The equilibrium scheme of the ligand–receptor system is as follows:



Taking into account the probability factors for the binding of the R and T forms to receptor molecules, we have the following equilibrium equations:

$$[\mathrm{T}]=L\,[\mathrm{R}],$$

$$[\mathrm{RX}]=r\,K_{\mathrm{R}}\,x[\mathrm{R}],\qquad [\mathrm{TX}]=r\,K_{\mathrm{T}}\,x[\mathrm{T}],$$

$$[\mathrm{RX}_2]=(r\,(r-1)/2!)\,K_{\mathrm{R}}{}^2\,x^2[\mathrm{R}],\ [\mathrm{TX}_2]=(r\,(r-1)/2!)\,\mathrm{K}_{\mathrm{T}}{}^2\,x^2[\mathrm{T}],$$

$$[\mathrm{RX}_i]=(r\,!/i\,!(r-i\,)!)\,K_{\mathrm{R}}i\,x^i[\mathrm{R}],\ [\mathrm{TX}_i]=(r\,!/i\,!(r-i\,)!)\,K_{\mathrm{T}}{}^i\,x^i\,[\mathrm{T}],$$

$$[\mathrm{RX}_r]=K_{\mathrm{R}}{}^r\,x^r[\mathrm{R}],\ [\mathrm{TX}_r]=K_{\mathrm{T}}r\,x^r[\mathrm{T}],$$

where x=concentration of ligand X, and K_{R} and K_{T}=binding equilibrium constants for a site in the R form and T form, respectively. Then the concentration of the R-form molecules, which is sometimes called the R state, is given by:

$$[\mathrm{R}]+[\mathrm{RX}]+[\mathrm{RX}_2]+\ldots+[\mathrm{RX}_r]=(1+K_{\mathrm{R}}\,x\,)^r\,[\mathrm{R}],$$

and that of the T-form molecules, the T state, is given by:

$$[\mathrm{T}]+[\mathrm{TX}]+[\mathrm{TX}_2]+\ldots+[\mathrm{TX}_r]=(1+K_{\mathrm{T}}x)^r[\mathrm{T}]=L\,(1+c\,K_{\mathrm{R}}\,x\,)^r[\mathrm{R}].$$

Therefore, the fraction of the R-form molecules to the total R-form and T-form molecules is expressed by:

$$Z=\frac{(1+K_Rx)^r}{(1+K_Rx)^r+L(1+cK_Rx)^r} \qquad (1)$$

Equation (1) is defined as the state function[6 7]. r≥2 is the necessary condition of cooperativity, and cooperativity is marked when L is much greater than 1.

Visual evoked potentials and nitrous oxide-induced neuronal depression: role for benzodiazepine receptors

M. DZOLJIC, W. ERDMANN AND M. R. DZOLJIC

Summary

We have examined the role of benzodiazepine receptors in nitrous oxide-induced neuronal depression in rats. The changes in neuronal excitability induced by nitrous oxide and the benzodiazepine inverse agonist, Ro15-4513, were monitored by measurement of visual evoked potentials (VEP). Administration of Ro15-4513 10 mg kg^{-1} i.p., in rats breathing air, did not affect the amplitude or latency of VEP. However, the same concentrations of Ro15-4513 antagonized nitrous oxide-induced depression of VEP amplitudes. We conclude that antagonism of nitrous oxide-induced depression by Ro15-4513 indicates that at least part of the decreased neuronal excitability caused by nitrous oxide could be ascribed to interactions with the GABA$_A$ receptor complex. (*Br. J. Anaesth.* 1996;**77**:522–525)

Key words

Anaesthetics gases, nitrous oxide. Hypnotics benzodiazepine, Ro15-4513. Monitoring, evoked potentials. Receptors, amino acid. Rat.

The high correlation between the degree of lipophilicity and potency of anaesthetic agents, ranging from inert gases such as xenon to alcohols of varying length, has always been interpreted as evidence that general anaesthesia occurs secondary to non-specific disruption of lipids of neuronal cell membranes[1]. Although the solubility relationships provide a framework for any proposed theory of anaesthesia, the mechanism of action of anaesthetics and corresponding membrane disturbances remain intriguing. Recent studies have focused on membrane proteins as a site of anaesthetic action[2 3]. In this respect two transmitter receptors, namely glutamate[4] and γ-aminobutyric acid (GABA)[5], were considered frequently as mediators of anaesthetic drugs.

GABA is the major inhibitory neurotransmitter in the mammalian brain and thus a prime candidate for a mechanism of the depressant effects of anaesthetic agents. The increase in Cl$^-$ conductance caused by GABA can be modulated by benzodiazepines[6], ethanol[7] and various inhalation anaesthetics[5]. Galindo[8] showed that halothane potentiated the inhibitory action of GABA in the cuneate nucleus. These results have been confirmed recently by Jones, Brooks and Harrison[5], who showed enhancement of GABA-activated Cl$^-$ currents in cultured rat hippocampal neurones by enflurane, halothane and isoflurane.

Glutamate-activated receptors are other obvious targets for general anaesthetics. The NMDA receptor, when activated, causes a Ca^{2+} influx modulating the excitability of a neurone. Ethanol-reduced, NMDA-induced Ca^{2+} currents in cultured hippocampal neurones[9] share this property with other general anaesthetics[10]. As many ion channels have been shown to be affected differently by anaesthetics[11–13], it appears that an interaction between a particular channel and an anaesthetic cannot provide a basis for a general mechanism of anaesthesia. Ethanol, for example, potentiates GABA binding and inhibits NMDA receptors, making more pathways possible for the clinically observed effects. An imidazobenzodiazepine inverse agonist, Ro15-4513 (ethyl-8-azido-5,6-dihydro-5-methyl-6-oxo-4H-imidazo [1,5α] [1,4] benzodiazepine-3-carboxylate) however, selectively blocks ethanol-stimulated Cl$^-$ uptake[14] and many of the behavioural effects[15 16].

Mice rendered tolerant to nitrous oxide also exhibit cross-tolerance to ethanol hypnosis[17], suggesting a similarity in mode of action between these two drugs. This study was undertaken to see if nitrous oxide-induced neuronal depression can be altered by a benzodiazepine inverse agonist. Changes in neuronal excitability induced by nitrous oxide and Ro15-4513 were measured in this study by visual evoked potentials (VEP). This method was used previously for monitoring the central effects of nitrous oxide in humans[18] and animals[19 20]. All of these studies showed that VEP is a reliable method for measurement of nitrous oxide-induced neuronal depression.

Materials and methods

We used male adult albino Wistar rats, weighing 250–300 g. Each rat was placed in a separate cage

and provided with food and water *ad libitum*. The holding room was maintained at approximately 22°C, 50% humidity and a 12-h light–dark cycle (light on at 08:00). The animals were allowed at least 7 days for adaptation to these circumstances before surgery. Before electrode placement, the rats were anaesthetized with Hypnorme 0.15 ml 100 g^{-1} (Hypnorme=fluanison 10 mg and fentanyl 0.2 mg ml^{-1}).

Individual stainless steel screw electrodes were implanted surgically over the right and left visual cortices at points 7 mm posterior to the bregma and 3 mm lateral to the midline. A reference electrode was placed in the frontal sinus. The electrodes were soldered to a miniature socket, which was fixed to the skull with dental cement. After a 7-day postoperative recovery period, each rat was habituated to the recording procedure. The experiments and habituation were performed with rats moving freely and housed in an exposure chamber which was maintained at a temperature of 22 °C. The exposure chamber was made of glass surrounded on all sides by mirrors except for the top where the flash-lamp was placed. This allowed complete illumination of the exposure chamber in all directions. During habituation, the electrode leads were connected and a flash stimulus was induced once every 7 s for 10 min. Such treatment was repeated daily over the following 3–4 days, until VEP discharges stabilized. Previous studies have shown that under these conditions, VEP discharges stabilize after several days[21]. During the experiments the flashlight was triggered by a Grass S44 stimulator at a frequency of 0.14 Hz. Brain responses were amplified with a Grass model 79 B, connected to an analogue-to-digital converter (Lab Master, Scientific solutions Inc., OH, USA), which was triggered by the Grass S44 stimulator after every flashlight. A computer connected to the analogue-to-digital converter performed the averaging of 25 VEP over an 800-ms epoch after every flashlight and printed the results. Potentials less than −500 µV or more than +500 µV were defined as artefacts induced by movement and rejected automatically. With a few rejections per measurement a typical recording of one averaged VEP lasted for approximately 3 min. VEP discharges were recorded in animals breathing air before exposure to 70% nitrous oxide–30% oxygen.

A concentration of 70% nitrous oxide was selected because in many studies of nitrous oxide-induced dependence phenomena in animals[22] or nitrous oxide-induced changes in evoked potentials in humans[23], the same or a similar concentration of nitrous oxide was used. In addition, a concentration of 70% nitrous oxide is used frequently during clinical anaesthesia. While exposed to nitrous oxide for 60 min, i.p. administration of drug (Ro15-4513 10 mg kg^{-1}) or vehicle (Tween 0.3%, volume 1 ml) was given. VEP were measured at intervals of 15 min for the following 45 min. During the recording session the animal was observed closely to ensure that recording was performed while the eyes were open. The flashlight itself was usually enough to alert the animal. Nitrous oxide, oxygen and carbon dioxide were monitored during the experiment with a Datex Capnomac Ultima (Datex Instrumentarium Corp., Helsinki, Finland). Nitrous oxide was withdrawn by exposing the animals to air. Tween was obtained from Sigma Chemical Co (St Louis, MO, USA) while Ro15-4513 was obtained from Hoffmann-La Roche. A VEP during the first 500 ms normally includes three positive–negative component complexes. Peak-to-peak amplitudes and peak latency were determined. Peak-to-peak amplitudes obtained during exposure to nitrous oxide were compared with values recorded while the rats were breathing air. Data are presented as mean (SEM); *n*=number of animals tested. Significance of differences in mean values was examined by analysis of variance (ANOVA) (P<0.05).

Results

An example of a visual evoked potential response in one rat, in air, is shown in figure 1. The typical evoked potential is characterized by six waves, labelled P1 to N3. As the baseline may vary throughout the experiment we looked at top-to-top amplitudes. Although all top-to-top amplitudes showed a decrease when the rat was exposed to nitrous oxide[20], only potentials with a latency of 100 ms or more were studied because of their stability. Therefore, only amplitudes P2-N2, N2-P3 and P3-N3 were studied.

To asses the effects of Ro15-4513 without the interference of nitrous oxide, a group of eight rats, while breathing air, was given Ro15-4513 10 mg kg^{-1} in 0.3% Tween i.p. Top-to-top amplitudes are shown in figure 2. After obtaining control measurements, an i.p. injection was given (arrow in fig. 2) and the first

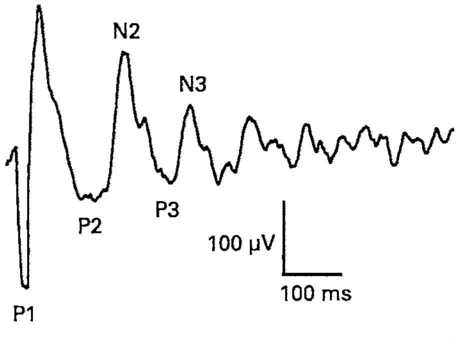

Figure 1 An example of a visual evoked potential (VEP) in one rat while the animal was breathing air. Amplitude peaks are marked P1 to N3.

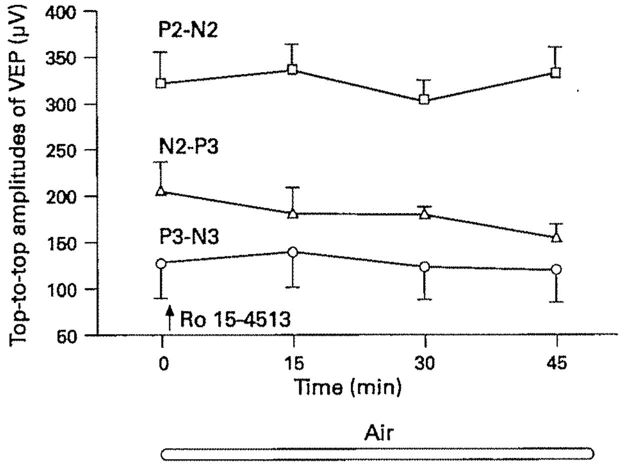

Figure 2 Top-to-top values P2-N2 (□), N2-P3 (△) and P3-N3 (○) were not influenced by injection of Ro15-4513 10 mg kg^{-1} (arrow) while the animals breathed air (*n*=8).

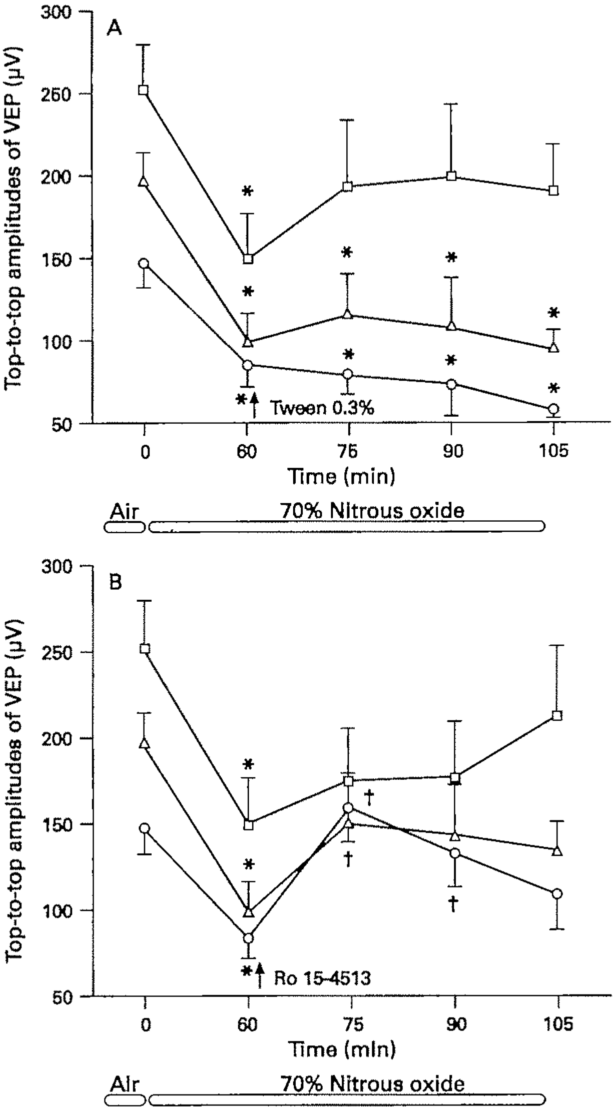

Figure 3 Peak-to-peak amplitude values of VEP (P2-N2 (□), N2-P3 (△) and P3-N3 (○)) in rats (n=20) during exposure to air and 70% nitrous oxide. A: Amplitude values after injection (arrow) with the solvent Tween while animals were breathing nitrous oxide (n=10). Note that N2-P3 and P3-N3 did not recover to normal values while P2-N2 showed a tendency towards recovery. B: Normalization of amplitude values towards those obtained during exposure to air after injection of Ro15-4513 (n=10). *P<0.05 compared with initial values obtained in air; †P<0.05 compared with values obtained after 60 min exposure to nitrous oxide.

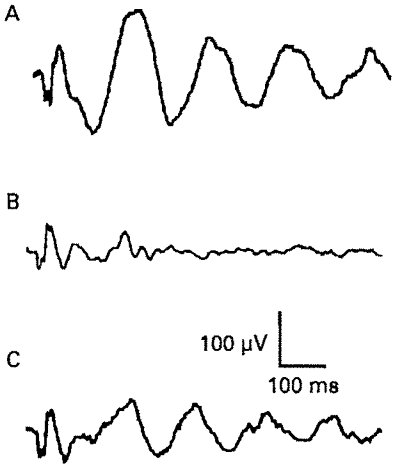

Figure 4 Three VEP measurements in one rat. A: VEP during breathing air. This is an example of a normal VEP after some training of the animal and habituation to the flashlight. B: VEP measured while the animal was breathing 70% nitrous oxide in oxygen (note marked depression of amplitudes with a long latency). C: VEP measured while the animal was exposed to nitrous oxide but 15 min after injection of Ro15-4513.

VEP after injection was measured 15 min later. No significant changes in top-to-top amplitudes were observed within 45 min after administration of Ro15-4513 and no change in general behaviour was observed.

Figure 3A and 3B depicts top-to-top amplitudes of 20 rats showing an expected depression of all three amplitudes after 60 min of exposure to nitrous oxide compared with values obtained in air (control values)[20]. While breathing nitrous oxide, 10 animals were given the solvent 0.3% Tween 1 ml i.p. (arrow in fig. 3A) while others received Ro15-4513 (fig. 3B). In the following 45 min VEP were measured at 15-min intervals in both groups. Animals given Tween showed no normalization of amplitudes towards values obtained in air, except for P2-N2. As this top-to-top amplitude proved to be sensitive to handling or i.p. injection of solvent, or both, it was not evaluated further. After administration of Ro15-4513, however, top-to-top values for N2-P3 and P3-N3 increased significantly compared with values obtained after 60 min exposure to nitrous oxide. Additionally, all observed amplitudes recovered to values that were not significantly different from baseline. Administration of nitrous oxide and i.p. injection of the solvent Tween or Ro15-4513 had no influence on latency (not shown).

Figure 4 shows examples of three VEP measurements in one rat. The first VEP (fig. 4A) was measured while the animal was breathing air. Pronounced depression of the VEP amplitudes could be observed when rats were exposed to nitrous oxide (fig. 4B). The last VEP (fig. 4C), was measured in the same animal, still breathing nitrous oxide, but 15 min after i.p. injection of Ro15-4513 10 mg kg^{-1}.

An additional observation was that after injection of Ro15-4513, animals showed increased activity caused by rotational behaviour, which did not occur in rats while breathing air but was common in rats exposed to nitrous oxide. Therefore, although aroused, the animals did not behave normally until exposure to nitrous oxide was discontinued.

Discussion

The mechanism of action of inhalation anaesthetic agents remains obscure, although there is substantial evidence that at least part of the effects may be explained by potentiation of the GABAergic system[5,24]. The role of the GABAergic system on the effects produced by inhalation of nitrous oxide has, to our knowledge, never been explored. When involvement of the GABAergic system is investigated, and particularly when the benzodiazepine site of the GABA receptor complex is of interest, a benzodiazepine antagonist or inverse agonist, or both, may be used. Using an antagonist such as flumazenil (Ro15-1788) may give results easier to interpret compared with inverse agonists. Unfortunately, flumazenil has some intrinsic activities. This drug decreased the minimum alveolar concentration of isoflurane in dogs when given i.v., suggesting partial agonist activity[25]. In addition, flumazenil was unable to alter methoxyflurane-induced sleep time in mice, but antagonized the reduction in sleep time produced by Ro15-4513[26]. This combined with unfavourable pharmacokinetics[27] made a study with flumazenil, in freely moving rats, unsuitable. Our control experiments showed that Ro15-4513 did not have any effect on the VEP when given at a concentration of 10 mg kg^{-1} (fig. 2). The same concentration of Ro15 4513, however, reversed the changes in VEP induced by nitrous oxide (fig. 3B). The fact that the animals persisted in their unusual rotational behaviour suggests that this reversal in nitrous oxide-induced anaesthesia was only partial, although with regard to VEP, complete reversal was obtained. Higher concentrations of Ro15-4513 may have produced further improvement towards normal behaviour but would make interpretation less obvious as higher concentrations have epileptogenic properties.

In summary, our results indicated that neuronal depression induced by nitrous oxide was sensitive to antagonism by Ro15-4513. In this respect nitrous oxide resembles alcohol and other inhalation anaesthetics. Although the precise interaction between nitrous oxide and the GABA receptor is not clear, our results indicate that at least part of the decreased neuronal excitability caused by nitrous oxide could be ascribed to interactions with a binding site on the $GABA_A$ receptor complex.

Acknowledgement

We thank Dr Eran Geller and Dr Joze Rupreht for their interest and helpful comments during the experiments. Dr Bert Van Duijn is acknowledged for his interest, encouragement and critical reading of the manuscript.

Pancuronium increases pulmonary arterial pressure in lung injury

H. Du, R. Orii, Y. Yamada, M. Hayashita, N. Kin, K. Suwa and K. Hanaoka

Summary

We studied 25 mongrel dogs who were anaesthetized and their lungs ventilated for investigation of the effects of pancuronium on pulmonary arterial pressure (PAP) in the normal lung, in oleic acid-induced lung injury and in lung injury with hypoxaemia. In the normal lung, PAP was not affected by pancuronium. During lung injury, however, PAP was increased from 21.5 (SD 2.8) to 24.6 (4.2) mm Hg ($P<0.01$) and from 22.0 (4.2) to 27.0 (5.8) mm Hg ($P<0.01$) after pancuronium 0.08 mg kg^{-1} and 0.16 mg kg^{-1}, respectively, and from 26.0 (2.9) to 37.1 (3.1) mm Hg after pancuronium 0.16 mg kg^{-1} when hypoxaemia was present ($P<0.01$). The increase in PAP induced by pancuronium was associated with increases in cardiac output and pulmonary vascular resistance. Pretreatment with phentolamine attenuated the pancuronium-induced increase in PAP. The increase in PAP induced by pancuronium was also reduced by vagotomy. If these results in dogs are relevant clinically, then pancuronium should be avoided as a neuromuscular blocker in lung injury. (*Br. J. Anaesth.* 1996;**77**:526–529)

Key words

Neuromuscular block, pancuronium. Lung, damage. Lung, intravascular pressures. Dog.

Pancuronium increases heart rate and systemic arterial pressure in both humans and animals. It has been shown that these increases result from the vagolytic effect of pancuronium on the heart[1 2] and its indirect sympathomimetic effect[3–5]. Pancuronium also changes airway resistance. When administered at low doses (less than 0.14 mg kg^{-1}), pancuronium enhances the increase in airway resistance induced by vagal stimulation, which is thought to be the effect of block of muscarinic receptor subtype 2 (M_2) by pancuronium. When administered at larger doses, pancuronium attenuates the increase in airway resistance, which is thought to be the effect of block of muscarinic receptor subtypes 1 and 3 (M_1 and M_3)[6 7]. The effects of pancuronium on the pulmonary circulation, however, have not received much attention. In the pulmonary circulation, M_1, M_2 and M_3 receptors have been identified in both humans and animals[8]. Recently, Altiere and colleagues[9] and McCormack and colleagues[10] have shown, using isolated pulmonary arterial strips, that the pulmonary circulation is functionally innervated by M_3 receptors, and M_3 antagonists contracted acetylcholine-dilated pulmonary arteries.

Therefore, we have investigated the changes in pulmonary arterial pressure in response to pancuronium in normal lung and in oleic acid-induced lung injury in dogs. The possible neural mechanism in the responses were also investigated.

Materials and methods

The study was approved by the Animal Care Committee of the University of Tokyo.

Adult mongrel dogs of both sexes (10–13 kg) were sedated with ketamine 100 mg i.m. Anaesthesia was induced with α-chloralose 100 mg kg^{-1} and urethane 100 mg kg^{-1} i.v. The lungs were ventilated via a tracheostomy using a Harvard respirator (Model 618). Tidal volume was adjusted to maintain an arterial $P\text{CO}_2$ of 4.8–5.6 kPa at a rate of 16 bpm at baseline. Ventilator settings were not changed during the experiment, except the inspired fraction of oxygen ($F\text{I}_{\text{O}_2}$), as described below. Anaesthesia was maintained with α-chloralose 25 mg kg^{-1} and urethane 25 mg kg^{-1} i.v. when necessary. Lactated Ringer's solution was infused at a rate of 3 ml kg^{-1}. Dextran 40 was infused within the first hour after injection of oleic acid to maintain systolic systemic arterial pressure greater than 90 mm Hg.

The femoral artery was cannulated for measurement of mean arterial pressure (MAP) and sampling of arterial blood. Arterial blood-gas tensions were measured using an automatic blood-gas analyser (Stat Profile 3, Nova, MA, USA). A Fr.5 balloon-tipped pulmonary artery catheter was advanced into the pulmonary artery via the femoral vein for measurement of pulmonary arterial pressure (PAP), pulmonary arterial wedge pressure (PAWP), cardiac output (CO) using the thermodilution method (MTC-6210, Nihon Kohden), and for injection of oleic acid into the central vein. The correct positioning of the pulmonary artery catheter was confirmed by PAP wave and verified further by postmortem examination. Heart rate was monitored (ECG lead II) and pulmonary vascular resistance (PVR) was calculated using the formula: PVR=(PAP−PAWP)/CO (mm Hg $litre^{-1}$ min^{-1}).

Accepted for publication: May 22, 1996.

Correspondence to: H. D.

After the experimental preparation, the dogs were placed in the prone position. Oleic acid 0.12 ml kg^{-1} (Sigma) was infused into the central vein within 1 min. Arterial blood-gas tensions were measured every 30 min thereafter. Pa_{O_2}/FI_{O_2} was used as the parameter of the severity of lung injury. The effects of pancuronium during lung injury were tested only when Pa_{O_2}/FI_{O_2} was within 100–140. If Pa_{O_2}/FI_{O_2} remained greater than 140 at 3 h after the first dose of oleic acid, further oleic acid (0.06 ml kg^{-1}) was given.

Twenty-five dogs were allocated to one of four groups.

Group I: effects of pancuronium on PAP in the normal lung, during lung injury and during lung injury with hypoxaemia (*n*=10). After the experimental preparation, baseline measurements, including PAP, MAP, HR and arterial blood-gas tensions, were undertaken with an FI_{O_2} of 0.21. The effects of i.v. pancuronium (Sankyo, Tokyo, Japan) 0.08 mg kg^{-1} and 0.16 mg kg^{-1} were investigated in an alternate sequence. The injections of two doses were separated by more than 90 min. FI_{O_2} was then increased to maintain Pa_{O_2} greater than 12 kPa while lung injury was induced by oleic acid. During lung injury, when Pa_{O_2}/FI_{O_2} was 100–140, the effects of pancuronium i.v. at the two doses were investigated as was done in the normal lung. FI_{O_2} was then decreased to produce a Pa_{O_2} of 6–8 kPa (hypoxaemia). The effects of pancuronium 0.16 mg kg^{-1} were studied during lung injury with hypoxaemia.

Group II: effects of pancuronium on cardiac output and pulmonary vascular resistance in lung injury (*n*=5). Lung injury was induced as in group I while FI_{O_2} was increased to maintain Pa_{O_2} greater than 12 kPa. The effects of pancuronium 0.16 mg kg^{-1} were investigated during lung injury. The maximum increase in PAP within 60 s after administration of pancuronium was recorded. CO was then measured using thermodilution, followed immediately by measurement of PAWP. The value of PAWP was read from a pre-calibrated recorder chart (paper speed=10 mm s^{-1}), 15 s after inflation of the pulmonary artery catheter balloon at the end of expiration. Consequently, measurements of PAP, CO and PAWP were finished within 2.5 min after administration of pancuronium in all animals. Calculation of PVR using PAP, PAWP and CO at different times may introduce some error. This was minimal as in preliminary experiments we found the influence of pancuronium 0.16 mg kg^{-1} on PAP, CO, and PAWP remained stable for more than 3 min, and a cardiac output monitor with good reproducibility (*n*=10, coefficient of variance=4%) was used.

Group III: influence of pretreatment with an α adrenergic blocker on the pancuroniuminduced increase in PAP (*n*=5). Lung injury was induced as in group II. The effects of pancuronium 0.16 mg kg^{-1} were then investigated. Eighty minutes later, phentolamine 2 mg kg^{-1} (Ciba-Geigy, Swiss) was administered into the central vein over 60 s. The effects of pancuronium 0.16 mg kg^{-1} were investigated again 10 min after injection of phentolamine.

Group IV: influence of vagotomy on the pancuronium-induced increase in PAP (*n*=5). One hour after the effects of pancuronium 0.16 mg kg^{-1} during lung injury were investigated as in group II, bilateral vagotomy was performed at the level of the first tracheal ring. The effects of pancuronium 0.16 mg kg^{-1} were investigated 30 min after vagotomy.

DATA ANALYSIS

All values are expressed as mean (SD), and statistical difference was accepted at $P<0.05$. Variables before administration of pancuronium were compared with those after pancuronium by paired Student's *t* test. In groups III and group IV, the increase in PAP induced by pancuronium during normal innervation was compared with that under the conditions of α block or vagotomy using the paired Student's *t* test.

Results

EFFECTS OF PANCURONIUM ON PAP IN NORMAL LUNG AND LUNG INJURY

In the normal lung, pancuronium had no significant effect on PAP, MAP or HR. During lung injury, however, pancuronium 0.08 mg kg^{-1} and 0.16 mg kg^{-1} increased PAP by 3.1 mm Hg and 5.0 mm Hg, respectively ($P<0.01$). HR was also increased significantly by both doses of pancuronium ($P<0.01$). The increase in PAP induced by pancuronium lasted for 3–10 min. During lung injury with hypoxaemia (Pa_{O_2} 6.8 (0.5) kPa), pancuronium 0.16 mg kg^{-1} increased PAP by 11.1 mm Hg ($P<0.01$), which lasted 5–15 min (fig.1, table 1).

EFFECTS OF PANCURONIUM ON CARDIAC OUTPUT AND PULMONARY VASCULAR RESISTANCE IN LUNG INJURY

The pancuronium-induced increase in PAP during lung injury was associated with simultaneous increases in CO ($P<0.05$) and PVR ($P<0.01$) indicat-

ing that the increase in PAP resulted from both an increase in pulmonary blood flow and contraction of the pulmonary circulation. PAWP did not change significantly after pancuronium (table 2).

INFLUENCE OF PRETREATMENT WITH PHENTOLAMINE OR VAGOTOMY ON THE PANCURONIUMINDUCED INCREASE IN PAP

Pretreatment with the α blocker, phentolamine, decreased the pancuronium-induced increase in PAP ($P<0.05$). PAP immediately before administration of pancuronium was not significantly different from that immediately before phentolamine administration ($P>0.05$). In contrast, the increase in PAP by pancuronium after vagotomy was less than that before vagotomy ($P<0.05$). Vagotomy itself consistently increased PAP, from 21.1 (8.7) to 24.2 (11.0) mm Hg ($P<0.05$) (fig. 2).

Discussion

The results of this study showed that during lung injury, pancuronium increased pulmonary arterial pressure, especially when there was hypoxaemia. In group II, PAWP did not change when PAP was increased by pancuronium. Pulmonary capillary pressure, therefore, should increase according to the equation of Gaar and colleagues[11]. As a small increase in pulmonary intravascular pressure accelerates fluid outflux into lung interstitium and worsens lung injury in permeability lung injury[12], if our results are clinically relevant we suggest that pancuronium should be avoided as a neuromuscular blocker in lung injury.

Table 2 Effects of pancuronium during pulmonary oedema (mean (SD)) (n=5). PVR	9.6 (3.5)	12.6 (3.6)**

In our study, the increase in PAP in response to pancuronium was attenuated by pretreatment with an α adrenergic blocker. This suggests that high activity in α adrenergic nerves plays a role in the pancuronium-induced increase in PAP. Pancuronium has been shown to be an indirect sympathomimetic agent. It stimulates the release of catecholamines from nerve endings and inhibits neuronal uptake of noradrenaline[3, 4]. Administration of pancuronium may also increase plasma catecholamine concentrations[5]. In contrast, inhibition of the pancuronium-induced increase in PAP by pretreatment with an α blocker in our study was not complete. The increase in PAP induced by pancuronium decreased from 6.6 (2.7) mm Hg to 2.5 (0.9) mm Hg after administration of phentolamine. Therefore, there may be some other pathway by which pancuronium increases PAP.

Pancuronium is known to possess vagolytic effects by inhibiting muscarinic receptors[1, 2]. If the pancuronium-induced increase in PAP were not related to the vagus nerve, the increase in PAP by pancuronium before vagotomy would be same as that after vagotomy. In contrast, if the vagal pathway were the only route by which pancuronium increased PAP, there would be no change in PAP induced by pancuronium after vagotomy. In our study, the increase in PAP produced by pancuronium was 3.4 (1.9) mm Hg after vagotomy compared with 5.9 (3.5) mm Hg before vagotomy ($P<0.05$). It may be considered that the vagus plays some role in the pancuronium-induced increase in PAP.

Block of muscarinic receptors by pancuronium may involve both the heart and pulmonary circulation. The increase in cardiac output has been suggested to be the result of inhibition of atrial muscarinic receptors[1, 2]. The increase in PVR in this study, on the other hand, indicates that block of muscarinic receptors in the pulmonary circulation may also be involved in the pancuronium-induced increase in PAP. In the lungs, muscarinic receptors consist of at least three subtypes, M_1, M_2 and M_3 receptors[8]. Using isolated pulmonary arterial strips,

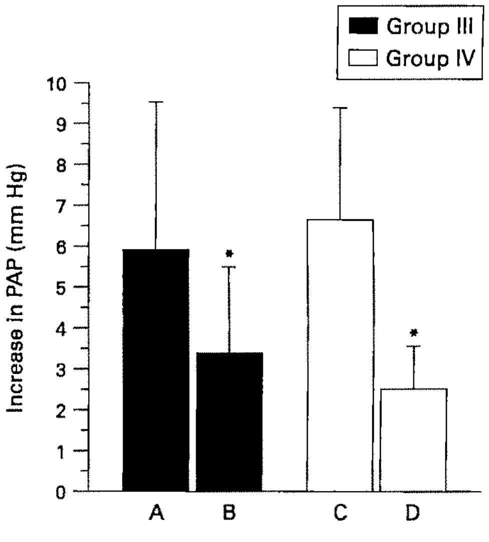

Figure 2 Increase in pulmonary arterial pressure (PAP) caused by pancuronium 0.16 mg kg^{-1} before administration of α blocker (A), after administration of α blocker (B), before vagotomy (C) and after vagotomy (D) during lung injury. *$P<0.05$ compared with before administration of α blocker or before vagotomy.

it has been found recently that the pulmonary circulation is functionally innervated by M_3 receptors and M_3 antagonists contracted acetylcholine-dilated pulmonary arteries[9 10]. We have also shown that vagotomy increased PAP in lung injury in another study[13] and in group IV in this study. As vagal activity is increased in lung injury[14] and vagotomy increased PAP during lung injury but did not alter PAP in the normal lung[13], we infer that muscarinic inhibition by pancuronium also increased PAP in lung injury *in vivo*. It is not known what muscarinic receptor subtype is responsible for the pancuronium-induced increase in PAP. However, as block of M_3 receptor causes constriction of the pulmonary artery[9 10] and large doses of pancuronium may block M_3 receptors in the airway[6], M_3 receptor involvement is likely at the doses used in this study.

Efficacy of intraoperative heat administration by ventilation with warm humidified gases and an oesophageal warming system

E. BECK, M. LANGER, P. DI MAURO AND P. PRATO

Summary

We measured changes in body temperature in 12 hypothermic (mean aural temperature 34.4 (SD 1.0) °C) pigs during general anaesthesia with an open abdominal cavity and the effect of two warming systems: heating of inspired gases to 39 °C (intratracheal temperature) and oesophageal warming to 39 °C by a water perfused oesophageal heat exchanger. Each animal underwent both treatments and the control period in random sequence. Each condition was studied over 1 h. No additional protection against heat loss (drapes, blankets, i.v. fluids warming, etc.) was used. Anaesthesia, room temperature and relative humidity, amount and temperature of infusions and extension of exposed visceral surfaces were standardized. Mean decrease in body temperature was 1.0 (0.7) °C ($P<0.005$) without warming and 0.6 (0.2)°C ($P<0.005$) with heated inspired gases: this difference was not statistically significant. Oesophageal warming was very efficient as mean body temperature did not change significantly (–0.1 (0.2) °C; ns). (*Br. J. Anaesth.* 1996;**77**:530–533)

Key words

Anaesthetic techniques, hypothermia. Equipment, warming devices. Temperature, body. Temperature, monitoring. Temperature, effects. Pig.

Mild hypothermia is relatively frequent during and after surgery under general anaesthesia. Several factors contribute to body heat loss: inhibition of the hypothalamus, peripheral vasodilatation induced by anaesthetic agents, paralysis, exposure of the viscera to the atmosphere and large amounts of i.v. infusions at room temperature. Mild hypothermia is not generally a problem during operation. However, in the immediate postoperative period, activation of some physiological mechanisms of thermogenesis (metabolic heat production, muscles activity, shivering) with a consequent increase in oxygen consumption and peripheral vasoconstriction are untoward and may even be harmful in patients with impaired cardiovascular reserve[1 2]. Moreover, hypothermia has been implicated in some cases of delayed recovery from general anaesthesia[3].

Several methods are commonly used to reduce body heat loss. Heating inspired gases[4–8] and oesophageal warming[9–11] are easily applied during surgery and have been proposed for providing (central) warming, which is probably more "physiological" than other methods which deliver heat peripherally (warming the operating room, warm mattresses, thermal blankets, infrared heating lamps, forced air warmers[1–2 12–18]).

The aims of this study were: to evaluate, in an animal model, under strictly controlled conditions, changes in body temperature during general anaesthesia with an open abdominal cavity, with standardization of most confounding factors such as anaesthesia, room temperature, amount and temperature of infusions, and extension of exposed visceral surfaces; to evaluate, in the same controlled conditions, the efficacy of two warming systems (heating inspired gases and oesophageal warming) in reducing body heat loss.

Materials and methods

After obtaining approval from the Ethics Committee of our institution, we studied 12 female, 3-month-old White Landrace pigs, weighing 18.4 (SD 1.2) kg. These animals were chosen as, among non-primate laboratory animals, the pig is the most comparable with adult humans[19].

Each animal underwent three study periods (control; heating of inspired gases; oesophageal warming) in a randomized sequence according to a Latin square design. The sample size was based on the results of an unpublished pilot study, by assuming a type I error (α) of 0.05 and a type II error (β) of 0.2, taking into account the randomization design and the statistical analysis method (repeated-measures analysis of variance)[20].

Anaesthesia was induced with thiopentone 5 mg kg^{-1} and maintained with 1.5% enflurane and fentanyl 2–3 μg kg^{-1} h^{-1}. Neuromuscular block was produced with pancuronium 50–60 μg kg^{-1} h^{-1}. Mechanical ventilation (Servo ventilator 900A, Elema, Schönander, Sweden) via a tracheostomy was set at 3.8–4.2 litre min^{-1} to maintain a Pa_{CO_2} of 4.7–6.0 kPa. The total inspiratory time was 35% (25% inspiration+10% inspiratory pause).

A carotid artery catheter and a 5-French gauge pulmonary artery catheter were inserted for haemodynamic monitoring and blood sampling. Arterial pressure (AP), pulmonary artery pressure (PAP), central venous pressure (CVP) and pulmonary

EDUARDO BECK, MD, MARTIN LANGER, MD, PIERO DI MAURO, MD, PAOLO PRATO, MD, Istituto di Anestesiologia e Rianimazione, IRCCS Ospedale Maggiore di Milano, Via F. Sforza 35-20122 Milano, Italy. Accepted for publication: May 23, 1996.

wedge pressure (PWP) were measured with HP 1290A pressure transducers and a 78354A monitor (Hewlett Packard GmbH, Böblingen, Germany). Cardiac output (CO) was measured by thermodilution (mean of three measurements at expiratory pause) with a 9520A CO computer (Edwards, Santa Ana, CA, USA). Blood pH, $P\text{co}_2$ and $P\text{o}_2$ were determined with an IL1302 analyser, and haemoglobin and oxygen saturation with an IL802 co-oximeter (Instrumentation Laboratory, Milano, Italy).

Room, oesophageal, tracheal and aural temperatures, and four cutaneous temperatures (anterior leg (A), nipple (B), thigh (C) and calf (D)) were monitored with an MC9200 electronic thermometer (Exacon, Roskilde, Denmark) using site-specific probes (Exacon, Roskilde, Denmark). Relative humidity of the room was measured with a standard hygrometer.

I.v. infusions (at room temperature) were standardized at 10 ml kg^{-1} h^{-1}. A laparotomy was performed with standardized partial exposure of the viscera. The surgical drapes were then removed and the animal was left exposed to the environment.

Each animal underwent three conditions in randomized sequence.

(1) Inspired gases were warmed and saturated using a Kontron Pearl Humidifier 4150 (Kontron Instruments, Milan, Italy) modified to exceed the 37 °C temperature limit. The humidifier was adjusted to obtain an inspiratory tracheal temperature of 39±0.5 °C. The tracheal temperature probe also allowed measurement of end-expiratory gas temperature. The inspiratory branch of the ventilator circuit was wrapped in aluminium sheets. The oesophageal heat exchanger was not in place. The 60-min study started as soon as the inspiratory tracheal temperature was stabilized at 39±0.5 °C for at least 5 min.

(2) The oesophageal warmer is composed by a water perfused oesophageal heat exchanger and a water heating pump (water flow 4 litre min^{-1}) with a built-in thermostat adjustable up to 42 °C (Thermal Therapy System (TTS) TT8200, Exacon, Roskilde, Denmark). The oesophageal heat exchanger consists of a light rigid inner supply tube, surrounded by a 50-cm long, non-elastic and thin-walled outer tube (surface area ~0.05 m^2). Distilled water is circulated through the inner tube to the tip, fills up the entire volume of the outer tube and returns to the pump through the proximal end of the oesophageal tube. After the oesophageal heat exchanger was placed, the system thermostat was set to obtain an oesophageal temperature of 39±0.5 °C. A Kontron Pearl Humidifier 4150 (Kontron Instruments, Milan, Italy) at room temperature was used in the ventilator circuit. The 60-min study started as soon as oesophageal temperature was stabilized at 39±0.5 °C for at least 5 min.

(3) No warming systems were used. The oesophageal heat exchanger was not in place and the Kontron humidifier was at room temperature.

Temperature, haemodynamic measurements and blood samples were obtained at the beginning (pre) and end (post) of each 60-min study period. The following variables were calculated:

Mean skin temperature (MST) according to Ramanathan's formula[21]:

$$\text{MST }(^\circ\text{C})=0.3\times(T\text{A}+T\text{B})+0.2\times(T\text{C}+T\text{D})$$

Mean body temperature (MBT) according to Colin and colleagues' formula[22]:

$$\text{MBT }(^\circ\text{C})=0.66\times T\text{aural}+0.34\times\text{MST}$$

Total body heat (TBH) relative to 0 °C according to Burton's formula[23]:

$$\text{TBH (kJ)}=\text{MBT}\times3.47\times\text{body weight (kg)}$$

Oxygen consumption ($\dot{V}\text{o}_2$) according to Fick's equation:

$$\dot{V}\text{o}_2\ (\text{ml min}^{-1})=10\times Ca_{O_2}-Cv_{O_2}\ (\text{ml 100 ml}^{-1})\times\text{CO (litre min}^{-1})$$

Right to left shunt fraction ($\dot{Q}\text{va}/\dot{Q}\text{t}$) according to the following equation:

$$\dot{Q}\text{va}\dot{Q}/\text{t}=(Cc'_{O_2}-Ca_{O_2})/(Cc'_{O_2}-Cv_{O_2})$$

where Cc'_{O_2}(ml 100 ml^{-1})=1.34×Hb (g 100 ml^{1})+0.003×($P\text{I}_{O_2}$ (mm Hg)− $P\text{a}_{CO_2}$ (mm Hg); Ca_{O_2} (ml 100 ml^{-1})=1.34×Hb×$S\text{a}_{O_2}$ (fraction)+0.003×$P\text{a}_{O_2}$ (mm Hg); and Cv_{O_2} (ml 100 ml^{1})=1.34×Hb× $S\bar{v}_{O_2}$ (fraction)+0.003×$P\bar{v}_{O_2}$ (mm Hg).

At the end of the experiment, specimens of tracheal and oesophageal wall were obtained to detect possible heat-related damage[24].

Statistical analysis was performed using the SAS/GLM procedure, release 6.03 (SAS Institute Inc., Cary, NC, USA) on a AST Bravo LC 3/33s personal computer (AST Research, Inc., Irvine, CA, USA).

Results

Each animal completed both treatments and the control period.

Data for all measured variables at the beginning (pre) of each 60-min condition, and differences between the beginning and final values (post–pre) are shown in table 1. Pre values were not significantly different between the three conditions.

Room temperature and relative humidity were monitored continuously and did not change significantly during the experiment. All measured temperatures and derived variables (MST, MBT and TBH) decreased significantly under both control ($P<0.005$) and warm inspired gas ($P<0.005$) conditions. With oesophageal warming, only cutaneous temperature A (anterior leg) showed significant variations.

As shown by the variation in all measured body temperatures and derived variables, heat loss was significantly greater during the control period than during oesophageal warming, while the difference between the control period and that during warming of inspired gases was not statistically significant, except for nipple temperature (B) and MST (table 1).

$\dot{V}\text{o}_2$ decreased significantly ($P<0.001$) by 8–15% during the control period and during the two treatments (table 1), but there were no significant differences between the three conditions. $\dot{Q}\text{va}/\dot{Q}\text{t}$ did not change significantly and there were no differences between the three conditions.

The animals were haemodynamically stable throughout the experiment.

There were no pathological changes at the histological examination of both tracheal and oesophageal walls at the end of the study.

Discussion

There have been several clinical studies on the effects of different warming systems in preventing perioperative hypothermia with controversial results. Both heating of inspired gases and oesophageal warming have been demonstrated as either effective and ineffective in different studies[4-11]. The "within study" and "between studies" variability of the experimental conditions (patients, type of surgery, type of anaesthesia, fluid infusions, room temperature and relative humidity, etc.) makes it difficult to compare these studies.

In our study such confounding factors were standardized and controlled carefully. Moreover, in order to maximize the differences between treatment and control conditions, we chose to avoid any system used clinically to reduce heat loss (drapes, warming of i.v. fluids, etc): during the experiment our animals became hypothermic more quickly than usually seen in anaesthetic practice (approximately 0.5 °C h^{-1}[25]). This greater heat loss may also have resulted from the smaller body size and mass of our animals compared with an adult human.

The mean decrease in temperature (aural and the four cutaneous temperatures) was approximately 1 °C h^{-1} without warming. Mean body temperature (MBT), calculated according to the formula used in humans, reflects very well this heat loss. Some may argue that the derived variables (MST, MBT and TBH) may not be quantitatively accurate because they were computed using formulae developed for humans and which might not apply to pigs. However, as we were interested in evaluating variations rather than absolute values for each condition, we believe that our results are not invalidated by the use of human formulae.

Our study clearly showed the efficacy of oesophageal warming in attenuating the decrease in MBT and TBH. Warming of inspired gases was not as effective and the reduction in heat loss was not statistically significant. The variation in efficacy may be explained by important differences in the way the two systems work. Heat transport is much higher for oesophageal warming (~5000 kJ h^{-1} from 34 to 39 °C at a water flow of 4 litre min^{-1}) than for warming of inspired gases (~8 kJ h^{-1} from 34 to 39 °C at $\dot{V}e$=4 litre min^{-1}[26]) because of the low specific heat of air compared with water. This difference appears to be important in overcoming the larger heat exchange area during warming of inspired gases (trachea and large bronchi)[27] and probably higher heat transfer efficiency of the respiratory system (as suggested by the small difference between the temperature of the expired gas and core temperature). The technical characteristics of oesophageal warming did not allow measurement of the temperature at the outlet of the oesophageal heat exchanger and consequently calculation of net heat transfer during oesophageal warming. However, the large amount of heat transported during oesophageal warming (~5000 kJ h^{-1}) would have resulted in a greater temperature change if efficiently transferred to the body.

There were no side effects in our study. Heat damage to the tracheal and oesophageal walls was not demonstrated at histological examination or by deterioration in respiratory function ($\dot{Q}va/\dot{Q}t$).

Oesophageal warming requires a specific device but it is easily used and has no complications. It is not only the most effective non-invasive core-warming system that can be used during operation, but it may also be used successfully in other non-surgical situations of severe accidental hypothermia (exposure, cold water immersion, etc.).

Extraction of nitric oxide and nitrogen dioxide from an oxygen carrier using molecular sieve 5A

B. B. Poulton, L. Foubert, J. Klinowski, R. D. Latimer, P. R. Knowles and A. Vuylsteke

Summary

Nitric oxide (NO) is effective in the management of pulmonary hypertension and shunt-related hypoxia. Nitrogen dioxide (NO_2) is formed when the gas is delivered with oxygen. Both oxides of nitrogen have well recognized adverse effects. The scavenging properties of several forms of soda lime have been investigated. A gas flow containing NO 70 ppm and NO_2 5 ppm in oxygen was introduced into a vertically mounted Waters' canister containing: (i) 125 g of molecular sieve 5A (a calcium aluminosilicate zeolite) and (ii) 135 g of soda lime containing a potassium permanganate marker. NO and NO_2 concentrations were measured at hourly intervals at the entry and exit points using an electrochemical analyser. Extraction ratios (gradient/inlet × 100) were calculated for a 24-h period. High extraction ratios (in excess of 90%) of NO and NO_2 were observed with both compounds for up to 1 h but these declined rapidly after this time with soda lime. In contrast, the molecular sieve produced extraction ratios in excess of 98% for both gases over the 24-h period. We conclude that the molecular sieve 5A is a highly effective scavenger of NO and NO_2. (*Br. J. Anaesth.* 1996;**77**:534–536)

Key words
Equipment, scavenging devices. Gases non-anaesthetic, nitric oxide. Gases non-anaesthetic, nitrogen dioxide.

Therapeutic administration of nitric oxide (NO) is complicated by the formation of nitrogen dioxide (NO_2). Extraction of NO and NO_2 by several forms of soda lime has been investigated but these failed to demonstrate high extraction ratios for both oxides of nitrogen over prolonged periods under conditions which are relevant to the clinical situation (i.e. with an oxygen-rich carrier gas and an appropriate $NO:NO_2$ ratio)[1-4].

We have investigated the extraction properties of zeolite Ca-A (known commercially as molecular sieve 5A because of its 5 Å channel aperture) under such conditions. A comparison was made with soda lime containing a potassium permanganate indicator which was shown by Pickett and colleagues to have higher extraction ratios than other forms of soda lime[1 2].

Methods

A vertically mounted Waters' canister (id 6.5 cm, length 10 cm) was filled with: (1) molecular sieve 5A, pellet size 1.5 mm, mass 125 g (BDH Chemicals, Poole, UK) or (2) soda lime, green-to-brown, 8–12 mesh, mass 135 g (Sofnolime, Molecular Products, Thaxted, Essex, UK). As the intra-crystalline space of the zeolite is normally filled with water, before use the material was dehydrated by heating at 400 °C for 24 h. A gas flow containing NO 70 ppm and NO_2 5 ppm in oxygen was introduced at a flow rate of 10 litre min^{-1}. A calibrated Bedfont EC 90 electrochemical analyser (Bedfont Scientific Limited, Upchurch, Kent, UK) was used to assess concentrations of NO and NO_2 at the entry and exit points. Measurements were recorded hourly for 24 h with each absorber. Calibration of the electrochemical analyser was verified on completion of each set of readings. Gas pressure at the entry and exit points was recorded for each compound; the gradient remained at less than 1.5 cm H_2O throughout. Extraction ratios of NO and NO_2 for each compound were calculated for the 24-h period.

Results

High extraction ratios (in excess of 90%) of NO and NO_2 were observed with both compounds for up to 1 h. Subsequent observations revealed a rapid decline in the soda lime extraction of both NO and NO_2. This was more marked for NO. In contrast, the molecular sieve gave extraction ratios in excess of 98% for both gases over the 24-h period. Complete extraction of nitrogen dioxide was observed at 24 h (figs 1, 2).

Discussion

Zeolitic molecular sieves are aluminosilicates built from corner-sharing SiO_4 and AlO_4 tetrahedra linked by the apical oxygen atoms to form frameworks of high internal surface area with regular channels and cavities of molecular dimensions[5-7]. The channel systems, which may be one-, two- or three-dimensional, may occupy more than 50% of

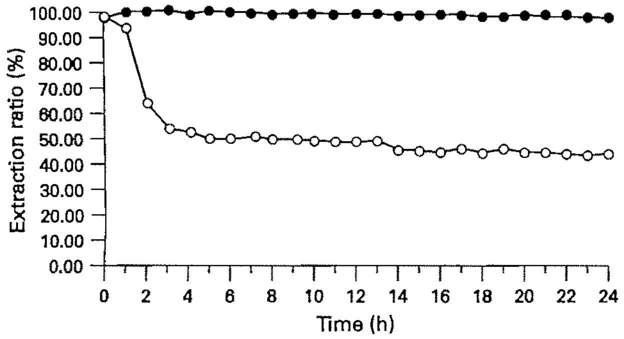

Figure 2 Extraction ratio of nitrogen dioxide from an oxygen carrier using molecular sieve 5 (●) and soda lime (○).

crystal volume. Their microporous structure enables zeolites to be used as molecular sieves as they can only adsorb molecules of certain size. The net negative charge of the framework, equal to the number of the constituent aluminium atoms, is balanced by exchangeable cations, Mn^+, located in the channels which normally also contain water. The general oxide formula of zeolite 5A is:

$$Ca_6\,[Al_{12}\,Si_{12}O_{48}]\times 27\,H_2O$$

There are approximately 40 identified zeolite minerals and at least 140 synthetic species with a wide range of compositions. The most important properties of zeolites are their ability to adsorb organic and inorganic substances and to act as cation exchangers and catalysts. Depending on pore diameter and molecular dimensions, species such as gaseous elements, ammonia, alkali metal vapours, hydrocarbons and many other organic and inorganic species may be accommodated in the intra-crystalline space of dehydrated zeolites. This process, known as molecular sieving, is a powerful method for the resolution of mixtures. Commercial applications include the drying of organics, separation of hydrocarbons and of N_2 and O_2 in air, and removal of NH_3 and CS_2 from industrial gases. Cations neutralizing the electrical charge of the aluminosilicate framework can be exchanged for other cations from solution. Zeolites often possess selectivities for certain cations, and this is used for their isolation and concentration.

Molecular sieving properties of zeolites are further modified by ion exchange. Thus sodium aluminosilicate zeolite absorbs both N_2 and O_2 while calcium aluminosilicate zeolite (molecular sieve 5A) absorbs nitrogen preferentially to oxygen. We have demonstrated slightly preferential uptake for NO_2 over NO with 5A. Uptake of both oxides of nitrogen by 5A is marginally reduced when nitrogen is used as the carrier gas (data not shown), but more efficient extraction from an oxygen-rich carrier is desirable if the compound is to be used as a scavenger. A reduction in efficiency of uptake can also be expected with the introduction of carbon dioxide and water to the carrier gas. Water vapour is a particular problem as it reacts with nitrogen dioxide to form nitric acid which leads to gradual degradation of the sieve. This problem has been encountered in the commercial production of nitric acid which involves the catalysed oxidation of ammonia. Degradation can be delayed substantially by the interposition of a bed of silica gel (US patent specification 3674429). Other properties which make the molecular sieve 5A suitable for use as a scavenger are its low cost and lack of toxicity[6].

Green-to-brown soda lime uptake of NO and NO_2 for the first hour was similar to that reported by Pickett and colleagues who showed green-to-brown Sofnolime to have a higher extraction ratio for NO than that of pink-to-white or violet-to-white Sofnolime[2]. Using a ratio of 8.6:1 of $NO{:}NO_2$, Ishibe and colleagues reported an extraction ratio of 11.9% NO for Sodasorb lime[3].

Uptake of NO appears to depend on the presence of NO_2 (indirectly proportional to the $NO{:}NO_2$ ratio). This observation is consistent with the reactions suggested by Ishibe and colleagues[4] and Kain[8]:

$$2NO + 2NO_2 + 2NaOH + Ca(OH)_2 \rightarrow 2NaNO_2 + Ca(NO_2)_2 + 2H_2O$$

$$4NO_2 + 2NaOH + Ca(OH)_2 \rightarrow 2NaNO_2 + Ca(NO_3)_2 + 2H_2O$$

The higher NO extraction ratio observed with soda lime containing a potassium permanganate marker is explained by the powerful oxidizing properties of this material. The reaction proceeds as follows[9]:

$$NO + KMnO_4 \rightarrow KNO_3 + MnO_2$$

The contribution of potassium permanganate to NO uptake is supported by our observation that the rapid reduction in NO extraction coincided with the colour change from green to brown of the soda lime. Prolonged efficiency of any form of soda lime as a scavenger of both oxides of nitrogen has yet to be demonstrated. Ishibe and colleagues reported a 5% breakout time of 30 days for NO_2 using high purity nitrogen as the carrier gas and a flow rate of 1 litre min^{-1}.

We conclude that the molecular sieve 5A was a highly effective scavenger of NO and NO_2. We have demonstrated this property with a clinically relevant gas composition over a 24-h period. Advantages over soda lime include lower cost and greater efficiency.

Sevoflurane degradation to compound A in anaesthesia breathing systems

D. D. CUNNINGHAM, S. HUANG, J. WEBSTER, J. MAYORAL AND R. W. GRABENKORT

Summary

Determination of an effective rate constant and activation energy allowed the application of steady-state theory to predict concentrations of compound A from sevoflurane concentrations, fresh gas flow rate, absorbent temperature and amount of absorbent. Studies by eight research groups were compared. Lower concentrations of compound A than predicted were observed at low flow rates, suggesting that its degradation by the absorbent is important in limiting the maximum observed concentrations in closed and low-flow breathing systems. Trial-to-trial and batch-to-batch variations in compound A concentrations were observed in model system tests of commercial and pilot-plant absorbents. Chemical modification of the absorbent with glycerol lowered concentrations of compound A, possibly by formation of a nucleophilic addition product. An ideal chemical scavenger would remain stable and non-volatile in the absorbent before irreversibly reacting with compound A to form a stable non-volatile product. (*Br. J. Anaesth.* 1996;**77**:537–543)

Key words

Anaesthetics volatile, sevoflurane. Carbon dioxide, absorption. Equipment, breathing systems.

Sevoflurane may degrade to form compound A and other degradation products (fig. 1). Methanol may further add to compounds C, D and E to form progressively larger molecular weight degradation products (structures not shown). In most studies reported in the literature, the concentration of compound A increases to a near steady-state concentration[1-14]. In this study, determination of an effective rate constant and activation energy allowed the application of a steady-state theory to predict steady-state compound A concentrations from sevoflurane concentrations, fresh gas flow rate, absorbent temperature and amount of absorbent. Development of the theoretical model allowed comparison of results from eight research groups during July 1995. Confirmation of the theory was attempted using a model breathing system with standard and modified absorbent canisters.

The composition of the absorbent has also been viewed as a factor in the generation of compound A[2,3,9,13-17]. Pilot-plant batches of absorbent with different concentrations of sodium hydroxide and potassium hydroxide were tested in a model breathing system under conditions designed to produce high concentrations of compound A. The possible role of moisture is discussed.

Previous detection of compound B in low-flow breathing systems[3,8,10,13,14] suggested that addition of an alcohol to compound A readily occurred. Laboratory batches of absorbent were modified with two non-volatile alcohols, glycerol and polyvinyl alcohol, and tested.

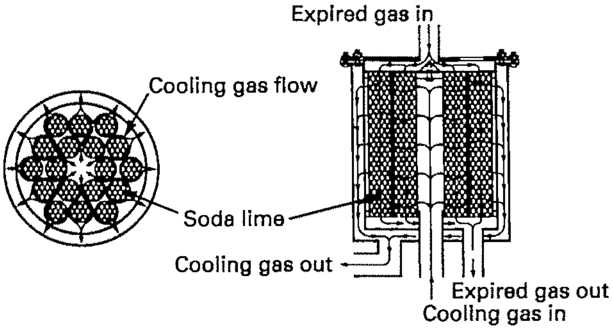

Figure 2 Schematic diagram of the modified absorbent canister. An orifice plate near the top directed the expired gas flow through the soda lime. A Dayton centrifugal fan introduced room air into the centre of the device, then around the cylinders to side holes at the periphery, and down the outside to the bottom.

Materials and methods

Simulated clinical conditions were produced using a Drager Narcomed anaesthesia machine with ventilator, Drager vaporizer, Marquest humidifier, breathing system and humidification chamber with a Gibeck heavy wall test lung attached to the y-site. Standard conditions of 1.5% sevoflurane, oxygen 250 ml min^{-1}, nitrous oxide 250 ml min^{-1} and carbon dioxide 340 ml min^{-1} into the y-site, tidal volume 500 ml, 16 bpm and carbon dioxide absorbent 1 kg were monitored using a Datex Capnomac Ultima gas analyser, unless otherwise noted. The carbon dioxide flow rate was large to produce high temperatures in the absorbent and production of compound A.

A range of temperatures for the Arrhenius plot (fig. 2) was generated using standard conditions, except for carbon dioxide 0–400 ml min^{-1}. Flow rate dependance was studied over the range 0.5–4 litre min^{-1}, otherwise using standard conditions. The rates were tested randomly and each held constant until a near steady-state compound A concentration was reached. Sevoflurane concentrations of 1.5% and 4.0% were used to test concentration dependence. One batch of Sodasorb was separated into 4, 6, 8 and 12 mesh fractions. The amounts of 4 and 12 mesh material were insufficient for testing.

Absorption of compound A to materials in the breathing system was tested using 0.7–3.4 ppm of compound A in 1–5% sevoflurane without absorbent in the canisters. Temperatures were measured with custom-made type K thermocouples using a National Instruments A/D converter with Lab View software. Forced air cooling was conducted using modified absorbent canisters constructed using 18 equally spaced 0.5-mm thick metal cylinders which were inserted in place of the standard double canister (fig. 2). Convective cooling was conducted using canisters with 19 cylinders (0.5–1.2 mm) without the outer baffled shroud shown in figure 2. Laboratory batches of absorbent were prepared with a water content of approximately 35%, passed through a grinder with 3–4 mm holes in the extrusion plate, and dried further to values reported before use.

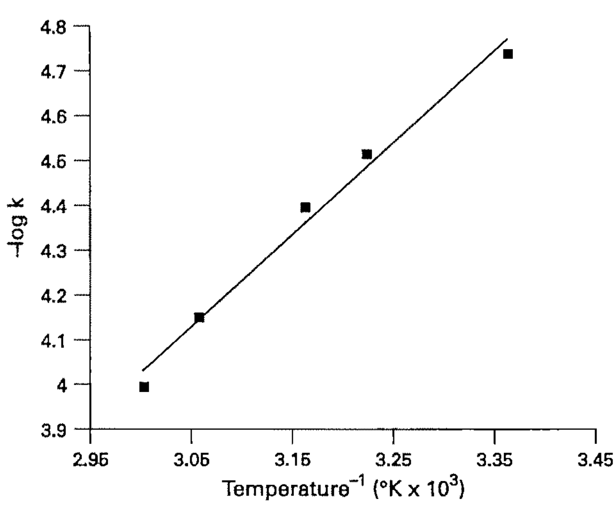

Figure 3 Arrhenius plot of near steady-state rates of formation of compound A against 1/*T*. Slope =−2027 °K, RSD=7%.

Concentrations of compound A were measured using a gas chromatography method described previously[18]. Standard addition/recovery experiments performed by two analysts in the range 4–32 ppm were found to give an overall recovery of 102% (n=12, range 88–117%, sd 9%). The variation in the standard addition/recovery results included any variation in the preparation of the samples, and the normal variation in the assay. Generally, concentrations of compound A were measured in the model breathing system every 15–30 min for at least 150 min. For convenience, only the maximum concentration found during each experiment is reported.

THEORY

A steady-state approximation was formulated to predict the steady-state concentration of compound A based on the factors of sevoflurane concentration, fresh gas flow rate, temperature and amount of absorbent. At steady-state, the amount of compound A formed in the breathing system is assumed to be equal to the amount of compound A carried out of the system by the fresh gas flow, as shown in equation (1):

$(V \times k \times [\text{sevo}]) - ([\text{cpd A}] \times \text{fresh gas flow rate}) = 0$ (1)

where V=volume of reaction, k=effective rate constant, [sevo]=volatile fraction of sevoflurane, and [cpd A]=near steady-state concentration of compound A in the breathing system. As the degradation reaction probably occurs in the highly basic aqueous coating over the insoluble portion of the absorbent, the reaction volume was taken as the approximate

volume of water in the absorbent. The effective activation energy can be calculated from:

$$Ea = \frac{-R2.303(\log(k_2) - \log(k_1))}{(\frac{1}{T_2} - \frac{1}{T_1})} \qquad (2)$$

where k_1 and k_2=rate constants at temperatures T_1 and T_2 and R=gas constant. Therefore, by plotting log k against $1/T$ (an Arrhenius plot) for a range of temperatures, the slope of the line provides the net result of all the unknowns in equation (2). When the activation energy is known, and the rate constant at one temperature T_1 is also known, the rate constant at any other temperature T_2 can be determined by rearranging equation (2) and solving for k_2.

Results

The effective rate constant for degradation to compound A was determined at 24 °C with 1 kg of Sodasorb and 18% water, using standard conditions without introduction of carbon dioxide. The near steady-state compound A concentration in the system was then 6 ppm, produced from a reaction volume of 180 ml (18% of 1 kg), a sevoflurane fraction of 0.015 and a fresh gas flow rate of 500 ml min^{-1}. The calculated rate constant from equation (1) was 1.9×10^{-5} s^{-1}.

The temperature dependence of the near steady-state compound A concentration in the breathing system for maximal temperatures of 24–60 °C is presented in the form of an Arrhenius plot in figure 3. The effective activation energy for the formation of compound A, Ea, calculated from the slope of the line in figure 3 using equation (2), is 39 kJ mol^{-1}.

An effective activation energy of 39 kJ mol^{-1} and an effective rate constant of 1.9×10^{-5} s^{-1} at 24 °C were used to calculate (from a rearranged equation (2)) the effective rate constants for the maximum temperatures reported in different studies. Then, equation (1) was used to calculate the predicted near steady-state compound A concentration from the sevoflurane fraction, fresh gas flow rate and amount of absorbent used in the study (assuming a water content of 18%). Studies from eight research groups are summarized in table 1. In some cases mean values for temperature were used. Although not strictly correct mathematically, use of mean values allowed comparison of the studies where temperatures for individual patients were not reported.

A typical temperature profile of the absorbent obtained using the standard conditions with two canisters of Sodasorb is shown in figure 4. Increasing the sevoflurane concentration from 1.5% to 4.0% after 2 h did not change the characteristic shape of the temperature profile (data not shown). Initially, carbon dioxide was absorbed in a narrow carbon dioxide reaction zone at the top of the absorbent. As observed by the change in colour of the pH indicator, this zone moved along the absorbent with time. As shown in figure 4, the maximal temperatures reached at the centre of the canister remained nearly constant with time, indicating efficient heat transfer from the carbon dioxide reaction zone. The wall portions of the absorbent reached temperature maxima at progressively later times, but the combined mean temperature of the wall sites remained approximately constant.

Results from studies performed with commercially available absorbents are shown in table 2. Using 1 kg of Sodasorb in a single canister, maximum concentrations of compound A were in the range 23–41 ppm (mean 29 (SD 5) ppm; n=9) using four different batches of absorbent. Convective cooling of the modified canister gave maximum concentrations of compound A of 15–21 ppm (mean 17 (2.3) ppm; n=5). Forced air cooling of the modified canister gave maximum concentrations of compound A of 9–12 ppm (mean 10 (1.2) ppm; n=6). The predicted and found values are included in table 1.

Results from the fresh gas flow rate study are shown in figure 5. The measured absorbent temperature was approximately constant (46 ± 3 °C) at each flow rate. Increasing the sevoflurane concentration from 1.5% to 4.0% increased mean maximal steady-state concentrations of compound A from 22 to 69 ppm (n=3). The 6 and 8 mesh fractions gave maximum compound A concentrations of 34 ppm and 33 ppm (table 2). In the absorption study, recovery of compound A from the breathing system in the absence of absorbent was 102–114%.

Results from pilot-plant batches of absorbent prepared with different concentrations of sodium and potassium hydroxide are shown in table 3. During initial studies, the lowest concentrations of compound A were observed with about 5% sodium hydroxide, which led to the preparation of a production batch which gave a higher concentration of compound A than any of the pilot-plant batches. The ranges of values observed for both sodium hydroxide batches (9–34 ppm) and potassium hydroxide batches (19–38 ppm) were wide. Correlation of the concentrations of compound A with percentage base was stronger for potassium hydroxide batches (r^2=0.90) than for sodium hydroxide batches (r^2=0.15).

The composition and test results for laboratory batches of absorbent are shown in table 4. Note that the sodium hydroxide and potassium hydroxide types of absorbents were prepared with approximately equal amounts of base on a molar basis.

Discussion

The temperature profiles within the canister were complex (fig. 4), but attainment of near steady-state concentrations of compound A over long periods of time showed that the effective temperature was relatively constant. Thus an effective activation energy and effective reaction rates could be calculated. Arrhenius plots of near steady-state concentrations of compound A reported in previous studies (plots not shown) gave effective activation energies of 29 kJ mol^{-1} [10], 76 kJ mol^{-1} [11], 55 kJ mol^{-1} [19] and 28 kJ mol^{-1} [13], compared with our value of 39 kJ mol^{-1}.

Values of individual factors used to predict the near steady-state compound A concentrations are shown in table 1; with some exceptions, the predictions agreed with the measured values. Thus in

human clinical studies the predicted values are comparable with the measured variables (within +6 to −11 ppm of predicted values), except for the study of 16 patients at site three using a fresh gas flow of 0.5 litre min^{-1}, where a much higher concentration was predicted. However, in clinical practice the entire fresh gas flow is not available to carry compound A out of the breathing system as approximately 80–250 ml min^{-1} of oxygen are converted to carbon dioxide by the patient[5]. If this were corrected for by using a smaller fresh gas flow in equation (1), the predicted concentration would be even higher. In model systems (with no oxygen absorption), the predictions were also much higher than the measured values at fresh gas flow rates of less than 0.5 litre min^{-1}. The steady-state approximation(equation (1)) predicts that as the fresh gas flow rate approaches 0, concentrations of compound A should approach infinity, in contrast with the finite experimental results for closed systems. The most likely explanation for this discrepancy is that a substantial fraction of compound A is degraded during recirculation through the carbon dioxide scrubber. Degradation of compound A in the presence of soda lime has been described[13]; however, insufficient detail exists to calculate the magnitude of removal of compound A from the breathing system by this mechanism. Large non-volatile products could be formed from compound A by repeated additions of methanol and elimination of hydrogen fluoride (an extension of the reaction scheme in fig. 1). Absorption of compound A to the breathing system in the absence of a carbon dioxide absorbent did not appear to be a factor. Further clarification of the degradation of compound A was beyond the scope of our studies.

As described here and elsewhere, results for the individual factors of sevoflurane concentration[12 13], and temperature[10 11 13 19] were in general agreement with the theory. In previous studies, fresh gas flow rate dependence was noted; however, in these studies the temperature varied over a range greater than 15 °C so the true flow rate dependence was not determined[1 11]. However, table 1 sheds no light on the effect of the amount of absorbent on the concentration of compound A because most of the experiments with smaller amounts used fresh gas flows of less than 0.5 litre min^{-1}. The limited data from our own experiments (table 2) tend to contradict the theory showing lower concentrations with larger amounts.

The effective reaction volume may be affected by the moisture content of the absorbent. The surface area of 4–8 mesh absorbent has been estimated as 600 cm^2 cc^{-1}, but only 16% of the area is active in absorbing carbon dioxide because water fills much of the internal pores[20]. The moisture content may change during absorption of carbon dioxide, as the heat of reaction of 1 mol of carbon dioxide (which produces 1 mol, i.e. 18 g of water) is sufficient to vaporize 25 g of water[21]. Measurements of actual vaporization and calorimetry of the system are complex as the heat of reaction is carried away by the recirculating gas, increases the temperature of the soda lime and vaporizes water. The humidity of the recirculating gas should also affect the amount of water vaporized and the increase in temperature in the absorbent. Thus the initial moisture content of the absorbent may significantly affect the sevoflurane degradation reaction volume, and many factors may affect the moisture content and surface area of the

absorbent during use. Drying Sodasorb from 16% to 11% moisture had little effect on the concentrations of compound A, but drying to 2–6% moisture produced greater concentrations, contrary to the effect of V in equation (1) and different ratios of degradation products[18], suggesting that the chemical mechanism of degradation is dramatically different on a dry surface.

There are contradictory reports on the role of sodium hydroxide, potassium hydroxide and barium hydroxide on the degradation of sevoflurane to compound A [2 3 5 9 13–17]. Significant variability was observed with commercial absorbents (table 2). Pilot-plant batches of absorbent containing 5% sodium hydroxide from vendor 1 (table 3) gave concentrations of compound A which were less than half the concentrations found for Sodasorb. A 5% sodium hydroxide absorbent batch made to production scale by the vendor and pilot-plant batches prepared by a second vendor gave high concentrations of compound A. Pilot-plant batches prepared without either sodium or potassium hydroxide still absorbed carbon dioxide, but with lower efficiency, and produced significant compound A concentrations.

The cause of the variation in compound A concentrations observed with commercial absorbents is unclear (table 2). The variability in size distribution and composition of an absorbent during normal production is low. Thus variability in drying conditions and other manufacturing steps, which may lead to different amounts of reactive surface area, is a more likely explanation. More accurate measurement of the variability of commercial absorbents and clarification of the role of production variables was not pursued.

A chemical approach to scavenge compound A from the breathing system was investigated. An ideal chemical scavenger would be stable and non-volatile in the chemically basic conditions of soda lime or Baralyme, would react with compound A, and form a relatively stable non-volatile product with compound A. The reaction scheme in figure 1 shows that methanol adds across the double bond of compound A to form compound B. Although concentrations of methanol were not measured (fig. 1), low concentrations would be expected as little sevoflurane degrades and the formation of hydrogen from basic solutions of formaldehyde competes with the Cannizarro reaction[22]. Low concentrations of compound B have been detected in breathing systems[3 8 10 13 14]; thus, the nucleophilic addition of methanol readily occurred. Glycerol and polyvinyl alcohol were tested as additives in various calcium hydroxide-based absorbents. As the results in table 4 show, for each type of absorbent tested the concentration of compound A was lower when glycerol was present. These results support the principle of chemical scavenging. The concentrations of compound A with sodium hydroxide-type absorbents were lower than with the potassium hydroxide-type absorbents. Absorbent prepared with polyvinyl alcohol additive gave high concentrations of compound A, possibly because of increased absorption of sevoflurane into the non-polar portion of the polyvinyl alcohol polymer, which effectively increased the contact area with the highly basic absorbent. Results for the Molecular Products Sofnoline GB (table 2), which is not used routinely in breathing systems for general anaesthesia, showed that potassium permanganate used as the indicator may also affect the concentration. Identification of a more reactive additive was not pursued as the maximum concentration of compound A formed in the breathing system appears to be limited by the main factors in the steady-state model, and at low fresh gas flow rates the maximum concentration appears to be limited further by degradation of compound A.

SHORT COMMUNICATION

Evaluation of the usefulness of intrathecal bupivacaine infusion for analgesia after hip and knee arthroplasty

L. NIEMI, M. PITKÄNEN, P. DUNKEL, E. LAAKSO AND P.H. ROSENBERG

Summary

Spinal anaesthesia in 47 ASA I–II patients was induced with 0.5% bupivacaine 2 ml via a 28-gauge spinal catheter (L3–4 interspace) and 0.5-ml increments were given if needed before or during hip or knee arthroplasty. Intrathecal 24-h infusions consisted of 0.5% bupivacaine 0.4 ml h^{-1} (2 mg h^{-1}) (n=12), 0.5% bupivacaine 0.2 ml h^{-1} (1 mg h^{-1}) (n=12) or saline (n=11) (12 exclusions). Patients received oxycodone 0.1–0.14 mg kg^{-1} i.m. for rescue analgesia. Infusion of bupivacaine 2 mg h^{-1} provided significantly better postoperative analgesia (19 oxycodone doses per group in 24 h) compared with bupivacaine 1 mg h^{-1} (36 doses of oxycodone per group) and saline (52 doses per group) ($P<0.05$). Five patients in the bupivacaine 2-mg h^{-1} group and none in the other groups had measurable sensory block 24 h after the infusion was started. Three patients in the bupivacaine 2-mg h^{-1} group, two with concomitant arterial hypotension, and one patient in the bupivacaine 1-mg h^{-1} group experienced an increase in block on the ward. The incidence of nausea and vomiting was similar in all groups. Although an effective analgesic, intrathecal infusion of bupivacaine 2 mg h^{-1} cannot be recommended for routine pain relief because of the risk of increasing spinal block. Technical problems (19%) also reduced the overall efficacy of the continuous intrathecal analgesic regimen. (*Br. J. Anaesth.* 1996;**77**:544–545)

Key words

Anaesthetic techniques, subarachnoid. Pain, postoperative. Anaesthetics local, bupivacaine. Surgery, orthopaedic.

Spinal catheter techniques permit flexibility in titrating the extent of spinal anaesthesia and increasing its duration as needed. Spinal catheters can also be used for postoperative pain relief. Opioids are the drugs most often administered intrathecally for postoperative pain[1 2]. However, technical problems with the microcatheters[1–4] and opioid side effects[1 2] are disturbingly frequent.

We decided therefore to evaluate the use of continuous low-dose intrathecal bupivacaine infusion in the treatment of postoperative pain after hip and knee arthroplasty.

Methods and results

The study was approved by the local Ethics Committee and patients gave their verbal informed consent.

We studied 47 ASA I–III patients undergoing hip or knee arthroplasty. All patients were premedicated with oral diazepam 5–15 mg depending on the patient's weight and age. Subarachnoid puncture was performed in the midline at the L3–4 interspace with the patient in the lateral position. A 28-gauge spinal catheter (CoSPAN Kendall, Basingstoke, UK) was inserted via a 22-gauge spinal needle. The catheters were advanced 3–4 cm past the needle tip into the subarachnoid space. Plain 0.5% bupivacaine 2 ml was administered via the catheter and incremental doses of bupivacaine 0.5 ml (maximum four doses=2 ml) were administered with the aim of reaching T6.

Patients were allocated randomly to one of three groups. Patients in group 1 received an intrathecal infusion of plain 0.5% bupivacaine 0.4 ml h^{-1} (2 mg h^{-1}), those in group 2 received 0.5% bupivacaine 0.2 ml h^{-1} (1 mg h^{-1}) and those in group 3 received an intrathecal infusion of saline 0.2 ml h^{-1}. The infusion was given using a syringe pump (JMS Syringe pump SP-100, JMS Company Ltd, Hiroshima, Japan) which was started 60 min after induction of spinal anaesthesia, if the level of spinal block was less than T6. If not, the infusion was started after the block had decreased to less than T6. Increments of bupivacaine 0.5 ml were administered via the catheter during surgery, if needed. All patients had a urinary catheter in place during the study. For postoperative pain (at the operation site), oxycodone 0.1–0.14 mg kg^{-1} i.m. was given on request.

Patients were interviewed by the authors 3, 6, 12 and 24 h after intrathecal infusion was started. Each interview included an assessment of the intensity of pain at rest and on movement of the operated leg using a 20-cm visual analogue scale (VAS) (0–10). Cephalad extension of the sensory and degree of motor block in the lower extremities were recorded. If the spinal block was increasing, the infusion rate was decreased by 50%. Heart rate, arterial pressure, nausea and vomiting were also recorded.

Correspondence to L. N.

Table 1 Postoperative 24-h requirement of oxycodone and mean (range) time to first dose in the three intrathecal infusion groups. ** $P < 0.01$ compared with saline

	Bupivacaine 2 mg h^{-1}	Bupivacaine 1 mg h^{-1}	Saline
No. of patients needing oxycodone	7/12	11/12	10/11
No. of doses per group	19**	36	52
No. of doses per patient	1.6 (0–8)	3 (0–9)	4.7 (0–9)
Mean time to first dose (min)	498 (195–940)	408 (30–675)	428 (140–1470)

The spinal catheters were removed by one of the investigators on the first day after operation. For removal, the patient was in the same flexed recumbent position as during spinal puncture.

The Student's *t* test was used for comparison of the differences between mean values for weight, height and age. Fisher's exact test was used for comparison between frequencies. For other data comparisons, the Kruskal–Wallis one-way analysis of variance was applied followed by Dunn's test.

The study was terminated after the 47th patient because of two cases of hypotension related to the reappearance of spinal block during infusion (see below). Twelve patients were excluded from assessment of analgesia, mainly because of technical problems (five accidental disconnections of the catheter, adequate level of spinal analgesia was not reached in three patients and single-dose spinal anaesthesia was given, one failure to insert the catheter and two patients needed intensive care because of haemodynamic instability). One patient wanted the infusion interrupted (bupivacaine 1 mg h^{-1}) because of the disturbing reappearance of sensory and motor block.

Patients receiving bupivacaine 2 mg h^{-1} required significantly less oxycodone (19 doses in 12 patients) than those receiving bupivacaine 1 mg h^{-1} (36 doses in 12 patients) and saline (52 doses in 11 patients) ($P<0.05$). Mean time to administration of i.m. opioid from induction of spinal anaesthesia was comparable in the three groups (table 1). Median VAS scores at 6,12 and 24 h were comparable.

Five patients receiving bupivacaine 2 mg h^{-1} had apparent sensory and motor block 12 h after the infusion was started compared with two patients receiving bupivacaine 1 mg h^{-1} and none receiving saline. Four patients experienced an increase in spinal block on the ward (three in the bupivacaine 2-mg h^{-1} group and one in the bupivacaine 1-mg h^{-1} group). All of these patients also had motor block. The intrathecal infusion was halved at 6.5 h, 8 h and 9.3 h, respectively. Two patients in the bupivacaine 2-mg h^{-1} group developed transient hypotension associated with the increase in block. Five patients in the bupivacaine 2-mg h^{-1} group had detectable sensory block at 24 h. In the bupivacaine groups, of those patients who did not receive any opioid, two of six patients experienced PONV.

Comment

Intrathecal infusion of bupivacaine 2 mg h^{-1} for 24 h provided satisfactory postoperative analgesia in patients undergoing hip or knee arthroplasty. However, because of technical problems, unpredictability of the spread of intrathecal bupivacaine with reappearance of spinal block in some instances, and occasional sudden hypotension, this regimen cannot be recommended as a routine method for postoperative pain relief.

CASE REPORTS

Bilateral compartment syndrome complicating prolonged lithotomy position

J. TUCKEY

Summary

A case of bilateral compartment syndrome after prolonged Lloyd-Davies lithotomy position is described. The diagnosis was made early, despite effective extradural bupivacaine–fentanyl analgesia. The aetiology, diagnosis, pathology and treatment of compartment syndrome are described. Complications of the syndrome may be life-threatening and permanently disabling. The anaesthetist should be aware of the potential complications of the operative positions of the unconscious patient. (*Br. J. Anaesth.* 1996;**77**:546–549)

Key words

Position, lithotomy. Position, effects. Complications, compartment syndrome.

The compartment syndrome describes a self-propagating cycle which occurs in the osseofascial compartments of the extremities. After a period of ischaemia, with reperfusion, the integrity of the capillaries may be compromised. This causes interstitial oedema and an increase in compartmental pressure. Untreated, it may lead to permanent neurovascular damage, myoglobinuria, renal failure, sepsis and death[1]. The compartment syndrome may complicate fractures, burns and crush injuries of the extremities[2]. It has also been described as a complication of some positions adopted for surgery, notably the lithotomy and knee–chest positions[3].

Case report

The patient was a 28-yr old man with a 10-yr history of ulcerative colitis. The previous year he had undergone an emergency total colectomy with ileostomy formation for acute exacerbation of the colitis. After colectomy he continued to pass blood and mucus per rectum and did not tolerate the ileostomy. Therefore, he was admitted for formation of an ileal pouch, excision of rectum and pouch–anal anastomosis. He had no other medical conditions of note.

Anaesthesia was induced with thiopentone 3 mg kg^{-1} and fentanyl 2 μg kg^{-1} and neuromuscular block was produced with atracurium 0.5 mg kg^{-1}. The trachea was intubated and the lungs ventilated with 1–2% inspired isoflurane and 35% oxygen in air. An extradural catheter was introduced at the T12–L1 interspace. Extradural analgesia was produced using fentanyl 100 μg and 0.5% bupivacaine 17 ml, with a 3-ml test dose. An extradural infusion of fentanyl 4 μg ml^{-1} and 0.125% bupivacaine was commenced during operation at a rate of 8 ml h^{-1}, 2 h later. Right internal jugular cannulation provided measurement of central venous pressure, and left radial arterial cannulation enabled continuous arterial pressure monitoring.

The patient wore thigh-high anti-embolism stockings and was positioned in the Lloyd-Davies lithotomy position, with the legs well padded and the pressure points protected. For most of the procedure, the table was in the Trendelenburg position. Surgery lasted 7 h 35 min.

Arterial pressure was maintained at or greater than 90/50 mm Hg throughout the procedure. Haemoglobin concentration was maintained greater than 10.2 g dl^{-1} in the peroperative period. Total blood loss was 4.2 litre. The patient's body temperature was 34.5 °C at the end of surgery. He was transferred to the intensive care unit for artificial ventilation of the lungs until his core temperature had returned to normal and fluid status was stable. He was sedated lightly with propofol until the tracheal tube was removed 3 h after operation. By then he was warm, had a stable cardiovascular state and the extradural infusion provided satisfactory analgesia.

The following day, 15 h after operation, with the extradural providing complete abdominal wound analgesia, the patient complained of bilateral painful lower legs. On examination, both lower legs were tense and swollen. The pedal pulses were present and sensation was intact, but the legs were very tender on palpation and pain was elicited on minimal dorsiflexion of the ankle.

No calf muscle pressure monitoring was available. A diagnosis of bilateral compartment syndrome was made clinically. Decompressing fasciotomies were scheduled urgently to minimize the risk of permanent sequelae.

The patient was transferred immediately to theatre. On each side, a 12-cm lateral incision was made under general anaesthesia. Bilaterally, a 3-cm segment of fibula was excised allowing four-compartment decompression. The wounds were left open. The extradural infusion was maintained.

Despite repeated wound inspection under general anaesthesia, on day 4 after operation footdrop was noted. The patient was pyrexic and unwell and so an

---

JENNIFER TUCKEY, MB, CHB, FRCA, DCH, Humphry Davy Department of Anaesthesia, Bristol Royal Infirmary, Marlborough Street, Bristol BS2 8HW. Accepted for publication: May 23, 1996.

infection screen was carried out. Blood cultures yielded coagulase-negative *Staphylococcus aureus*, and the leg swabs grew coliforms and bacillus. Appropriate antibiotics were given and he was returned to theatre for further leg wound inspection. The extradural had become dislodged and was therefore removed.

On this occasion, large amounts of liquefied muscle were found bilaterally. In the lateral and anterior compartments, extensive areas of necrotic muscle were excised, with blood loss of 4.5 litre. The patient was septicaemic and required cardiovascular support with inotropic agents guided by pulmonary artery catheter studies. Myoglobinuria was detected and creatine kinase concentration peaked at 13 000 iu litre^{-1} on day 5 after the original operation. Urine output was maintained throughout, facilitated by daily infusion of mannitol 0.5 g kg^{-1} and dopamine 3 μg kg^{-1} min^{-1}.

He subsequently required seven additional operations for debridement of wounds and change of dressings during the next 3 weeks. The ankles were splinted to minimize the equinus deformity. The final procedure involved application of split skin grafts to close the wounds.

The abdominal procedure was successful. The patient was discharged 3 months after admission with bilateral foot drop. He could walk short distances with the aid of crutches and ankle supports, after intensive physiotherapy. Despite early diagnosis, the development of compartment syndrome in this patient resulted in significant long-term handicap.

Discussion

Compartment syndrome is defined as a symptom complex that is caused by increased pressure of tissue fluid in a closed osseofascial compartment of the limb and this interferes with circulation to the myoneural components of the compartment[4]. It was first described as a complication of the lithotomy position in a healthy 38-yr old man after urethroplasty lasting 6.5 h[5].

Prolonged lithotomy position may predispose the patient to compartment syndrome in several ways. Leg perfusion may be decreased by elevation of the limb above the heart, excessive local pressure from improper placement of the legs in holders, external pressure from equipment or personnel, or excessive dorsiflexion of the foot. Other intraoperative factors may include hypotension, hypovolaemia, compression of the pelvic blood vessels in association with surgery and hypothermia with vasoconstriction. Initial hypotension on lowering the legs at the end of the procedure may compound the problem. Pre-existing arterial disease may further reduce peripheral perfusion.

Ischaemia results in tissue membrane damage and leads to "leakage" of fluid through capillary and muscle membranes. With arterial reperfusion, the damaged membranes continue to leak and aggravate oedema formation and thus increase the pressure in the closed osseofascial compartment.

It has been shown that at rest the pressure within the calf compartments is normally less than 20 mm Hg[6]. Pressures as high as 50–55 mm Hg for 4–8 h have been cited to result uniformly in compartment syndrome[6]. The patient's baseline arterial pressure must be taken into account. For example, a patient with ankle systolic pressure of 100 mm Hg requires greater occlusion pressures and a longer exposure to these than a patient with peripheral vascular disease with an ankle systolic pressure of 40 mm Hg.

It is important to identify patients at risk of developing compartment syndrome. Patients in the lithotomy position for more than 5 h are at risk[7]. Although the lithotomy position is useful, patients should remain in this position no longer than is necessary.

During a staged operation, repositioning patients during the procedure so that they are in the lithotomy position only when necessary for surgical access should reduce the risk[7]. Care should be taken to ensure correct padding of the extremities. While elevation of the legs above heart level is unavoidable, direct pressure on calf muscles is preventable by using stirrups of the conventional Allen type, where the feet are supported but no pressure is exerted on the muscles of the posterior compartment. In the Lloyd-Davies leg supports, the lower legs rest in cradles, which increase the pressure in the calf muscles.

Irreversible muscle damage is likely to occur with occlusion times greater than 6 h[7]. In those cases in whom prolonged use of the lithotomy position is unavoidable, clinical vigilance is necessary.

Some workers have recommended pulse oximetry of the toes as a monitor of adequate lower limb perfusion during the lithotomy position[1 8]. Others found that the presence of an oximeter signal and a normal saturation reading did not necessarily imply adequacy of tissue perfusion[9]. In the absence of arterial trauma, peripheral pulses are usually present in the compartment syndromes. Pulse oximetry does not appear to be a reliable aid in the diagnosis or monitoring of impaired perfusion caused by increased intra-compartment pressure[10].

Because compartment syndrome is a reperfusion injury, signs and symptoms may not be immediately apparent and may develop insidiously. It develops during the postoperative period where the level of clinical observation may be less intense if the patient is not being nursed in a high dependency area. Residual lower extremity sensory block produced by intraoperative regional block with local anaesthetic may interfere with the early detection of subtle sensory changes. In our patient, and in other reported cases[4 11], effective extradural block did not mask the pain of compartment syndrome.

Urine should be checked for the presence of myoglobin. Serum creatine kinase is increased. The diagnosis of compartment syndrome is essentially clinical. There should be a high index of suspicion in patients at risk. The diagnosis can be confirmed by direct measurement of compartment pressure[12]. It is a simple, although invasive, procedure and therefore there is a risk of introducing infection. The differential diagnoses include deep venous thrombosis and peripheral nerve injury.

The definitive treatment of compartment syndrome is surgical decompression. In our patient, the diagnosis was made early, within 15 h, despite effective extradural analgesia. The fasciotomies must be of sufficient length in all compartments at risk to decompress effectively, and this should be confirmed by direct compartment pressure monitoring. Development of motor neurone signs and loss of pulses are late signs and indicate that irreversible damage has already occurred.

The end result of untreated or inadequately treated compartment syndrome is rhabdomyolysis which has been defined as reversible or irreversible injury of skeletal muscle which alters the integrity of the cell membrane sufficiently to allow escape of cell contents into the extracellular fluid[13]. The association between rhabdomyolysis, myoglobin and acute renal failure was first described during the World War II in patients who had sustained severe muscle injury[14]. Numerous non-traumatic causes of rhabdomyolysis have been described of which compression, alcohol abuse and generalized convulsions are the most common aetiologies[13,15].

Myoglobin is similar in structure to haemoglobin, but smaller and more easily filtered in the kidney. It gives urine a classic red/brown colour. The amount of myoglobinuria does not correlate with the degree of underlying tissue injury[16–18].

The cause of acute renal failure after rhabdomyolysis is multifactorial[19]. It includes intratubular plugging with myoglobin and urate (see below), nephrotoxicity of iron from haem[20,21] which catalyses the formation of oxygen-free radicals and inactivation of the intra-renal nitric oxide vasodilatory influence[19,22], possible associated hypovolaemic or septic shock, hyperphosphataemia and possible tubular blockage from microthrombi secondary to associated disseminated intravascular coagulation.

The biochemical features characteristic of myoglobinuric acute renal failure include hyperphosphataemia, marked hyperuricaemia and severe hypocalcaemia, in addition to increased urea and creatinine concentrations, hyperkalaemia and metabolic acidosis. Hyperuricaemia may be caused by increased production of uric acid in the liver, secondary to increased liberation of adenine nucleotides by damaged muscle[23]. Severe hypocalcaemia may be caused by a combination of marked hyperphosphataemia and skeletal resistance to the calcaemic effect of parathormone in patients with acute renal failure[24]. A transient hypercalcaemia is sometimes seen during the diuretic phase of myoglobinuric acute renal failure. It has been postulated that this phenomenon could be attributed to a transient secondary increase in parathormone, immobilization or remobilization of calcium previously deposited in the damaged muscle[25].

The treatment and prophylaxis of renal failure associated with rhabdomyolysis should commence with cardiovascular resuscitation, where applicable, with aggressive prompt fluid therapy to encourage urine flow. Thereafter, forced alkaline diuresis is beneficial[26,27]. Better suggests a regimen of 12 litre per day of a solution containing sodium 110 mmol litre^{-1}, chloride 70 mmol litre^{-1}, bicarbonate 40 mmol litre^{-1} and mannitol 10 gl^{-1} in 10% glucose[19]. The end-point is to produce diuresis in excess of 8 litre per day, maintaining pH ≥ 6.5. The fluid regimen should be continued until myoglobinuria ceases. Bicarbonate can be discontinued at 36 h. Acetazolamide can be given if arterial pH is ≥ 7.45.

Urate and myoglobin are more soluble in alkaline urine. The renal protective effect of alkalinizing the urine has been demonstrated in animals injected with myoglobin[26,28]. Mannitol also has a beneficial action in the prophylaxis of rhabdomyolysis acute renal failure. The beneficial extra-renal effects include increasing mean arterial pressure[19], increasing cardiac contractility[19,29] and decreasing skeletal muscle oedema, hence decompression of muscle tamponade[30]. The beneficial direct renal effects include a decrease in blood viscosity and oncotic pressure across the glomerulus causing an increase in glomerular filtration rate (GFR), dilatation of glomerular capillaries and stimulation of vasodilatory prostaglandin release, increase in proximal intratubular flow and hence reduction of obstruction, and possible reduction of tubular cell swelling in addition to free radical scavenging[31,32].

Extradural anaesthesia for Caesarean section in a patient with moyamoya disease

W. D. NGAN KEE AND C. D. GOMERSALL

Summary

We report a case of moyamoya disease in a patient presenting for Caesarean section at 37 weeks' gestation. Extradural anaesthesia was administered using 0.5% bupivacaine and pethidine 25 mg. A stable haemodynamic state was produced using left lateral uterine displacement, i.v. crystalloids and an i.v. infusion of ephedrine. The patient suffered no neurological deficit and there was no significant intraoperative decrease in cerebral oxygenation measured by near infrared spectroscopy. (*Br. J. Anaesth.* 1996;**77**:550–552)

Key words
Anaesthesia, obstetric. Anaesthetic techniques, extradural. Complications, moyamoya disease.

Moyamoya disease is a rare occlusive disease of the large intracranial arteries. Patients are at risk of cerebral ischaemia and haemorrhage, and neurological deterioration may occur during pregnancy. Delivery by Caesarean section has been recommended but the optimal anaesthetic technique is not known and monitoring of cerebral perfusion or oxygenation during anaesthesia has not been described. We report the use of extradural anaesthesia in a term parturient with moyamoya disease, with continuous monitoring of cerebral oxygenation by near infrared spectroscopy.

Case report

The patient, a 36-yr-old, para-1, gravida-4 woman, was admitted at 28 weeks' gestation for observation with a plan for elective Caesarean delivery at 37 weeks' gestation. She had been diagnosed angiographically to have moyamoya disease 4 yr previously after a spontaneous left temporal intracerebral haematoma. Treatment had been conservative and she had made a good recovery with a residual right visual field defect but no other neurological deficit. She had had one normal delivery 13 yr previously. On this admission, there were no abnormal neurological findings other than the visual field defect. Arterial pressure was in the range 100–120/60–80 mm Hg. We planned extradural anaesthesia with invasive haemodynamic monitoring and continuous measurement of cerebral oxygenation by near infrared spectroscopy (NIRS).

The patient remained well for the remainder of the pregnancy, but went into spontaneous labour 4 days before the date of planned surgery and was scheduled to the emergency operating list. She was premedicated with ranitidine 50 mg i.v. and 0.3 mol litre^{-1} sodium citrate 30 ml orally. On arrival in the labour ward, her cervix was 5 cm dilated and pethidine 100 mg i.m. was given for analgesia by the obstetric team. Standard monitoring was applied and 35% oxygen was given by face mask. A radial artery cannula and central venous catheter (via the antecubital fossa) were inserted. Intrathoracic placement of the central venous catheter was confirmed by observation of fluctuations in central venous pressure with respiration. Bifrontal regional cerebral oxygen saturation was measured continuously by NIRS using the Invos 3100 (Somanetics Corp., Troy, MI, USA) and NIRO 500 (Hamamatsu Photonics KK, Hamamatsu City, Japan) (fig. 1). Unfortunately, because the time of operation out of normal hours, there was a delay in preparing the equipment and recordings could only be started after commencement of anaesthesia.

After i.v. preload with lactated Ringer's solution 1000 ml, an extradural catheter was placed in the L2–3 interspace with the patient in the lateral position. She was then turned supine with left lateral tilt. Incremental injections of 3 ml of 0.5% bupivacaine (plain) were given at 4–5-min intervals, followed by pethidine 25 mg via the extradural catheter. I.v. infusion of ephedrine 100–500 μg min^{-1} was titrated throughout the anaesthetic to maintain arterial pressure as near as possible to preoperative values. After 27 ml of bupivacaine, the level of sensory analgesia to pinprick was T6 and surgery was started. A healthy 2.61-kg male infant was delivered with Apgar scores of 9 (1 min) and 10 (5 min). Arterial umbilical cord blood gas tensions were pH 7.294, $P\text{CO}_2$ 6.6 kPa and $P\text{O}_2$ 1.6 kPa, and venous umbilical cord blood gas tensions were pH 7.297, $P\text{CO}_2$ 6.6 kPa and $P\text{O}_2$ 1.8 kPa. Oxytocin 10 u. was given i.v. over 15 min after delivery. Blood loss was approximately 300 ml. A total of 1500 ml of lactated Ringer's solution was given in the perioperative period. To maintain normothermia, all i.v. fluids were warmed, the operating theatre temperature was increased to 22 °C and the patient's upper body was covered with blankets. Continuous temperature monitoring was not available because of technical problems, but the patient's sublingual temperature measured by mercury ther-

mometer at the end of the procedure was 36.7 °C. Verbal contact was maintained throughout and bilateral hand grip was checked intermittently. The intraoperative record of arterial pressure, heart rate and cerebral oxygenation is shown in fig. 2. Slight decreases in arterial pressure occurred after establishment of extradural block and after delivery, the latter episode coinciding with administration of oxytocin, but this was not associated with changes in mental state or hand grip and no significant concurrent change in cerebral oxygenation was detected by either spectrometer. A slight increase in deoxyhaemoglobin concentration occurred shortly after skin incision which was matched by an increase in total haemoglobin concentration and no change in cytochrome oxidase redox state.

After operation, the patient was observed in the high dependency area of the labour ward for 24 h where oxygen, pulse oximetry and direct arterial pressure and ECG monitoring were continued. Analgesia was provided by patient-controlled extradural analgesia using pethidine 10 mg ml^{-1} (bolus 20 mg, lockout 10 min). Subsequent progress was uneventful with no new neurological signs and no respiratory depression. The patient was discharged 4 days after delivery.

Discussion

Moyamoya disease is a rare disease named after the Japanese word describing the characteristic "puff of smoke" appearance that is seen on cerebral angiography. It has most often been reported in the Japanese, is more common in children and females and there may be a familial predisposition[1].

Elective Caesarean section has been recommended for the pregnant patient with moyamoya disease to avoid possible deleterious effects of pain, hyperventilation and bearing-down during labour[2]. Although the principles of anaesthesia in moyamoya disease have been described previously[1], the optimal technique during pregnancy is unknown. General anaesthesia has been used[3] and has the potential advantages of decreasing the cerebral metabolic rate for oxygen which may confer some protection against ischaemia[4]. However, there are risks of difficult tracheal intubation, aspiration of stomach contents and neonatal depression. The hypertensive response to intubation may precipitate intracerebral haemorrhage and although this response may be obtunded by the use of adjuvant drugs such as vasodilators, sympathomimetic antagonists and rapidly acting opioids, care must be taken to avoid hypotension and

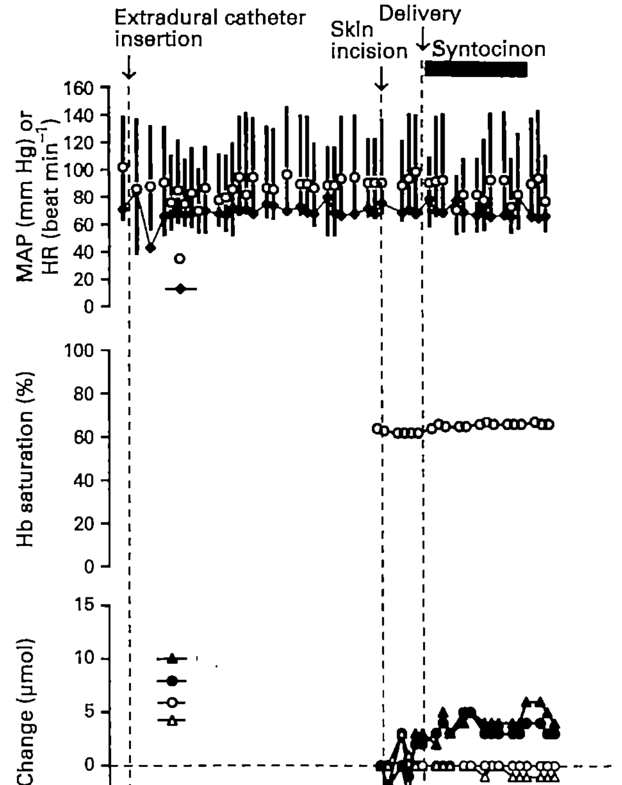

Figure 2 Intraoperative recordings of mean arterial pressure (MAP) (○) and heart rate (HR) (◆) (top), regional cerebral haemoglobin (Hb) saturation measured by the Invos 3100 (middle) and changes in oxyhaemoglobin (▲), total haemoglobin (●), deoxyhaemoglobin (△) and cytochrome oxidase redox state (○) measured by the NIRO 500 (bottom).

consequent cerebral ischaemia. Hypocapnia may cause neurological deficit[5] so use of capnography during controlled ventilation is mandatory. Regional anaesthesia avoids these risks but the associated sympathetic block may lower cerebral perfusion pressure causing ischaemia distal to the stenotic vessels. Spinal anaesthesia was associated with convulsions and hemiparesis in a child[6]. Sharma and colleagues[7] used extradural anaesthesia for Caesarean section in a parturient at 31 weeks' gestation and reported advantages that included continuous monitoring of conscious level and cerebral function in an awake patient. They emphasized the need to avoid hypotension but relied solely on crystalloid preload and uterine displacement to negate the effects of sympathetic block and did not provide details of haemodynamic changes. Because the parturient at term is particularly susceptible to hypotension during extradural anaesthesia[8] more active management may be necessary to maintain cerebral perfusion. However, large upward swings in arterial pressure should also be avoided because of the potential for intracerebral haemorrhage. In our patient we found, using an infusion of ephedrine in addition to fluids and lateral tilt, arterial pressure was well maintained without marked fluctuations.

The absence of signs of cerebral insufficiency in our awake patient in the intraoperative period and the absence of a neurological deficit after operation make it unlikely that significant cerebral ischaemia occurred. However, in the presence of extradural block, signs of transient ischaemia in the anterior cerebral territory may be masked. Anterior cerebral artery occlusion, in the absence of the inconstant recurrent artery of Heubner, leads to flaccid paralysis and cortical sensory loss in the legs, incontinence of urine, and intellectual and memory deficit[9]. However, the level of block required for Caesarean section precludes assessment of neurological function of the legs and bladder. Therefore, we used NIRS to confirm adequacy of oxygenation in the anterior cerebral artery territory.

NIRS uses spectral analysis of reflected infrared light to measure cerebral oxygenation[10]. It has been used to assess cerebral haemoglobin oxygen saturation in both adults[11] and neonates[12], and has been described as a monitor of cerebral oxygenation during carotid endarterectomy[13]. The Invos 3100 gives an absolute value of regional haemoglobin saturation while the NIRO 500 displays changes in regional oxyhaemoglobin, deoxyhaemoglobin, total haemoglobin and cytochrome oxidase redox state. Both monitors are simply and non-invasively applied using probes attached to the patient's forehead. As the maximal distance that can be penetrated by infrared spectrometers is approximately 8 cm[14], the regions of the brain monitored in our patient would have been predominantly within the territory of the anterior cerebral arteries. Although there was a slight increase in deoxyhaemoglobin concentration after skin incision, the concurrent increase in total haemoglobin concentration suggests that any decrease in cerebral oxygenation was likely to be minimal and the absence of a change in cytochrome oxidase redox state shows this did not lead to a change in oxygen delivery at a cellular level.

A disadvantage of using near infrared spectroscopy in emergency surgery is the time required to prepare the equipment: approximately 30 min was required for the lasers of the NIRO 500 to warm up to operating temperature which precluded measurement of cerebral oxygenation before the start of anaesthesia.

Acknowledgement

Purchase of the Hamamatsu NIRO 500 was partially funded by a grant from the University and Polytechnics Grant Committee, Hong Kong.

Unrecognized "crack" cocaine abuse in pregnancy

D. CAMPBELL, M. J. A. PARR AND L. E. SHUTT

Summary

We report a case of "crack" cocaine abuse in a pregnant patient associated with haematuria, proteinuria, haemolytic anaemia, renal impairment, thrombocytopenia and pulmonary oedema. The case illustrates the problems for clinicians where unrecognized cocaine abuse interferes with the diagnosis and management of a complicated pregnancy. In addition, we discuss the principles for the safe conduct of anaesthesia in the pregnant cocaine abuser. (*Br. J. Anaesth.* 1996;**77**:553–555)

Key words

Anaesthesia, obstetric. Complications, cocaine abuse. Pregnancy.

"Crack" cocaine abuse in pregnancy is well recognized in the USA. In the UK the level of awareness to this increasingly common problem needs to be improved[1]. This case illustrates the difficulties in differentiating the effects of cocaine abuse from the more usual complications of pregnancy. Cocaine has complex effects on many systems. It was not apparent until post-partum that the patient continued to abuse crack cocaine even while an inpatient. In retrospect the relationship between drug abuse and the course of her illness became clear.

Crack cocaine abuse increases maternal morbidity, fetal morbidity and death[2-4]. It is likely that maternal crack cocaine abuse will be an increasing problem in the UK and at present the clinical effects may not be fully recognized.

Case report

A 32-yr old, gravida 5, para 3, Afro-Caribbean woman presented to her general practitioner for antenatal assessment at 10 weeks' gestation. Her haemoglobin concentration was 10.1 g dl^{-1} and the blood film showed macrocytosis. Cervical and high vaginal swabs were infected with *Gonococcus* and *Trichomonas*. Her infection was treated and she attended again at 19 weeks' gestation when urinalysis showed moderate haematuria and mild proteinuria. Arterial pressure was 120/70 mm Hg.

She did not attend again until 31 weeks' gestation when she complained of fatigue and dyspnoea on exercise. On physical examination her conjunctivae were pale, arterial pressure was 125/70 mm Hg and she had bilateral pitting oedema of the ankles. Cardiovascular and respiratory system examinations were otherwise unremarkable. Abdominal examination was consistent with a 31-week pregnancy with normal fetal heart sounds and movements. Urinalysis showed excessive blood and moderate protein. The full blood count result a week later showed haemoglobin 6.8 g dl^{-1}, mean cell volume 110 fl and platelets 63×10^9 $litre^{-1}$, and therefore hospital admission was arranged.

In hospital, physical examination revealed an apical ejection systolic murmur. Deep tendon reflexes were normal. Her blood film showed a reticulocyte count of 4.9%. Serum creatinine concentration was 99 mmol $litre^{-1}$, which is high for a pregnant patient. Urea and electrolyte concentrations, liver function tests, uric acid and clotting screen were within normal limits. Autoimmune profile, lupus and platelet antibodies and haemosiderin were within normal limits but haptoglobin concentrations were low at 0.2 g $litre^{-1}$. The 24-h urine volume was 2125 ml and protein 1.32 g $litre^{-1}$. Creatinine clearance was impaired at 90 ml min^{-1}. Free haemoglobin concentration was detected in urine. She was treated with folic acid 10 mg orally twice daily and transfused with 2 u. of packed red blood cells.

A bone marrow aspirate was performed and showed some megakaryocytes and a microangiopathic picture. Later the same day she became hypertensive with an arterial pressure of 145/95 mm Hg which decreased with bed rest alone. The patient admitted also to a history of smoking crack cocaine for the past year. At this stage the differential diagnoses being considered were pre-eclampsia, haematological illness related to renal disease or pregnancy, such as haemolytic–uraemic syndrome, or renal disease, probably secondary to drug abuse.

Additional blood transfusions were given over the next 2 days; haemoglobin concentration was then 9.3 g dl^{-1}. On day 4 of admission she left the ward for the afternoon and on her return she had a dry cough, left-sided pleuritic chest pain, shivering, temperature of 37.5 °C, heart rate 110 beat min^{-1}, arterial pressure 140/80 mm Hg, ventilatory frequency 34 bpm and

Correspondence to L. E. S.

crackles on auscultation of the chest. Blood cultures were obtained, oxygen was given by face mask and antibiotic therapy with Augmentin was started. The next morning the patient had another episode of breathlessness thought to be caused by fluid overload. ECG was normal but a chest x-ray showed cardiomegaly and pulmonary oedema. Frusemide 20 mg i.v. produced improvement. However, an echocardiogram showed tachycardia, hyperdynamic left ventricle, ejection fraction of 62%, small pericardial effusion and mild tricuspid regurgitation.

There was an additional episode of breathlessness the next morning and a decision to expedite delivery was made. It was felt that she would not tolerate vaginal delivery and a Caesarean section was planned. The preoperative anaesthetic assessment noted the history of crack cocaine abuse, hepatitis B positive, high risk for HIV infection and the need for appropriate precautions. Despite the uncertainty of the diagnosis there was some comfort in the patient having a normal arterial pressure, no clinical evidence of heart failure, haemoglobin 9.7 g dl^{-1}, and normal urea and creatinine concentrations, and clotting screen. As the platelet count was 60×10^9 $litre^{-1}$, arrangements were made for a platelet transfusion of 12 u. before surgery.

The patient was premedicated with ranitidine 50 mg i.v. and sodium citrate 0.3 mol $litre^{-1}$ (30 ml) orally before induction of anaesthesia. After local anaesthesia of the skin, cannulae were inserted via the right brachial artery and right internal jugular vein for monitoring of arterial pressure and central venous pressure. Her lungs were preoxygenated for 5 min and this was followed by rapid sequence i.v. induction with etomidate 20 mg, suxamethonium 100 mg and alfentanil 1 mg, and application of cricoid pressure. Anaesthesia was maintained with 1% isoflurane and 50% nitrous oxide in oxygen. Fourteen minutes later a live male neonate, weighing 2.07 kg with Apgar scores of 6 and 8, was delivered. Synthetic oxytocin (Syntocinon) 7.5 u., fentanyl 100 µg, vecuronium 6 mg and Augmentin 1.2 g were given i.v. The patient remained haemodynamically stable throughout and her trachea was extubated at the end of the procedure. The patient was monitored for a further 24 h in the intensive care unit. Pain was managed by intermittent i.v. boluses of morphine for 24 h and oral analgesia thereafter. The only problem was some oozing from the abdominal wound.

After operation a more discerning drug history was obtained. The patient had been smoking crack cocaine on hospital premises immediately before each episode of dyspnoea and this was thought to precipitate the presumed episodes of acute pulmonary oedema. Urine toxicology confirmed the presence of cocaine metabolites in urine.

The patient was discharged home 9 days after operation. A renal biopsy before discharge showed glomerular immune complex deposits (M dominant) on immunohistology and evidence of intraglomerular intravascular coagulation with some features of haemolytic–uraemic syndrome on electron microscopy. These findings are consistent with the mixed renal disease found in drug abuse. Additional blood investigations showed a haemoglobin concentration of 9.8 g dl^{-1}, platelets 120×10^9 $litre^{-1}$ and serum creatinine concentration 130 mmol $litre^{-1}$. Follow-up of her suspected drug-induced haemolytic–uraemic syndrome by a renal physician was planned.

Discussion

Cocaine is an alkaloid derived from the shrub *Erythroxylon coca* and is available as a hydrochloride or free base crack cocaine. Cocaine hydrochloride is usually "snorted" achieving peak plasma concentrations in less than 15 min. Crack cocaine is smoked and produces euphoria in less than 1 min with a duration of only 5–10 min[5 6].

The effect of cocaine as a local anaesthetic is a result of its action on sodium channels preventing nerve depolarization. The systemic effects of cocaine are caused by block of reuptake of noradrenaline and dopamine from synapses in the central and sympathetic nervous systems thereby potentiating the effects of these neurotransmitters. The euphoric effect of cocaine is caused by excess neurotransmitters at the synapses of the limbic system. Sympathetic nervous system effects include vasoconstriction, tachycardia, hypertension and arrhythmias. Chronic abuse causes tachyphylaxis resulting from depletion of presynaptic neurotransmitters[7 8].

Our patient had features in common with other reports[3 7], including a poor socioeconomic background and infrequent attendance for antenatal care. The paroxysmal dyspnoea was related to pulmonary oedema associated with acute intoxication after smoking crack cocaine. This has been described previously[9 10] in the non-obstetric population and may reflect transient left ventricular dysfunction or a direct pulmonary microcirculatory effect.

Cocaine abuse can be confused with pre-eclampsia[11] in its presentation. In this case hypertension was not a prominent feature although the patient did have proteinuria, ankle oedema and thrombocytopenia. Haemolysis has been reported rarely and only as haemolytic–uraemic syndrome associated with cocaine abuse[12]. Thrombocytopenia is well described[13]. Many cardiovascular complications are reported[14] but we can find no evidence of pericardial effusion associated with cocaine abuse.

The routine questioning of patients about recreational drug use should become standard in our preoperative assessment. Where cocaine is implicated, non-emergency surgery should be delayed until signs of acute cocaine intoxication have disappeared. This may not be possible in obstetric patients where acute cocaine intoxication may cause fetal distress or placental abruption[2 5]. Propranolol has been used for the control of acute hypertension in cocaine intoxication but may increase hypertension and coronary vasoconstriction because of unopposed α adrenoceptor stimulation[15]. For this reason labetalol[16], which antagonizes α and β adrenergic receptors, and esmolol[17], the short-acting β_1 selective antagonist, may be more appropriate agents to use. Hydralazine controls hypertension but does not restore uterine blood flow[18]. Arrhythmias are best treated with the β adrenoceptor antagonists labetalol or esmolol. Cocaine lowers the seizure threshold and therefore lignocaine is contraindicated. Nifedipine has been shown to be protective for cardiovascular side effects in animal models of cocaine toxicity only if given before cocaine[19]. Calcium antagonists have also been associated with increased mortality during cocaine intoxication in animals but there is no evidence in humans[20]. Diazepam is the drug of choice for controlling seizures in acute cocaine intoxication but barbiturates may be necessary[21]. Other systemic complications of acute cocaine intoxication are best managed by waiting for the acute cocaine intoxication to wear off.

Regional anaesthesia is possible in cocaine abusing obstetric patients but is associated with several pitfalls. Regional anaesthesia requires a relaxed cooperative patient which may not be the case in acute intoxication. The cocaine abusing patient may suffer vasoconstriction and have a reduced circulating blood volume which would make extradural anaesthesia preferable to spinal anaesthesia. The interaction of cocaine with other local anaesthetics makes the calculation of a safe maximum dose difficult. Thrombocytopenia is common in the chronic cocaine abusing patient[13] and may be a contraindication to regional anaesthesia.

Where it is not possible to delay surgery in the acutely cocaine intoxicated patient, selected balanced general anaesthesia seems to be without risk. No specific induction agent is recommended but thiopentone and etomidate have been suggested as suitable for induction of anaesthesia[7]. Ketamine increases the risk of cocaine-associated arrhythmias[22]. Alfentanil has been used to prevent the hypertensive response to laryngoscopy and intubation in patients undergoing general anaesthesia for Caesarean section[23]. For hypertensive disorders of pregnancy, many agents have been used to attenuate the cardiovascular response to laryngoscopy, including labetolol, alfentanil and fentanyl[24]. These agents appear to be safe in the context of acute cocaine intoxication.

Halothane increases the chance of arrhythmias with cocaine[21]. Isoflurane anaesthesia preserved blood flow to most major organs but also increased the incidence of arrhythmias in a swine model of acute cocaine toxicity[25]. It is theoretically possible that indirectly acting vasoconstrictors such as ephedrine may be less effective in chronic cocaine abusers because of neurotransmitter depletion from nerve terminals[5]. More dangerous is the interaction between cocaine and direct-acting sympathomimetics causing tachycardia, hypertension, left ventricular failure and pulmonary oedema[21 26].

In conclusion, we have reported a case in which crack cocaine abuse was associated with major complications during pregnancy. In the light of evidence of increasing drug abuse, we encourage anaesthetists to be aware of the pathophysiological effects of acute cocaine intoxication and the multiple organ involvement observed in chronic abuse.

Heparinase-guided thrombelastography in an anticoagulated parturient

D. C. ABRAMSON, E. I. ABOULEISH, E. G. PIVALIZZA, S. L. LUEHR, T. MYERS AND M. D. PHILLIPS

Summary

We describe the use of heparinase-guided thrombelastography in the assessment of a parturient who had been anticoagulated with heparin for suspected thromboembolic disease. Reversal of the heparin effect in the heparinase-treated sample facilitated administration of protamine and successful subarachnoid analgesia for delivery. (*Br. J. Anaesth.* 1996;**77**:556–558)

Key words

Anaesthetic techniques, subarachnoid. Blood, anticoagulants, heparin. Measurement techniques, thrombelastography.

Case report

A 35-yr-old gravid 1 para 0 presented at 29 weeks' gestation with right upper extremity weakness, scintillating scotomata of her right visual fields and drooping of her left facial muscles. She had a significant smoking history and family history of paternal cerebrovascular accident (CVA) at 27 yr of age, followed by three further CVA and death from myocardial infarction at 46 yr. Her sister, 32 yr, had recently had a CVA with documentation of an abnormal mitral valve.

Magnetic resonance imaging (MRI) revealed an ischaemic injury in the distribution of the right middle cerebral artery without evidence of cortical venous or sinus thrombosis. Prothrombin time (PT) was 12.4 s (normal 10.5–13 s) and accelerated partial thromboplastin time (aPTT) was 29.9 s (normal 25–34 s). Heparin 1500 u. h^{-1} was started i.v. and her aPTT was 70 s before transfer to our hospital.

On admission, the fetus was active and the patient was not in labour. History and examination were otherwise unremarkable. Transoesophageal echocardiography (TEE), performed to elucidate a possible thromboembolic source, demonstrated an 8-mm mobile mass on both mitral valve leaflets. Magnetic resonance angiography (MRA) revealed right middle cerebral artery occlusion suggestive of embolic origin.

Carotid arteriogram, 24-h Holter monitoring and lower extremity Doppler examination for venous thrombosis were negative. Serial blood cultures were negative for infection, as were tests for connective tissue disorders and homocysteinuria. Although protein C concentrations were normal, functional protein S was reduced at <10% (normal 65–140%), but total and free protein S fractions were normal. The test for functional protein S was repeated and a more appropriate result of 116% was obtained. Activated protein C resistance testing was negative. Serum cholesterol concentration was marginally increased and triglycerides were twice normal. Haematological variables, including antithrombin III and D-dimers, were normal.

As the patient had no biochemically definable coagulopathy present, a presumptive diagnosis of familial valvulopathy was made. Heparin was infused i.v. for 5 days to maintain an aPTT of 50–80 s, followed by heparin 2000 u. h^{-1} s.c. which was continued for the duration of her confinement.

The patient was readmitted 3 months later, at 39 weeks' gestation, for planned induction of labour. Repeat echocardiography revealed no masses on her mitral valve. Her aPTT on admission was >100 s. Heparin was discontinued 8 h before the intended placement of an extradural catheter for analgesia during labour. Nine hours later prothrombin time (PT) was 13.0 s (normal 11.1–13.1 s), packed cell volume 33.6% and platelet count 154 000 ml^{-1} (normal 133 000–333 000 ml^{-1}). However, aPTT was prolonged at 84.5 s (normal 25–34 s). Thrombelastography (TEG) with native blood (fig. 1A) confirmed a heparin-like effect, evidenced as a prolonged *r* (reaction) time, prolonged *k* time and decreased angle (suggesting poor clot formation), and a narrow maximum amplitude (MA), implying poor platelet function. Simultaneously, a TEG was performed on a heparinase-treated sample (fig. 1B), which revealed a normal trace.

The demonstrated heparin effect was then reversed *in vivo* with protamine 50 mg, given slowly i.v. The repeat TEG trace after protamine was normal (fig. 2), although the aPTT remained prolonged at 46.1 s.

As labour had begun with the fetus in the occipito-posterior position and considerable maternal discomfort, regional anaesthesia was considered desirable. With TEG evidence of adequate coagulation,

NR:		39–40	0–13	48–60	29–43

Figure 2 Thrombelastograph trace after administration of protamine. Abbreviations as in figure 1.

sufentanil 10 µg and bupivacaine 2.5 mg were given into the subarachnoid space via a 27-gauge Whitacre needle by an experienced operator (E. A.) at the first attempt. Analgesia was effective, labour progressed rapidly, and a healthy 3.8-kg female was delivered with low forceps 1 h after intrathecal drug administration.

Post-partum TEG (1 h after delivery) showed no evidence of coagulopathy, heparin therapy was recommenced, and mother and child were discharged 3 days later with planned haematology follow-up for management of maternal warfarin.

Discussion

This report describes several issues in the preoperative haematological management and assessment of obstetric patients for regional anaesthesia.

Heparin is the currently favoured agent for anticoagulation in the parturient[1]. This patient with suspected thromboembolic disease required substantial doses (2000 u. h^{-1} s.c.) for optimal effect, as measured by aPTT. Although a lower dose of unfractionated s.c. heparin has a half-life of 3–4 h[2], the anticoagulant response of heparin increases disproportionately at increased doses[3]. In our patient, a minimum of 8 h was anticipated to allow for waning of the anticoagulant effect before proposed extradural catheter insertion. However, 9 h after discontinuation, the prolonged aPTT suggested a heparin effect. Monitoring of the clinical heparin effect using the activated clotting time may be unreliable (in the presence of low heparin doses)[4], and not representative of *in vivo* activity with plasma heparin concentrations. As heparinase-guided thrombelastography has been introduced into cardiac surgery[5] and orthotopic liver transplantation, we used this method to assist clinical decision making in this patient.

Thrombelastography is enjoying widespread use in obstetrics. While value ranges for healthy parturients have not corresponded, they have all tended towards hypercoagulability compared with healthy non-pregnant patients[6 7]. Investigation continues into TEG changes during preeclampsia[8] and the HELLP syndrome, and the TEG is useful in the algorithm for the thrombocytopenic patient requiring assessment for extradural analgesia. The availability of heparinase, isolated from *Flavobacterium heparinum*[9], further extends the usefulness of this test, as the enzyme degrades heparin and heparin-like linkages even in the presence of the large doses of heparin required for cardiopulmonary bypass[5].

The native TEG trace in this patient showed marked prolongation of the *r* and *k* times and a narrow angle and MA, compatible with a heparin effect. Addition of heparinase to the sample restored the trace to that of the typical parturient. With this evidence of a heparin effect, systemic administration of protamine to the patient was followed by return to normal of the native trace.

Although safe neuraxial access has been described in anticoagulated patients[10], correction of the anticoagulation in this patient (in the presence of normal platelet number and function) significantly improved the risk–benefit ratio of regional analgesia. As labour was progressing adequately, it was felt that single-shot spinal analgesia would provide the necessary analgesia for completion of the second stage of labour without the risk of an indwelling extradural catheter. The addition of bupivacaine 2.5 mg to sufentanil 10 µg prolongs subarachnoid analgesia[11 12]. The normal TEG trace obtained with native blood 1 h post-partum was further assurance that there was no significant (if any) release of heparin from the s.c. tissues after administration of protamine.

CORRESPONDENCE

Failed tracheal intubation

Sir,—I read with interest the article by Hawthorne and colleagues detailing failed intubations over 17 yr in a teaching maternity unit[1]. One result reported was that in only one of seven failed intubations for Caesarean section for fetal distress was neonatal outcome poor. In that instance it was thought that antepartum factors rather than the delay in delivery may have been responsible. Good neonatal outcome despite the considerable delays in delivery that would have occurred in these cases raises the question of the value, if any, of providing general, rather than regional, anaesthesia to expedite Caesarean section for fetal distress.

As discussed by Hawthorne and colleagues, general anaesthesia is a potential cause of maternal morbidity and mortality[2 3]. It also causes increased neonatal respiratory depression and the need for active resuscitation[4]. Regional anaesthesia may take longer to establish, but this delay does not necessarily cause neonatal morbidity even when the indication for surgery is fetal distress. A study of 212 emergency Caesarean sections by Quinn and Kilpatrick found that the use of a regional anaesthetic technique in cases classified as urgent did not influence the incidence of admission to the special care baby unit[5]. The authors concluded that while general anaesthesia was indicated for cord prolapse, severe sustained bradycardia and significant antepartum haemorrhage, its use for cardiotocograph diagnosed fetal distress can generally be avoided.

General anaesthesia carries considerable risk for mother and baby. Obstetric anaesthetists need to be aware that its use for Caesarean section for fetal distress is often not justified.

Sir,—Dr Norman's letter concerns itself with the choice of anaesthetic technique for the compromised fetus and our audit dealt specifically with intubation during general anaesthesia. Our series of failed intubations spanned 17 yr, during which time techniques and attitudes have changed. Dr Norman touches on one point in a series of complex arguments, all of which are outside the remit of our audit. While we appreciate his interest and comments on our article, it would be inappropriate to comment further.

Sir,—I read with interest the review of the management of failed intubation in obstetric anaesthesia by Hawthorne and colleagues[1]. In their series of 23 failed intubations, manual ventilation of the lungs was difficult or impossible in 39% of patients while the airway was maintained before patients regained spontaneous ventilation. Despite this, the authors advocate in their failed intubation drill that all patients should be managed in the left lateral, head-down position during this critical period.

In my opinion there is no evidence to suggest that the traditional teaching of adopting the lateral position in such circumstances is better than leaving the patient in the supine position with left lateral tilt. Turning these patients who are often obese into the lateral position exposes them to a greater risk of failed ventilation and ineffective cricoid pressure. Unfamiliarity with the lateral position is compounded by the need for two-handed techniques both to maintain an adequate seal between face mask and patient and adequate cricoid pressure. A third pair of often unskilled hands then becomes necessary to squeeze the reservoir bag to provide ventilation. The reduced risks of aspiration of gastric contents because of preferential gravitational spill from the mouth of any regurgitated material instead of into the trachea is of little benefit if the risks of hypoxia and regurgitation are increased by such a manoeuvre. I believe the anaesthetist's and anaesthetic assistant's abilities to maintain an airway and prevent regurgitation are optimized by leaving these patients supine when a failed intubation drill is implemented. A trial of release of cricoid pressure may still necessitate a head-down tilt. In addition, the authors suggested reducing cricoid pressure earlier in their regimen to improve a grade 4 view at laryngoscopy with the patient still supine, and no advantage is gained by turning the patients at a later stage to repeat the manoeuvre.

The second reason for leaving these patients supine is that the last recourse for managing the "failure to intubate, failure to ventilate" scenario is to perform a cricothyroidotomy, which I note was attempted in one case. The authors did not state if this was performed with the patient on their side, but I would suggest this is very difficult if not impossible to do in such circumstances.

Finally, I would suggest that spinal anaesthesia is the only method of regional anaesthesia suitable in the subsequent management of such patients for Caesarean section. If an extradural or a combined spinal–extradural technique is used, as occurred in 43% and 13% of patients, respectively, in the reported series, there remains a risk of intrathecal or intravascular injection of a large quantity of local anaesthetic via the extradural catheter, despite an initial negative test dose. Failure to intubate the trachea if then required in such circumstances would no doubt be catastrophic and could be avoided by the use of a spinal anaesthetic technique.

M. E. McBrien

Western Australia

1. Hawthorne LA, Wilson RC, Lyon G, Dresner M. Failed intubation revisited: 17-yr experience in a teaching maternity unit. *British Journal of Anaesthesia* 1996; 76: 680–684.

Sir,—McBrien makes two points in his letter. First, rather than turning the patient to the left lateral, head-down position, it may be advantageous to leave the patient supine, and second, because extradural anaesthesia has a risk of intrathecal or i.v. injection, spinal anaesthesia should be recommended. He does not provide evidence in support of his ideas.

The debate as to the best position in which to conduct the failed intubation drill is longstanding. On the one hand is the Tunstall view[1], and on the other is that of Rosen[2]. Rosen did not appear to provide any data in support of his view, but in our series of 17 cases there were no instances of regurgitation or aspiration. It is only at the point where general anaesthesia is abandoned that the patient is turned. In fact, turning to the left lateral position may facilitate a view of the vocal cords. When surgery is to continue and general anaesthesia is maintained, the patient remains in the semi-prone, head-down position.

Inadvertent intrathecal or i.v. injection with extradural anaesthesia is a remote, but real risk, as is high spinal anaesthesia. In our series we had no problems with any regional technique, and the relative risks of one against the other are unknown.

Much of the data concerning the problems with intubation in obstetric practice represent no more than the opinions of the authors. We have sought publication of the only audited performance of a failed intubation drill to provide the sub-specialty with some support for clinical practice.

2. Rosen M. Difficult and failed intubation in obstetrics. In: Latto IP, Rosen M, eds. *Difficulties in Tracheal Intubation.* London: Baillière Tindall, 1985.

Sir,—Hawthorne and colleagues' recent review of failed obstetric intubations in their maternity unit[1] stated that despite a decrease in obstetric general anaesthetics they have seen an increase in failed intubation from 1:300 in 1984 to 1:250 in 1994. Against a background of approximately 300 obstetric general anaesthetics per year and an incidence of failed intubation of approximately 1 per year, it is not possible to say that this change represents a real increase. Furthermore, the fact that they have seen an increase in the total number of Caesarean sections performed implies that a decrease in the use of general anaesthesia from 83% in 1981 to 23% in 1994 represented only an approximate 30% reduction in the total number of general anaesthetic Caesarean sections. Consequently, it is not surprising that they had the impression that they had not seen a reduction in the incidence of failed intubation. Fortunately, failed intubation is a rare occurrence. This implies that the effectiveness or otherwise of a difficult intubation drill is necessarily difficult to demonstrate.

In addition, the difficult intubation flow diagram described seems to suggest that in cases of fetal distress and maternal haemorrhage where direct laryngoscopy is grade 3 (Cormack and Lehane), failure to intubate should be followed by the use of the laryngeal mask but in grade 4 laryngoscopy one should institute the failed intubation drill. Precluding the use of a laryngeal mask airway in this type of emergency based on whether or not the tip of the epiglottis can be seen on direct laryngoscopy does not seem justified. Moreover, grade 2 laryngoscopy may be associated with difficult intubation, particularly in obstetric patients.

It is interesting that in the six patients who underwent indirect laryngoscopy after operation no abnormality was found. In a study nearing completion, we have found a highly significant association between difficult indirect laryngoscopy and difficult intubation. The only failed obstetric intubation that was included in our study was an easy indirect laryngoscopy. These findings support the suggestion that failure to intubate the trachea of obstetric patients is more often a result of changes caused by pregnancy and the particular problems of attempting to intubate in less that ideal circumstances than because of the anatomical features that make the intubation of non-pregnant patients difficult.

Royal Hallamshire Hospital
Sheffield

1. Hawthorne L, Wilson R, Lyons G, Dresner M. Failed intubation revisited: 17-yr experience in a teaching maternity unit. *British Journal of Anaesthesia* 1996; 76: 680–684.

Sir,—We thank Dr Kessell for the interest shown in our review of failed obstetric intubation in which he makes the following points. On the basis of the relative incidence of obstetric general anaesthetics and failed intubations, we would be unlikely to identify any changes, and the effectiveness of a failed intubation drill would be difficult to demonstrate. He also comments on the place of the laryngeal mask and supports our impression that the anatomical features are not the main culprit in failure to intubate in the obstetric setting.

The figures that Dr Kessell quoted are our own, and we do not wish to conceal our disappointment at our failure to reduce the incidence of failed intubation. We acknowledge that it is difficult to confirm the effectiveness of a failed intubation drill, and we wish to point out that ours is the only documented audit of its application in obstetric practice. We have not attempted to undertake a statistical analysis of this data as it would be inappropriate; none the less, we feel that our results are clinically relevant.

Dr Kessell may be correct about placement of the laryngeal mask airway (LMA). Since the publication of our article, we have become aware of a report of the use of the LMA in 224 women undergoing Caesarean section, including 49 emergencies, apparently without any significant problems and a success rate of 99%[1]. As more information supporting the safe use of the laryngeal mask becomes available, we anticipate that it may become the first alternative when tracheal intubation fails.

Perioperative mucosal pH_i in orthotopic liver transplantation

Sir,—We read with much interest the recent article by Welte and colleagues[1]. In their study, the authors found a significant decrease in intramucosal gastric pH (pH_i) during the anhepatic stage of liver transplantation, even though venovenous bypass (VVB) was used. These values became normal during the reperfusion stage of the graft. In our experience[2], with or without the use of VVB, pH_i was normal in the former group but a significant decrease was observed in the group without VVB (table 1).

As in Welte's study, pH_i values became normal after reperfusion of the graft. However, in contrast with these authors, our patients showed a higher baseline pH_i, which could explain the differences observed during the anhepatic stage in the VVB patients. Maintaining temperature in our patients and improved global oxygenation because of vena caval preservation during the anhepatic stage may account for these differences.

(VVB) in liver transplantation (LT): A randomized study. Preliminary results. *Liver Transplantation and Surgery* 1995; 1: 415 (abstract).

Sir,—We appreciate the letter of Camprubi and Sabate which relates to our recent article on mucosal pH (pH$_i$) during orthotopic liver transplantation (OLT)[1]. Their preliminary data suggest that the use of venovenous bypass (VVB) during the anhepatic stage of OLT may indeed be beneficial for mucosal oxygenation: in contrast with our results, gastric pH$_i$ was preserved with VVB, but decreased transiently without VVB. As pointed out in our article, we were unable to strictly test the hypothesis that VVB would maintain mucosal blood flow as VVB was used routinely at our institution. Therefore, we cannot exclude the possibility that pH$_i$ values might have decreased to even lower values without VVB. The main purpose of our study was to assess the ability of tonometry to detect intraoperative mucosal hypoxia, to measure gastric and sigmoid pH$_i$, and to relate the observed changes in pH$_i$ to the occurrence of endotoxaemia and primary graft function.

Although in the preliminary report of Camprubi and colleagues, important information on patient physical status and determinants of tissue oxygenation is lacking, the fact that cardiac index, oxygen extraction and lactate concentration are comparable with the values measured in our study suggests that the different results for gastric pH$_i$ during the anhepatic stage may be attributed to the more severe chronic impairment of intestinal perfusion in our patients with end-stage cirrhosis. This is supported by the lower pH$_i$ values measured early during hepatectomy in our study (7.28 *vs* 7.39). In fact, low pH$_i$ values (<7.32) have been reported in patients with chronic intestinal ischaemia and portal vein obstruction[2]. In agreement with our data, the pH$_i$ values of Camprubi and colleagues' patients without VVB had returned to baseline after reperfusion. However, in our patients with end-stage hepatic cirrhosis, pH$_i$ did not reach normal values (>7.32) before the second postoperative day, an observation that further supports the presence of chronic impairment of mucosal microcirculatory perfusion. Hence, pre-existing chronic mucosal hypoxia might explain why pH$_i$ decreased during the anhepatic stage, although overall portal flow was maintained by the use of VVB.

It also cannot be excluded that the apparent difference in baseline pH$_i$ values between our study and that of Camprubi and colleagues is a result of the use of different blood-gas analysers. Riddington and colleagues[3] and Takala and colleagues[4] have shown that direct comparison of pH$_i$ values obtained by different analysers is not valid. Therefore, it was recommended that each institution should determine its own reference values for pH$_i$.

Volatile anaesthetics and neuromuscular block

Sir,—I read with interest the article by Dr Vanlinthout and co-workers[1] and agree that the magnitude of potentiation of the effects of neuromuscular blocking agents by volatile anaesthesia is an important clinical question. We established recently that the dose of vecuronium required for a given effect during desflurane anaesthesia was 20% less than that required during isoflurane anaesthesia[2]. Consequent from this small reduction in vecuronium dose requirements there was a much greater degree of recovery from the neuromuscular blocking agent when the concentration of desflurane was reduced compared with equivalent reductions in isoflurane. Hence, even small differences in potentiation can be of great clinical significance if neuromuscular blockers are administered in response to monitoring (thereby taking advantage of reductions in dose requirements).

Dr Vanlinhout's group set out to clarify inconsistencies in the literature on the interaction between sevoflurane and neuromuscular blocking agents. Unfortunately their study merely adds to the confusion. They concluded that sevoflurane and isoflurane potentiated neuromuscular blocking drugs to a similar degree. It is not reasonable to draw such a conclusion from the data presented in their article.

For vecuronium alone, they found an ED_{50} value of 16.9 μg kg^{-1}. With the degree of variability reported and assuming that a 20% reduction in dose requirements is clinically relevant[2], their study had, at best, only an 11% chance of demonstrating such a reduction. That is, if the reduction in vecuronium dose reported in the presence of sevoflurane (ED_{50} of 14.4 μg kg^{-1}, 17% less than with isoflurane) was a real (rather than chance) occurrence, then 204 patients would have to have received each anaesthetic to have an 80% chance of demonstrating such a difference at the 0.05 significance level.

We should interpret their study with caution. The results of their study are entirely in keeping with there being a clinically important difference in the degree of neuromuscular blocker potentiation manifest by sevoflurane and isoflurane.

Sir,—Clinical interaction studies evaluating the influence of different anaesthetic techniques on the action of neuromuscular blocking agents often compare two or more groups of patients treated separately but concurrently as part of the same study. These studies are termed "parallel" to emphasize their difference from other clinical studies in which patients are their own controls. Parallel comparisons include most of the usual forms of interaction studies investigating the abilities of different inhalation anaesthetics to potentiate the neuromuscular effects of neuromuscular blocking agents. However, the large between-patient variability in dose–response and dose–duration studies with neuromuscular blocking agents may preclude demonstration of subtle differences in susceptibility to these agents. Paired crossover studies can minimize the effect of inter-individual variability[1]. However, these paired crossover studies are difficult to perform with surgical patients. Healthy ASA I or II patients that are anaesthetized two or more times, receiving on each occasion a different anaesthetic technique, are rare. Therefore, these paired crossover studies have to be performed with volunteers.

Our clinical study was designed as a parallel comparison of different anaesthetic techniques, that is opioid–nitrous oxide–oxygen, opioid–nitrous oxide–oxygen–isoflurane and opioid–nitrous oxide–oxygen–sevoflurane, in their ability to potentiate the neuromuscular effects of the most commonly used non-depolarizing neuromuscular blocking agents in surgical patients. Using one-way analysis of variance (ANOVA) and subsequently the Ryan–Einot–Gabriel–Welsh (REGW) multiple range test[2] to identify eventual sources of difference, there was a significant difference in magnitude and duration of neuromuscular action between the control group, receiving no volatile agent, and the groups receiving inhalation anaesthetics. We were unable to demonstrate any significant difference between opioid–nitrous oxide–oxygen–isoflurane and opioid–nitrous oxide–oxygen–sevoflurane anaesthesia on the effects of neuromuscular blocking agents. In the population investigated, the differences between opioid–nitrous oxide–oxygen–isoflurane and opioid–nitrous oxide–oxygen–sevoflurane anaesthesia on the magnitude and duration of neuromuscular blocking agents were small compared with the between-patient differences in these responses to neuromuscular blocking agents ($<10\%$ for the mean values of both magnitude and duration of action). In order to demonstrate significant differences in the potentiating abilities of isoflurane and sevoflurane on the effects of neuromuscular blocking agents, that is a significant difference in both depth and duration, sample sizes of several hundreds of patients per neuromuscular blocking group would have been required[3]. Such sample sizes are beyond practicable limits. We selected our population carefully, using rigid inclusion criteria, as described in the text, to reduce patient variability. This inevitably introduced constraints such as the availability of large numbers of eligible patients within a reasonable period of time. Any investigator is limited by both resources and time. Additionally, our study was intended as a phase II trial to evaluate the interaction between sevoflurane and neuromuscular blocking agents within a limited number of surgical patients.

Both the investigator and clinician should be concerned about the ability to detect an important clinical difference. Different investigators disagree on what is a clinically significant difference. They also disagree on the risk they are willing to take of missing a meaningful effect caused by drug interaction[4]. The choice of a 20% difference in ED_{50} as a clinically significant value is arbitrary. Such a difference is small compared with the large inter-individual differences in the response to neuromuscular blocking agents. With the degree of variability and sample sizes used in our study, a 30% reduction in the ED_{50} of pancuronium and atracurium and a 45% reduction in the ED_{50} of vecuronium had an 80% chance of being significant at the 0.05 level.

Finally, we still feel that further interaction studies on the influence of higher concentrations of volatile anaesthetics on larger doses of neuromuscular blocking agents are warranted. To elucidate small but significant differences in the ability of isoflurane and sevoflurane to potentiate the action of neuromuscular blocking agents, these interaction studies need to be performed in volunteers who are studied twice, receiving isoflurane on one occasion and sevoflurane on the other[5].

Cusum: a statistical method to evaluate competence in practical procedures

Sir,—It was interesting to read the commentary by Kestin[1] describing the use of cusum analysis to measure the competence of anaesthetic trainees at practical procedures. The cusum is a useful graphical tool for discerning trends from a series of observations. The derivation of boundary lines for sequential tests allows comparison of the observed proportions of success or failure against predetermined standard criteria. This could be developed into a continuous performance monitor in anaesthesia.

In his article, Kestin discussed the problems of keeping paper records and plotting fractions on the graphs. In response to this we set out to develop a computerized personal log book system for practical procedures to run in parallel with the electronic anaesthetic log book on the Psion 3a. However, in setting up the algorithms we have encountered a number of problems.

The values for s, h_0 and h_1 calculated using the formulae in the appendix do not agree with the values in table 1 of the article. On reviewing the original articles[2] on the application of the cusum, the value of Q should read $Q = \text{Ln}\ [(1-p_0)/(1-p_1)]$. The values in the table are indeed correct if this calculation is used for Q.

The null hypothesis in the article is stated as "the true failure rate is NOT different from the acceptable failure rate" and if the cusum exceeds h_1 then it is rejected. This does not imply that the true failure rate exceeds the unacceptable failure rate which is the performance indicator which interests us. Similarly the alternative hypothesis is stated as "the true failure rate is equal to or exceeds the unacceptable failure rate" and if the cusum decreases to less than h_0 then it is accepted. Surely this would imply that the falling cusum of registrar B in figure 1 has a true failure rate that is equal to or exceeds the unacceptable failure rate.

p_0 corresponds to the failure rate under the null hypothesis which should surely read "the true failure rate is not different from the unacceptable failure rate". If the cusum exceeds h_1 then this hypothesis is accepted and the trainee's performance is unacceptable with reference to the agreed unacceptable failure rate. Similarly p_1 corresponds to the failure rate under the alternative hypothesis which should surely read "the true failure rate is equal to or exceeds the acceptable failure rate". If the cusum decreases to less than h_0 then the this hypothesis is rejected and the trainee's performance is no worse than the accepted failure rate.

Furthermore, there appear to be clearcut criteria in the definition of success or failure for a particular procedure. This is confusing and it is difficult to see why type 1 and 2 errors of 10% (0.1) where chosen.

For reasons of convenience for the plotting of the graph, the values of s, h_0 and h_1 where multiplied by 10. It is not clear if, in the event of a success, $(1-s)$, $10\ (1-s)$ or $1-10s$ was plotted.

The statistical method described by Kestin appears to be a very powerful analytical tool and may have a wide range of applications in the assessment of trainees. However, the errors and inconsistencies in the appendix are a source of confusion. It would be useful if the derivation of the definitions, variables, hypotheses and theory behind the calculations were explained more clearly.

2. Williams SM, Parry BR, Schlup MMT. Quality control: an application of the cusum. *British Medical Journal* 1992; **304**: 1359–1360.

Sir,—I would like to thank Drs Hammond and McIndoe for their interest, and in particular for correcting the error in the formula for Q in the appendix—p_0 and p_1 have been transposed.

In answer to their other comments, the advantages of using α and β of equal magnitude is explained in the methods section; the choice of 0.1 was a compromise between the common values for α of 0.05 and for β of 0.1 or 0.2 used in clinical studies. The software on the Psion 3a can be used to record and display the cusum; in this case, it is not as helpful to have α and β equal than if graphical methods are used. The graphs used by our trainees were plotted using the nearest integers to $10s$ and $10\ (1-s)$ as the increments.

The original article in the *British Medical Journal* referred to by Drs Hammond and McIndoe was the article that stimulated my interest in this topic. However, I found it difficult to understand the basic statistical concepts of cusum analysis from this article. I found it even more difficult to write an explanation myself, and this article is the only one of mine which the reviewers have ever suggested that more text be included to clarify the argument! I would refer them and others to Davies' text[1] for a better explanation than I could provide.

BOOK REVIEWS

Critical Care: Standards, Audit and Ethics. J. Tinker, D. R. G. Browne and W. J. Sibbald (editors). Published by Arnold, London. Pp. 412; indexed; illustrated. Price £85.00.

This book is divided into four sections: critical care, resource standards, audit and ethics. The editors take the view that technology is no longer the limiting factor in the management of the critically ill patient and have therefore gathered together expert views on these other issues which challenge intensive care clinicians. The authorship is chosen to give a global perspective, and the variety of content to provide something for everyone (intensive care clinicians, students, trainees, lawyers and hospital managers). Indeed, it is difficult to avoid the opinion that many sections are written for lay persons.

The introductory sections suggest that critical care medicine is life-support biology and the unit where it is practised, the hospitals' hospital. Clear differences emerge between nations and their provision of intensive care and individuals involved in its delivery. "The clinical pharmacist has participated in the full care of the patient with special effectiveness during life-threatening crises, including those of cardiac arrest." Repetition of iatrogenic complications introduced by intensive care medicine is a good reminder of our responsibilities. On the whole, the text is well referenced, with the occasional exception (a reference to fatal consequences of tracheostomy, almost certainly performed surgically, from 35 yr ago). The book covers development and cost implications of intensive care medicine and implications for the future.

The second large section on resource standards is an odd mixture of chapters and topics covering primary care and transport, general structure of intensive care units, monitoring and a shopping list of the therapies that are provided. There are some good sections on the use of unevaluated invasive monitoring, excuses for compassionate use of unproved therapy, and the difficulties in defining risk benefit. The theme throughout is the lack of evidence for benefit of intensive care but the justification for failure of mortality to improve is that we are now treating older, sicker patients in whom more general medical effort has been put into sustaining those with chronic disease. "The logical progression of ethical arguments can be developed by which specific therapies or diagnostic procedures are defended."

The chapter on invasive haemodynamic monitoring suggests we should apply specific tests for documentation of the effectiveness of this monitoring and provides an excellent section on the fantasies of haemodynamic monitoring, particularly related to the limitations of measurement of pulmonary artery occlusion pressure. The need for future research studies, especially on the use of pulmonary artery catheterization to rationalize cost containment, is clearly evident. The chapter on imaging describes the basic techniques available and the radiological appearance of pathological processes in different anatomical sites. This would benefit from more illustrations of better quality. The section on the intensive care laboratory is particularly good as few of us have looked in adequate depth at our procedures for quality assurance and quality control. These authors have achieved their objective of presenting a philosophy to eliminate errors and the requirement for documentary evidence of QC, service records and staff training.

I had some anxiety that the views of the authors represented in the chapters on delivering respiratory, cardiac and renal support, although conventional, would be viewed as the standard approach for all patients, given the nature of the text.

There are very useful comparisons of nursing and medical staffing and training, including those for respiratory and physical therapy, between the UK, USA, Australia and Canada and an innovative chapter on the role of the clinical engineer and clinical scientist in patient care. This latter section bewails the lack of worldwide recognition for academic qualifications, certification or registration which the author suggests adversely affects the professional profile and status of clinical scientists, engineers and technologists at a time when complex technological management requires a highly qualified person with managerial skills who must also be proficient in computing and budgeting, in addition to being involved in clinical trials.

The section on audit which adapts the general principles to intensive care is well written and draws attention to the potential for patient data management systems to integrate information. There is some repetition in the later part of the book in relation to selection of patients for intensive care which is inevitable as it alludes to the means of quantifying illness. The limitation of outcome measurements is referred to and also the potential for "negative benefits". The overall outcome from intensive care has to be viewed however as part of the integrated process of health care delivery. The authors of the chapter on costs and consequences evaluating the evidence of benefit of intensive care has achieved its objective in providing insight into technology assessment and making clear recommendations that we improve our ability to critically evaluate the technologies we use, a challenge which is being met in the UK by Health Technology Assessment bodies and better liaison with industry to work towards developments which will help patients and not sales.

The section on ethics defines our need to establish priorities in order to make choices within health care and draws attention to the high incidence of withdrawing or withholding care as a prelude to death in the ICU. There are considerable international differences in practice and good if simplistic advice from the European author to resist fears of malpractice suits when facing futile prolongation of life.

The section on organ donation is very comprehensive although the use of xenografts is dismissed by a few lines without any reference to the potential for the spread of blood-borne viral disease in the immunocompromised host. The requirement to achieve good standards in clinical research is stressed and this chapter covers the ethical issues and the requirement of researchers to be not only good physicians but capable of conducting a study that will help to improve patient care in the future.

Inevitably, the medico–legal section contains a good deal of repetition, again from other sections of the book, but provides good insight into international differences in approach and indeed variations in pronouncements from our own legal system in the UK, particularly relating to withdrawal of care where the decisions of judges inevitably reflect their own moral stance. The book ends with a chapter on moral and religious dilemmas, with particular reference to management of the Jehovah's Witness.

Overall, I would recommend this book to all those involved in the delivery of intensive care. It does try to deliver all things to all people, but perhaps because of this we are encouraged in our multidisciplinary attitude to consider these important issues not only for ourselves but in the context of the rest of the developed world.

S. Willatts

Comprehensive Human Physiology from Cellular Mechanisms to Integration, vols 1 and 2. G. Greger and U. Windhorst (editors). Published by Springer, Berlin. Pp. 2527; indexed; illustrated. Price DM168.00.

The first thing that struck me about these volumes was their massive size—postage for the two volumes was just under £10. Together they contain about four times the content of a "standard" physiology text, such as Ganong, and each volume is equal to one of the larger textbooks, such as Best and Taylor. Thus, in content, it comes between the usual textbook range and the highly voluminous, highly expensive encyclopaedic work such as the *American Physiological Society Handbook of Physiology*. The hard cover binding is excellent in that the volumes remain open at any selected page on a flat surface. The paper and print quality are also excellent, although the print size is smaller than in most textbooks.

The editors state two main aims: first, to provide an up-to-date review of the subject of human physiology, and second, to combine molecular and cellular information with integrated whole-body physiology. To achieve this they have enlisted some 104 contributors, mainly from Germany (47) and North America (30 from the USA and nine from Canada); only four are from the UK. The 124 chapters (and two appendices) are organized into five major sections: basic principles and their coordination (476 pages); the nervous system (720 pages) (end of volume one); intake and excretion (434 pages); acute vital functions, heart, circulation and respiration (580 pages); and the life cycle (190 pages). There is an initial chapter on "Physiology past and future", the last chapters are on the physiology of aging and death and there are generous appendices (29 pages) on physiological units and normal values for physiological variables. The index covers 77 pages and is present only in volume two, whereas the preface, list of contents and contributors are given at the front of both volumes. As a sign of the times, the final page of each volume is entitled "Springer-Verlag and the environment", and states that the materials used, including paper from low- or no-chlorine pulp, are environmentally friendly.

The book is liberally illustrated (black/blue with occasional full colour) with high quality diagrams and original micrographs, traces and data. Most chapters end with 100 or more primary references. Overall the style is clear and elegant. Much of the book is written in a user friendly style but some readers may find some areas difficult to digest. Chapters often end with a conclusions section which may be a brief summary paragraph or extend to a full page.

I feel that the editors have achieved their aim of providing a state-of-the art comprehensive review of human physiology from the molecular to the whole organism level. The chapters, written by subject experts, are scholarly in style, with discussion of evidence and citation of numbered references at the end of each chapter. Content approximates to monograph level. The references cover the late 1980s and the 1990s. Thus in one highly referenced chapter, 35 of the 233 references are from the 1990s, including two in press, and 103 are from the 1980s. I feel that most would be gained from this book by reading complete chapters, some of which are heavy going in places, rather than using the book to check a point of basic detail in a short space of time, where established textbooks would probably be better.

From being personally involved in a (rather smaller) multi-author publication, I can appreciate the enormous effort required to get this huge enterprise off the ground. The preface records that, sadly, the two original editors (Mommaerts and Koepchen) both died before the work could be brought to fruition. The publisher's current advertisement gives the pages as approximately 1860, and from my own experience I would see the first edition as essentially a starting point and hope that the momentum can be maintained by further editions at relatively short intervals, now that modern word-processing makes updating and improving relatively painless.

In conclusion, this is certainly not a book for the trainee anaesthetist working for the fellowship. Even the intellectual high flyer would be better advised to use one of the excellent larger textbooks. However, at a cost of DM 168 (about £73) it represents excellent value and I would strongly recommend it for departmental and hospital libraries and for individuals looking for "in-depth" updates across the range of physiological knowledge. If the editors and authors can refine and update it every 2 or 3 yr then I think it could become a classic and perhaps confound the editors' prediction in the last paragraph of their preface that we are "on the verge of an era without printed textbooks".

W.F.M. Wallace

Critical Care of Infants and Children. I. D. TODRES AND J.-H. FUGATE (editors). Published by Little, Brown and Co., Boston. Pp. 725; indexed; illustrated. Price £85.00.

This single volume, competitively priced, American text joins an expanding list of books in the fledgling 38-yr-old specialty of paediatric intensive care which is still "*in utero*" in the UK, at least in terms of its provision, organization and training. The contents are prioritized well, with resuscitation, emergency management and practical procedures covered in the first 100 pages, with useful line drawings, photographs and radiographs sprinkled liberally throughout the text. I was surprised that there was no paediatric CPR algorithm in the first chapter and in the section on upper airway obstruction, the general anaesthesia technique used for securing the airway was given the body swerve, presumably because American intensivists do likewise by delegating this duty to the anaesthetist!

The "systems" are covered well and an interesting chapter on cardiac ultrasound is illustrated well with Doppler photographs, including five colour plates. Nitric oxide and high frequency oscillation are mentioned briefly and deserved more coverage, and liquid ventilation, which has great potential, was omitted. Pharmacology and poisoning are reviewed but it was interesting that the references on "propofol poisoning", which caused such problems in the UK, were not mentioned. The last part of the book attempts to deal with the extremely important ethical, psychosocial and organizational issues which impact more and more on paediatric intensive care practice. The key role of the intensivist as a coordinator is stressed and the dangers inherent in too much "multidisciplinarianism" illustrated nicely by the poem *The blind men and the elephant* by J. G. Saxe, which gives welcome light relief.

The last paragraph in the book sums up why some of us struggle on with our love–hate relationship with paediatric intensive care: "The importance of a well organised and smoothly run ICU is critical to the care of the child and the family. For the intensivist, the experience can be a most rewarding one, providing a great source of satisfaction and the opportunity to be a true healer".

N. S. Morton

Anaesthesia Review 12. L. KAUFMAN AND R. GINSBURG (editors). Published by Churchill Livingstone, Edinburgh. Pp. 259; indexed; illustrated. Price £35.00.

Wisely seeing no need to alter their tried and tested format, the (now joint) editors of *Anaesthesia Review* present the 12th volume in this popular series. Twelve chapters by invited contributors provide informative, up-to-date, relevant and mostly readable reviews of a diverse array of topics, with a bias in this volume towards pharmacological developments and aspects of pain relief. Dr Kaufman provides two rather less easy-to-read chapters packed with interesting tit-bits of information relating to recent publications in anaesthesia, and in medicine relevant to anaesthesia. These serve as a valuable reference source to further their knowledge in a particular field. Perhaps the inclusion of a research paper in a Dr Kaufman review chapter could be used as a marker of relevance to the average anaesthetist!

The 12 invited contributions, mostly by known authorities in their field, vary in style, length and depth; the authors appear to have had a fairly free hand in this matter. This is by no means a criticism, as it enables the reader to select his/her reading to suit the time and concentration faculties available. Topics range from alternative methods of ventilation in ARDS to end-tidal carbon dioxide monitoring, the spinal cord and chronic pain, controversies in pain, transdermal drug delivery, infusion techniques, paediatric analgesia, oxidant injury, metabolism of newer anaesthetic drugs, extradural anaesthesia, anaesthesia for burns patients and prevention of venous thrombosis. Every chapter is well-referenced and there is little to criticize. I found no factual errors and only a few spelling or typographical errors.

It is customary to recommend a book such as this to FRCA candidates. I would suggest that while examination candidates would undoubtedly benefit from selective reading of this book, there are probably more time- and cost-efficient methods of learning. It would be useful reading to have in the on-call room or on the train, or for regaining momentum in that post-written, pre-viva announcement period. For the rest of us with rather less pressure and a little more time, this book is an enjoyable read over a few weeks, with much of interest to most anaesthetists.

D. Campbell

Clinical Risk Management. C. VINCENT (editor). Published by BMJ Publishing Group, London. Pp. 570; indexed. Price £34.95.

This is a 500 page paperback book produced by the BMJ Publishing Group; each chapter is written by a different author and edited by the psychologist, Charles Vincent.

Resource management is a developing subject in health care in this country, which is fuelled by increasing clinical negligence cases for which trusts have to take responsibility, the realization of the frequency of mistakes in health care practice and that "human rather than technical failures now represent the greatest threat to complex and potentially hazardous systems".

This book gives a thorough and comprehensive review of the state of this subject in the UK at the present time and a rational opinion of both how it should, and how it is likely to develop. It does this by collecting together a series of essays by different authors which are mostly very readable and have some common thread of style. It is divided into three parts. The first part gives the background to the subject with a chapter on experiences from the United States and chapters on the psychology of human error and changing behaviour. The chapter on financial implications of risk management points out that if resource management is seen only in terms of litigation and finance, it is difficult to prove its worth, but in terms of quality improvement, there are both social and economic benefits to be gained from reducing untoward outcomes. The close link between risk management and quality improvement is discussed, but it is emphasized that they appear to be aimed at different groups and have different financing arrangements although they should be part of the same system. Also, the close link between clinical and management activities is firmly established.

In the second part of the book, risk management is dealt with in a more practical way, with chapters on the state of risk management in a number of specialties, including obstetrics, A&E and anaesthesia, and chapters on general practice and risk management in nursing and midwifery. Several of these chapters are well illustrated by case studies and other examples which make interesting reading to the practising clinician. They show the diverse interpretation of risk management in different specialties which, although partly a result of the different needs of the different specialties, also illustrates the need for considerable improvement in many areas.

The third part deals with the practical aspects of how to implement a risk management programme. Although some of the views in this part are expressed from a fairly narrow viewpoint, the whole section gives some excellent methods of how clinicians and their management colleagues in trusts should be considering the area of risk management. The arguments are compelling.

Finally, the book ends with a number of appendices on clinical negligence scheme for trusts, Governments proposals for the NHS complaints procedure, potential job descriptions for clinical risk managers and other such useful documentation.

This is an important book for anyone involved in risk management in hospitals in the UK. It can serve as a good reference book, each chapter being well referenced, but it is written well enough to be an interesting and useful read from cover to cover.

A. G. H. Cole

Neuromuscular Transmission. Fundamentals of Anaesthesia and Acute Medicine Series. L. H. D. J. Booij (editor). Published by BMJ Publishing Group, London. Pp. 196; indexed; illustrated. Price £27.95.

This small book is one of a series from the BMJ Publishing Group on the "Fundamentals of Anaesthesia and Acute Medicine". The series aims to update the reader on the principal clinical topics related to anaesthesia: this issue is on neuromuscular transmission. It is edited by Professor Leo Booij (Netherlands) and is written by an international team of well recognized contributors to the field of neuromuscular physiology and pharmacology.

The physiology of neuromuscular function is covered in detail: three chapters consider prejunctional events, postjunctional mechanisms, and perhaps most importantly, the central control of neuromuscular transmission. Such central control is an important factor during general anaesthesia (in contrast with the use of neuromuscular blocking agents in the critically ill), and it is apposite that a full chapter is dedicated to it. It is impossible as yet to give a full explanation of these effects, but recent advances have been detailed and some thought-provoking ideas are given.

As with any multi-author text, the standards vary between chapters and there is some repetition. Several are well referenced, particularly the chapters on drug interactions, non-depolarizing neuromuscular blocking agents, neuromuscular blockers and concurrent disease, and active reversal of neuromuscular block. In addition, these chapters are impressively detailed. How many readers realize that famotidine is the only H_2 receptor antagonist *without* a neuromuscular blocking effect? Or that the aminosteroids were derived from the African poison, *Malouetia bequaertiana*? I certainly did not. The work involved in such an exercise should not be underestimated. Professor Booij is to be congratulated on his efforts; despite the multiple authorship, his contribution is the most impressive.

Undoubtedly, it would be pedantic to mention the small referencing errors which exist throughout the text. There are also some factual errors, however. Pancuronium is certainly *not* one of the most frequently used non-depolarizing neuromuscular blockers in the UK: it has not been so for 15 yr. Only the older generation of anaesthetists now use it: in some hospitals it would be impossible to find. Nor does renal failure cause an exaggerated hyperkalaemic response to suxamethonium: the effect is more marked only because the baseline serum potassium concentration is higher, and therefore toxic concentrations are reached more easily.

I would prefer to have had more information on plasma cholinesterase in this text. Now that its structure has been defined and more is known about the various patterns of inheritance of abnormal cholinesterase, this would have been interesting. More mention of the latest knowledge on malignant hyperthermia and neuromuscular blockers would also have been useful in the concurrent disease chapter.

Nevertheless, every *twitcher* should have this book on their shelves (for the references alone), even though several similar texts are now available on neuromuscular function. We certainly do not need any more until the next millennium. There only remains a need for a tome on the physiology and pharmacology of neuromuscular function; a reference book which covers all aspects of this subject. I wonder who will have the energy to edit it!

ERRATA

British Journal of Anaesthesia 1996; **76**: 816–821

p. 819. In figures 1 and 2 of this article, the legend identifying the two groups was omitted. These two figures and the correct legends are reproduced below.

We apologize to the authors for this confusion, which arose during the editorial process.

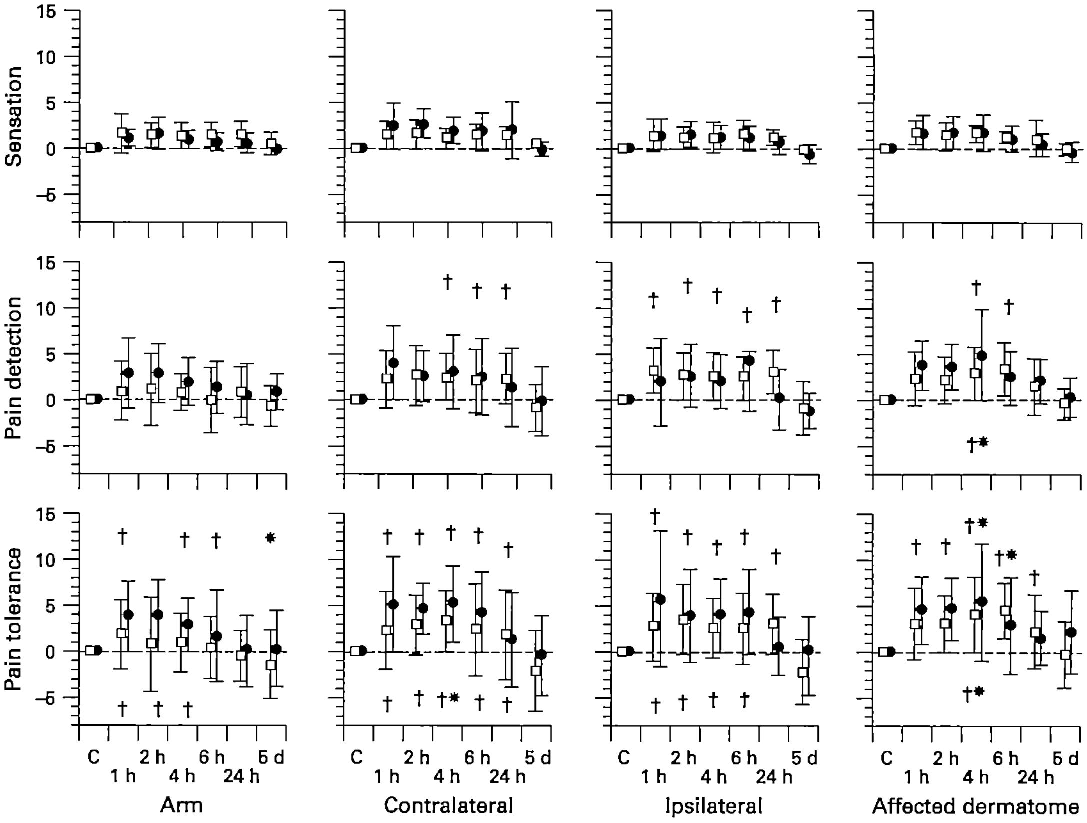

Figure 1 Changes from baseline of raw sensory thresholds (mean, SD mA). The dermatomes tested (X axis) and the types of threshold tests (Y axis) are indicated. $^*P<0.05$ *vs* baseline, $\dagger P<0.05$ *vs* day 5 value. The significances for the placebo group (□) are marked above the zero line, those for the fentanyl group (●), below. Only differences at individual times within a given graph are marked (for other results, see text).

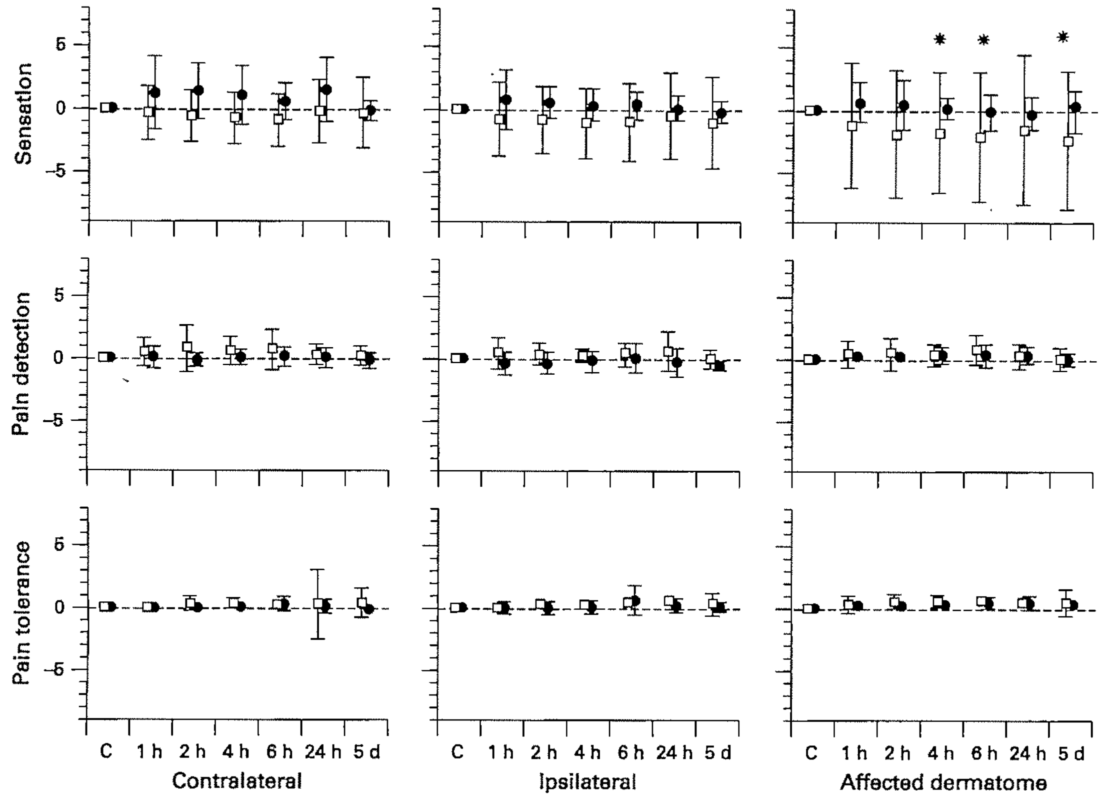

Figure 2 Changes from baseline of normalized sensory thresholds in arbitrary units (mean, SD ratios). The dermatomes tested (X axis) and the types of threshold tests (Y axis) are indicated. *$P<0.05$ *vs* baseline. The significances for the placebo group (□) are marked above the zero line, those for the fentanyl group (●), below. Only differences at individual times within a given graph are marked (for other results, see text).

British Journal of Anaesthesia 1996; **76**: 829–834

p. 831. In figure 2, the filled symbols were omitted and thereby the significance results. The correct figure is reproduced below.

We apologize to the authors for this confusion.

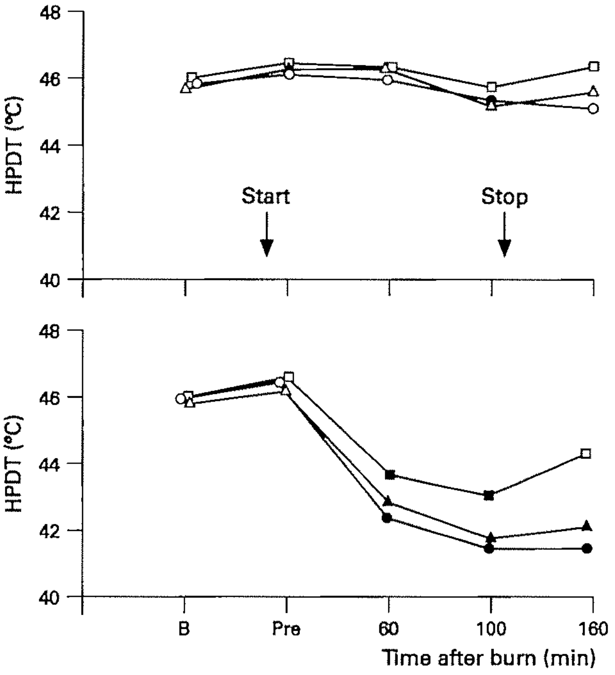

Figure 2 Heat pain detection threshold (HPDT) on the unburned (top) and burned (bottom) calf (medians) before (baseline (B) and before the burn injury (Pre)), during and after infusion of placebo (○), ketamine 0.15 mg kg^{-1} (△) or ketamine 0.30 mg kg^{-1} (□). Start, stop = Beginning and end of infusion of ketamine or placebo. Ketamine 0.15 mg kg^{-1} *vs* placebo: $P>0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P>0.05$, non-parametric two-way analysis for unburned calf; ketamine 0.15 mg kg^{-1} *vs* placebo: $P>0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P<0.05$, non-parametric two-way analysis for burned calf. Filled symbols = significant difference from baseline (Friedman's ANOVA).

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 77, No.5 NOVEMBER 1996

EDITORIAL

Does anaesthesia have long-term consequences?

The definition of anaesthesia as a triad of hypnosis, analgesia and neuromuscular block,[1] now seems simplistic; it ignores other less obvious effects, which may be either beneficial or detrimental to our patients. One example of a more subtle effect of anaesthesia is how it may influence communication between cells. Intact intercellular signalling underlies the ability of an organism to mount an appropriate physiological response to an insult. In many pathophysiological processes, including wound healing, ischaemia and malignancy, defective signalling is known to occur.[2] Progress in basic science has led to the identification of, and the technology to measure, a group of intercellular mediators termed *cytokines*. These comprise a family of small proteins and glycoproteins (molecular weight 15–30 kDa). Under normal conditions, baseline production of cytokines is low, but when triggered by appropriate stimuli, including infection or surgical injury, production can increase markedly.[3] Most cytokines act in an autocrine (i.e. on the producer cell) or paracrine (i.e. on neighbouring cells) manner.[4] A few members of the family, for example tumour necrosis factor-α (TNF-α), interleukin-2 (IL-2), interleukin-6 (IL-6) and transforming growth factor-β (TGF-β) are transported in the blood to act at distant sites, and thus resemble classical hormones. After stimulation by an insult, leucocytes, macrophages and endothelial cells either release stores, or rapidly switch on the synthesis of cytokines. These mediators regulate the activity, differentiation and growth of many types of cell belonging to the inflammatory and immune systems. Generation of transgenic animals, which either over-express or under-express a specific cytokine, has provided a useful tool to help unravel the functions of these mediators.[5]

Severe injury and infection produce well characterized neuroendocrine and metabolic changes in the host. These changes are mediated, at least partly, by cytokines. TNF-α, IL-1β, IL-2, IL-6 and interferon-α cause release of anterior pituitary hormones by acting on the hypothalamus and pituitary glands.[6 7] Although such cytokine responses are generally believed to be beneficial, some individuals develop an excessive or prolonged response, manifested clinically by the systemic inflammatory response syndrome (SIRS).[8] Many animal studies have been published demonstrating improved outcome after inhibition of cytokine responses. Most of this research has focused on sepsis. They conclude that attenuation of cytokine activity after lipopolysaccharide (LPS) administration, or caecal ligation and puncture, increases survival.[9 10] For many reasons, discussed by Yentis in an editorial in this journal, the expected benefit from cytokine manipulation in sepsis has not yet been realized in human studies.[11]

Cytokine responses to surgery have also been studied, particularly IL-1β, IL-6 and TNF-α, which have been shown to increase in proportion to the magnitude of the operation.[12] Although there is a paucity of data on the influence of anaesthetic drugs and techniques on cytokine responses, there is evidence that anaesthesia is capable of modulating these short-term responses. *In vitro* studies have demonstrated that volatile agents can suppress cytokine release from blood cells. Isoflurane inhibits the secretion of TNF-α and IL-1β from LPS-stimulated human peripheral blood monocytes.[13] In another study, sevoflurane and enflurane were found to inhibit TNF-α and IL-1β release from stimulated monocytes, but the release of IL-2 was unaffected.[14] *In vitro* assessment of anaesthesia and cytokine responses has not been restricted to general anaesthetic agents. Lignocaine inhibits the effect of recombinant human granulocyte colony-stimulating factor (rhG-CSF) on human neutrophil function: it reduces rhG-CSF-induced neutrophil superoxide release and down-regulates leucocyte adhesion molecule-1 expression in a dose-dependent manner.[15]

Few studies have been published on how anaesthesia affects *in vivo* cytokine responses to surgery. Crozier and colleagues compared the changes in plasma concentrations of IL-1β and IL-6 after abdominal surgery, using two different anaesthetic techniques.[16] Compared with anaesthesia using isoflurane and nitrous oxide, total i.v. anaesthesia (TIVA) with propofol and alfentanil caused a significantly reduced and delayed increase in IL-6 concentrations. No difference was observed when concentrations of IL-1β were measured. The authors concluded that alfentanil was the agent responsible for suppressing the release of IL-6. The effect of extradural anaesthesia on the IL-6 response to abdominal surgery has also been investigated: although it caused no overall significant change in cytokine concentrations, a delayed increase in IL-6 was noted.[17] Thus, there is evidence that anaesthesia has the potential to attenuate cytokine responses induced by surgical trauma.

For reasons which remain unclear, some individuals develop uncontrolled cytokine responses and could potentially benefit from appropriately timed cytokine inhibition. Until recently it has not been possible to predict which patients are at risk of mounting this excessive cytokine response to surgical injury. However, molecular biology may be able to offer a solution. Polymorphism is the existence in a population of two or more relatively common alleles at a genetic locus. Polymorphism, or variation in DNA sequence, may occur in an extron (coding portion of the gene) and after transcription and translation, result in the production of a defective protein. Equally, polymorphism may occur in an intron (non-coding portion), but still modify gene expression in other subtle ways.[18] For example, polymorphism may lie in the promoter region of the gene, a part of the gene that is important in determining initiation of transcription. Alternatively, polymorphism itself may be unimportant, except as a marker that may be linked to another, as yet unidentified, allelic variation that is responsible for the altered phenotypic response. Although it is accepted that particular genotypes can predispose individuals to long-term risks in response to environmental stress, for example the familial clustering of some types of cancer, until recently there was little evidence that genotype could alter outcome with respect to short-term stress. Stuber and colleagues have recently reported a genomic polymorphism within the TNF locus that influences concentrations of TNF-α and outcome in patients experiencing the short-term stress of severe sepsis.[19] They used the polymerase chain reaction (PCR) to amplify a 782-base pair fragment of genomic DNA, which included the polymorphic site of a restriction endonuclease (NcoI) within the TNF locus. Each patient's genotype was determined after digestion with NcoI and gel electrophoresis. Two TNF alleles, TNFB1 and TNFB2, were identified and correlated with maximum concentrations of TNF-α and outcome. The 42% of patients who were homozygous for TNFB2 had significantly higher concentrations of TNF-α and a worse outcome. This is the first attempt at using a genetic test to predict cytokine responses and outcome, and should be investigated prospectively. In the future it may be possible, using simple blood tests, to predict which patients are likely to mount excessive cytokine responses after major surgery (high responders). Such tests may help anaesthetists to predict outcome or the need for postoperative intensive care. They may also allow us to select the most appropriate anaesthetic, in terms of its ability to modulate cytokine activity, for each patient.

In addition to modulating cytokine responses to surgical injury, anaesthesia may influence the activity of cytokines involved in coincidental pathophysiological processes. Many cytokines have been identified as pivotal mediators in a wide range of chronic processes. Transforming growth factor-β (TGF-β) may be unfamiliar to most anaesthetists, but is an example of a cytokine which is known to be vitally important in the pathogenesis of many long-term disorders, including wound healing, fracture healing and malignancy. When soft tissue is injured, TGF-β is released from degranulating platelets to trigger a cascade of events, including recruitment of inflammatory cells, angiogenesis and the synthesis of collagen.[2] Application of topical TGF-β promotes wound healing in a variety of animal models and the topical application of anti-TGF-β antibodies reduces cutaneous scarring.[20] Interestingly, Amento and colleagues reported that a single dose of TGF-β administered systemically before wounding also enhanced healing.[21] Thus, transient changes in concentrations of TGF-β may have effects on the long-term process of wound healing. If anaesthesia is shown to change TGF-β activity, even for a short albeit critical period, then it could indirectly influence wound healing after surgery. TGF-β is also thought to contribute to fracture healing and embryonic bone formation. Injections of TGF-β onto the periostea of rat parietal bones induced new bone formation.[22]

Systemic administration of TGF-β protects against ischaemia. It was shown to have cardioprotective effects when administered after experimental myocardial infarction in rats.[23] Systemic administration of TGF-β in a model of splanchnic ischaemic–reperfusion injury was also shown to be protective.[24] Growth of most epithelial and lymphoid cells is inhibited by TGF-β. One postulated mechanism whereby cells undergo carcinogenic transformation and escape from normal growth control appears to involve an altered response to the negative regulation of TGF-β. Studies on a TGF-β-responsive human colonic carcinoma cell line implicated TGF-β as an autocrine and paracrine negative regulator of growth, and suggest that loss of response to TGF-β may contribute to tumour progression.[25]

Our understanding of cytokine biology is developing rapidly. Knowledge as to the identification of patients who are prone to mounting abnormal cytokine responses, and the roles of cytokines in the pathogenesis of disease, is increasing at a phenomenal rate. Anaesthesia must contribute to this exciting and expanding area of research. The study of how different anaesthetic agents and techniques affect cytokine concentrations and activity must continue. Certain agents and techniques could prove to be clinically useful in the modulation of cytokine activity in subjects who are high responders and also influence specific disease processes which are regulated by cytokines. Indeed, there may well be more to anaesthesia than sleep!

CLINICAL INVESTIGATIONS

Sleep after laparoscopic cholecystectomy

S. ROSENBERG-ADAMSEN, M. SKARBYE, G. WILDSCHIØDTZ, H. KEHLET AND J. ROSENBERG

Summary

The sleep pattern and oxygenation of 10 patients undergoing laparoscopic cholecystectomy were studied on the night before operation and the first night after operation. Operations were performed during general anaesthesia and postoperative analgesia was achieved without the administration of opioids. There were no significant changes in the total time awake or the number of arousals on the postoperative night compared with the night before operation. During the postoperative night, we found a decrease ($P = 0.02$) in slow wave sleep (SWS) with a corresponding increase in stage 2 sleep ($P = 0.01$). SWS was absent in four of the patients after operation, whereas in six patients it was within the normal range (5–20% of the night). The proportion of rapid eye movement (REM) sleep was not significantly changed after operation. There were no changes in arterial oxygen saturation on the postoperative compared with the preoperative night. Comparison of our results with previous studies on SWS and REM sleep disturbances after open laparotomy, suggests that the magnitude of surgery or administration of opioids, or both, may be important factors in the development of postoperative sleep disturbances. (*Br. J. Anaesth.* 1996; **77**: 572–575)

Key words
Sleep. Oxygen, saturation. Hypoxaemia. Surgery, laparoscopy.

Sleep disturbances have been described after major abdominal surgery[1–5] and herniorrhaphy[2 6]; the disturbances include decreases in total sleep time, proportion of rapid eye movement (REM) sleep and slow wave sleep (SWS). These changes are most pronounced on the first and second postoperative nights[1–6], with a subsequent rebound on the following nights.[1 3 5 6] The magnitude of surgery (the surgical stress response), the surroundings (noise, nursing procedures, etc.), pain and administration of opioids are all factors that may influence postoperative sleep,[7] but the relative importance of these factors is still unknown.

The aim of this study was to evaluate postoperative sleep in patients undergoing minimally invasive surgery (laparoscopic cholecystectomy) without administration of opioids during the postoperative period.

Patients and methods

The study was approved by the local Ethics Committee and patients participated in the study after giving informed consent. We studied 10 patients (eight females; median age 51 (range 34–72) yr, weight 83 (55–105) kg and height 167 (158–172) cm) undergoing laparoscopic cholecystectomy. None of the patients was receiving regular medication before operation and exclusion criteria included known sleep apnoea syndrome, neurological, cardiac or respiratory diseases, oxygen administration during the study nights and use of sedatives or hypnotics during the past 2 months at home or during hospitalization. All patients underwent elective surgery with no recognized risk factors and received routine postoperative care.

Anaesthesia was induced and maintained with thiopentone, isoflurane, low-dose fentanyl, midazolam, suxamethonium, atracurium and nitrous oxide in oxygen. After operation, including the first postoperative night, all patients received ibuprofen 600 mg every 8 h. Opioids were not used for postoperative analgesia.

Patients were studied in the surgical ward in a quiet single bedroom for 1 night before operation and on the first postoperative night, from 22:00 to 06:00. For sleep staging, patients were monitored with a Somnolog System (Ventec Aps, Hellerup, Denmark)[8] which records continuously the electroencephalogram (EEG) (alpha and delta activity by one-channel EEG—a modified F3-A2 lead), electromyogram (EMG) (electrodes placed under the base of the mandible), single lead ECG, eye and hand movements (by movement sensors placed on the upper eyelid and dorsally on the proximal joint of the left index finger) and noise level (by a standard microphone placed 1 m above the patient's head). Data were stored in the internal memory of the Somnolog with subsequent downloading to a

SUSAN ROSENBERG-ADAMSEN*, MD, MONA SKARBYE, MD, GORDON WILDSCHIØDTZ, MD, HENRIK KEHLET, MD, PHD, JACOB ROSENBERG, MD, DMSC, Department of Surgical Gastroenterology 235, Hvidovre University Hospital, DK-2650 Hvidovre, Denmark and Department of Psychiatry, Rigshospitalet, DK-2100 Copenhagen, Denmark. Accepted for publication: July 12, 1996.

*Address for correspondence: Department of Surgical Gastroenterology 235, Hvidovre University Hospital, DK-2650 Hvidovre, Denmark.

personal computer. The variables in the Somnolog were analysed manually for sleep stage using 6-s epochs throughout the night, according to the criteria of Rechtschaffen and Kales.[8 9]

During the study nights, arterial oxygen saturation (Sp_{O_2}) was measured with a pulse oximeter (Nellcor N-200, Nellcor Inc., Pleasanton, CA, USA) with an adhesive finger probe.[10] Sp_{O_2} data were sampled at 1-s intervals into a bedside personal computer with subsequent data print-out the following morning. Episodic hypoxaemia was defined as a decrease in oxygen saturation of more than 4% from baseline occurring within a 2-min period.[11] Analysis of oximetry data was performed without knowledge of the sleep data except when calculating the frequency of hypoxaemic episodes during periods of REM sleep.

For statistical analysis we used the Wilcoxon signed rank test. $P < 0.05$ was considered significant. Group data are given as median (range).

Results

Median duration of surgery was 85 (range 36–100) min. Duration of anaesthesia was 120 (75–140) min, during which the patients received a total of 1500 (600–2000) ml of isotonic saline. During operation, patients received a total dose of fentanyl 0.4 (0.25–0.50) mg. There was no correlation between fentanyl dose and magnitude of change in sleep pattern. None of the patients received perioperative blood tranfusions and none developed postoperative complications.

There were no significant changes in the total time awake or the number of arousals on the postoperative night compared with the night before operation (table 1). During the postoperative night, we found a significant decrease in SWS ($P = 0.02$) with a corresponding increase in stage 2 sleep ($P = 0.01$). SWS was absent in four patients (fig.1), whereas in six patients SWS was within the normal range (5–20% of the night) on the postoperative night. The proportion of REM sleep was not significantly changed after operation (fig.1). One patient showed a postoperative increase in SWS and REM sleep (fig.1).

Mean arterial oxygen saturation (Sp_{O_2}) and number of desaturations were not significantly changed after operation ($P = 0.2$ and $P = 0.5$). In order to assess the relationship between postoperative REM sleep and episodic hypoxaemia, we used the previously defined index of hypoxaemic episodes during REM sleep for individual patients[3] ((number of hypoxaemic episodes in REM sleep divided by total number of hypoxaemic episodes) divided by (REM sleep time divided by total sleep time)) (table 1). Thus an index of 1 indicates that the distribution of hypoxaemic episodes was equal between REM and non-REM sleep corrected for duration of REM sleep, and an index >1 indicates that episodic hypoxaemia was more frequent in REM than in non-REM sleep for that night. If the patient had no REM sleep on the study night, the index was 0. There were no significant changes in this index between the two study nights ($P = 0.67$).

Table 1 Sleep stages and arterial oxygen saturation (median (range)). *$P<0.05$ compared with preoperative night (Wilcoxon test). REM = rapid eye movement sleep; SWS = slow wave sleep; Sx = sleep stage x.
Index of hypoxaemic episodes in REM[3] =

$$\frac{\text{No. of hypoxaemic episodes in REM sleep/}\;\text{Total number of hypoxaemic episodes}}{\text{REM sleep time/Total sleep time}}$$

	Preoperative night	First postoperative night

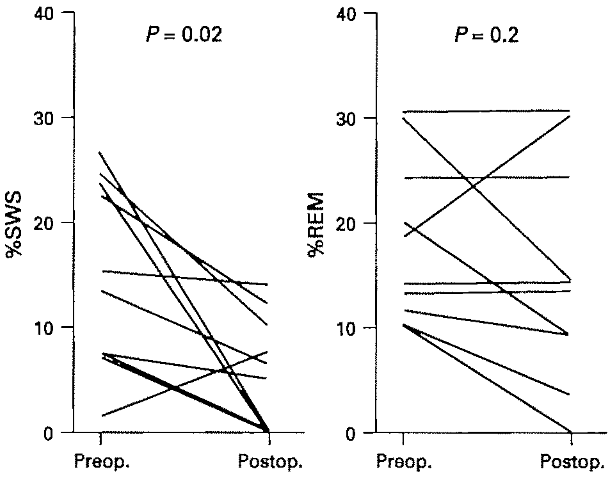

Figure 1 Individual values for the proportion of time spent in slow wave sleep (SWS) and rapid eye movement (REM) sleep on the preoperative and postoperative nights. Values are given as percentages of the study night.

Discussion

This study is the first to describe the sleep pattern after laparoscopic cholecystectomy. We found a slight decrease in SWS, but REM sleep on the first night after operation was unchanged. Also, arterial oxygen saturation (constant and episodic hypoxaemia) was unchanged.

Postoperative sleep disturbances in patients undergoing non-cardiac surgery have been described after major abdominal surgery[1–5] and herniorrhaphy.[2 6] The investigators found a marked reduction in SWS during the first 1–4 postoperative nights,[1–4 6] and in a previous study from our group, SWS was absent in all 10 patients on the first night after major abdominal surgery.[3] In our study there was only a slight decrease in SWS, and in six of our 10 patients, SWS was within the normal range on the first night after operation. It may be argued that recovery from a "first night effect" with impaired sleep on the preoperative night might have contributed to the relatively small changes seen from the preoperative (first night) to the postoperative night. However, we have shown previously that when monitoring surgical patients for 2 nights before operation and with the same monitoring equipment and experimental set-up, a first night effect was not present.[3]

After major surgery, REM sleep is usually absent on the first and sometimes the second and third postoperative nights,[1–6] followed by an increased duration of REM sleep and density (rebound) during the subsequent 2–4 nights.[1 3 5 6] In a previous study, performed after major abdominal surgery, there was a significant decrease from a median of 17% to 5% in the proportion of REM sleep on the first night after operation.[3] In this study, however, there were no significant changes in the proportion of REM sleep after minimally invasive surgery.

Our patients did not have decreased total sleep time. Previous studies in patients undergoing major abdominal surgery or herniorrhaphy have found that total sleep is reduced by up to 80% on at least one of the first postoperative nights,[2 4 6] and fragmented with numerous movement arousals and spontaneous awakenings.[1 2 6] In our study, however, patients were awake for a total of 13% (range 0–38%) of the first postoperative night, but without an increase in the number of arousals on the postoperative compared with the preoperative night (table 1). As sleep duration and fragmentation are important determinants for the subjective restorative capability of sleep,[11] our patients should have been less affected by their postoperative sleep changes than patients undergoing major abdominal surgery or herniorrhaphy, although we did not ask for subjective sleep quality.

The clinical consequences of postoperative sleep changes are unknown, although there may be several potential important implications.[7] Experimental deprivation of SWS produces a feeling of physical discomfort,[12] characterized by a depressive and hypochondriacal reaction.[12] This may contribute to the feeling of fatigue in postoperative patients, although a relationship between postoperative sleep disturbances and postoperative fatigue has yet to be demonstrated.[7] Postoperative REM sleep deprivation may be a factor in the development of postoperative impairment of mental function.[13] The postoperative rebound of REM sleep may contribute to the development of sleep-disordered breathing and nocturnal hypoxaemia,[3 5 7] as episodic hypoxaemia is more frequent in periods of REM rebound than during other sleep stages in the postoperative period.[3 5] Furthermore, postoperative REM sleep rebound may be associated with haemodynamic instability and increased mean arterial pressure.[14 15] In the postoperative period, these haemodynamic changes may be related to hypoxaemic episodes,[3] and the simultaneous decrease in myocardial oxygen supply (hypoxaemia) and increase in myocardial oxygen demand (tachycardia and hypertension) may lead to postoperative myocardial ischaemia[16 17] and infarction.

Several factors may contribute to the disturbed sleep in postoperative patients. The magnitude of surgery seems to be important, as the reduction in REM sleep, SWS and the lack of inherent rhythmicity were more pronounced after major (gastrectomy or vagotomy) compared with minor (hernia repair) surgery.[2] In addition, morphine, in doses of 0.1 and 0.2 mg kg^{-1} i.m. in healthy volunteers, disrupted sleep in a dose-dependent manner.[18] There are no studies on the effect of systemic or extradural morphine on sleep in postoperative patients.

This study has shown a slight decrease in SWS as the only significant sleep disturbance on the first postoperative night in patients undergoing minimally invasive surgery without administration of opioids during the postoperative period, thus supporting the hypothesis that the magnitude of surgery, administration of opioids, or both, may be important factors in the development of postoperative sleep disturbances. The anaesthetic technique *per se* does not appear to be an important factor as similar degrees of sleep disturbances have been found after general or regional anaesthesia for herniorrhaphy[6] or minor surgery.[19] A study in volunteers anaesthetized for 3 h with isoflurane found no significant disturbances in the post-anaesthetic sleep pattern other than a slight decrease in SWS on the first night[20]; this is comparable with the sleep pattern in our patients after laparoscopic cholecystectomy.

Gasless laparoscopic cholecystectomy: comparison of postoperative recovery with conventional technique

A.-M. KOIVUSALO, I. KELLOKUMPU AND L. LINDGREN

Summary

We have compared, in a randomized study in 26 patients, immediate and late postoperative recovery after elective laparoscopic cholecystectomy using the gasless, mechanical abdominal wall lift method with conventional carbon dioxide pneumoperitoneum. After the gasless method, tracheal extubation was performed significantly earlier than after the conventional method ($P < 0.01$). End-tidal carbon dioxide concentrations were significantly higher after pneumoperitoneum for 30 min after operation ($P < 0.01$). In the conventional group, deviation in Maddox–Wing recordings from preoperative values remained at a significantly higher level during the 3-h recovery room period ($P < 0.01$). There was a positive correlation between the total amount of carbon dioxide used and duration of drowsiness ($r = 0.61$, $P < 0.001$) and the Maddox–Wing deviation ($r = 0.62$, $P < 0.001$). Postoperative nausea and vomiting, and right shoulder pain occurred less often after the gasless method ($P < 0.05$). Late recovery criteria (ability to drink, void and walk) in patients in the gasless group were fulfilled approximately 7 h earlier than in those in the pneumoperitoneum group ($P < 0.01$). Gasless laparoscopic cholecystectomy resulted in more uneventful and faster immediate and late postoperative recovery than conventional carbon dioxide pneumoperitoneum. (*Br. J. Anaesth.* 1996; **77**: 576–580)

Key words
Surgery, laparoscopy. Complications, pneumoperitoneum. Recovery, postoperative.

Laparoscopic cholecystectomy has rapidly replaced open cholecystectomy as a standard treatment of symptomatic gallstones. Laparoscopic cholecystectomy restores pulmonary function better and enables less painful recovery, shorter hospitalization and faster return to normal activities than open cholecystectomy.[1] Induction and maintenance of carbon dioxide pneumoperitoneum can, however, have serious adverse physiological effects.[2–11] In addition to peroperative problems, postoperative sequelae are also seen not infrequently.[5] Insufflated carbon dioxide is absorbed into the circulation resulting in hypercapnia.[12] Furthermore, lung ventilation is the only mechanism for elimination of carbon dioxide. After conventional laparoscopic cholecystectomy, postoperative nausea and vomiting (PONV) have been reported in up to 68% of patients.[13 14] After laparoscopic cholecystectomy with combined low-pressure pneumoperitoneum and abdominal wall lift, the incidence of PONV was 8%.[5] In addition, postoperative drowsiness was also of significantly longer duration and right shoulder pain occurred more often after conventional carbon dioxide pneumoperitoneum.[5] Also, the more carbon dioxide used the more restless were patients in the recovery room.

Therefore, we evaluated to what extent a totally gasless method for laparoscopic cholecystectomy would affect the quality of immediate and late postoperative recovery.

Patients and methods

We studied 26 ASA I–II patients undergoing elective laparoscopic cholecystectomy. The study was approved by the local Ethics Committee and informed consent was obtained. Patients were allocated randomly to one of two groups. Patients in one group underwent laparoscopic cholecystectomy with conventional pressure pneumoperitoneum (CPP group) (intra-abdominal pressure (IAP) 12–15 mm Hg) with room temperature carbon dioxide insufflation. In the other group, a retractor (Laparolift TM, Origin Medsystems Inc., USA) (fig. 1) was used to elevate the abdominal wall upwards by 10–15 cm.[15] No carbon dioxide was used (retractor group). All operations were performed by the same experienced senior surgeon (I. K.).

Patients were premedicated with oral diazepam 0.2 mg kg^{-1} approximately 60 min before arrival in the operating theatre. Glycopyrronium 3 $\mu g\ kg^{-1}$ was given i.v. to all patients. Fluid administration of Ringer's acetated solution and hydroxyethyl starch (Plasmafusin, Pharmacia AB, Sweden) was standardized. Anaesthesia was induced with alfentanil 20 $\mu g\ kg^{-1}$ and propofol 1.6–2.5 mg kg^{-1}. Alfentanil 20 $\mu g\ kg^{-1}$ was given before the start of surgery in all patients. Neuromuscular block was provided with

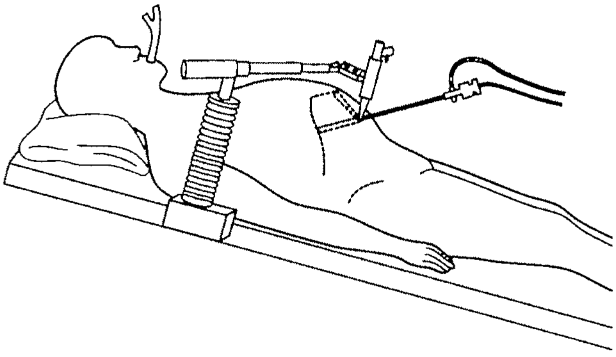

Figure 1 Schematic illustration of the retractor method.

atracurium and was monitored using the train-of-four technique. If the surgeon complained of stiffness of the abdominal muscles an additional bolus of atracurium 10 mg was given. Anaesthesia was maintained with desflurane at an end-tidal concentration of 6.1% (1 MAC) and oxygen in air ($F_{I_{O_2}}$ 0.4). No nitrous oxide was used. The lungs of all patients were ventilated mechanically at 10 bpm (Servo 900 C, Siemens Anmedic, Elema Schönander, Sweden). If needed, minute volume of ventilation was increased to maintain end-tidal carbon dioxide concentration at 4.5–5.0% (AS / 3, Datex Ltd, Finland). Analgesia was achieved with an infusion of alfentanil 10–200 $\mu g\ kg^{-1}\ h^{-1}$ titrated to avoid increases in arterial pressures of more than 20% from the pre-anaesthetic value. The total amount of alfentanil used during anaesthesia was noted and neuromuscular block was not antagonized with neostigmine. After operation, patients were allowed to breathe spontaneously and the trachea was extubated when breathing was regular, end-tidal carbon dioxide was decreasing and laryngeal reflexes had recovered. In all patients, end-tidal desflurane was 1% or less at the time of extubation. The time interval from extubation until patients responded to commands and gave their date of birth was recorded.

After operation patients were followed up for 3 h in the recovery room. Abdominal pain at rest and during coughing, and right shoulder pain were assessed using a verbal rating scale (0–3). If the pain score was 2 or more the patient received oxycodone 0.07 $mg\ kg^{-1}$ i.v. If the pain score remained 2 or more for more than 15 min the dose of oxycodone was repeated and ketorolac 30 mg i.v. was given. End-tidal carbon dioxide concentration was recorded after 1 deep breath hourly using a nose catheter (Cardiocap, Datex Ltd, Finland). Sedation was scored : 0 = fully awake, 1 = sedated, responding to commands, 2 = hardly responding to commands, 3 = not responding to commands. Restlessness was scored : 0 = calm, 1 = little movements all the time, 2 = needs someone to sit beside, 3 = needs sides for the bed. Drowsiness was scored : 0 = brisk, 1 = little tired, 2 = likes to sleep, 3 = does nothing but sleeps. A score of 2 or more was considered as sedation, restlessness or drowsiness. Duration of drowsiness and PONV were observed. Only vomiting was treated with droperidol 0.625 mg i.v. The baseline Maddox–Wing ocular test was performed on the day before operation after careful explanation of the use of the instrument to the patient.[16] Postoperative tests were performed hourly during the 3-h recovery room stay. Changes in the Maddox–Wing recording from the preoperative value were noted. All postoperative recordings were performed by a trained nurse unaware of the method used during operation.

Late recovery was recorded as the interval from tracheal extubation to the moment the patient was voluntarily able to void, drink and walk.

Patients were interviewed on the first day after operation, with special reference to pain and its location and PONV. All drugs needed during the first 27 h after operation were noted.

STATISTICAL ANALYSIS

Data within a group were analysed using one-way analysis of variance (ANOVA) with PLSD correction (least significant test). The differences between the two groups were analysed using two-way ANOVA with PLSD correction or Fisher's exact test for small groups.[17] Calculations were performed using Stat View 512 + TM software (Brain Power Inc., Calabasas, CA, USA). Correlations between the total amount of carbon dioxide and deviation in Maddox–Wing recordings from preoperative value and between duration of drowsiness were calculated. Data are expressed as mean (SD). $P < 0.05$ was considered statistically significant.

Results

The two groups were comparable in age, height, weight, ASA status and sex. Duration of operation was 108 (28) min in the retractor group and 85 (25) min in the CPP group ($P < 0.05$). Total amount of carbon dioxide was 55 (34) litre in the CPP group whereas in the retractor group carbon dioxide was not used ($P < 0.001$). Total amounts of alfentanil and propofol used were comparable in the two groups: in the retractor group 84 (70) $\mu g\ kg^{-1}$ and 2.3 (0.6) $mg\ kg^{-1}$, respectively, and in the CPP group, 104 (76) $\mu g\ kg^{-1}$ and 2.1 (0.4) $mg\ kg^{-1}$, respectively (ns). Atracurium was needed significantly more in the retractor group (1.0 (0.1) $mg\ kg^{-1}$) than in the CPP group (0.8 (0.2) $mg\ kg^{-1}$) ($P < 0.05$) (table 1).

Patients in the retractor group fulfilled the extubation criteria 10 (4) min after discontinuation of desflurane. This value was 23 (15) min in the CPP

group ($P < 0.01$). Patients in the retractor group responded to commands 0.4 (0.4) min and gave their date of birth 1 (1) min after extubation. These values were 3 (4) min and 5 (11) min, respectively in CPP group (ns) (table 2).

End-tidal carbon dioxide values in the retractor group were significantly lower compared with those in the CPP group during the first 30 min after operation (fig. 2).

The Maddox–Wing test was recorded in 19 of 26 patients as the remainder were unable to see without spectacles. The deviation in Maddox–Wing recording from the preoperative value was significantly lower in the retractor group than in the CPP group, 2 h after operation ($P < 0.01$) (fig. 3). There was a positive correlation between the total amount of carbon dioxide used and deviation in Maddox–Wing values during the 3-h recovery room period (table 3).

Two patients in the CPP group were so restless that they needed sides for their beds. Amount of carbon dioxide used during operation in these patients was 103 and 40 litre. These two patients and one patient who needed 47 litre of carbon dioxide during operation were sedated (score >2) for the 3-h recovery room period. None of the patients in the retractor group was restless or sedated.

30 min	0.55	< 0.01
60 min	0.5	< 0.01
120 min	0.5	< 0.01
180 min	0.62	< 0.001

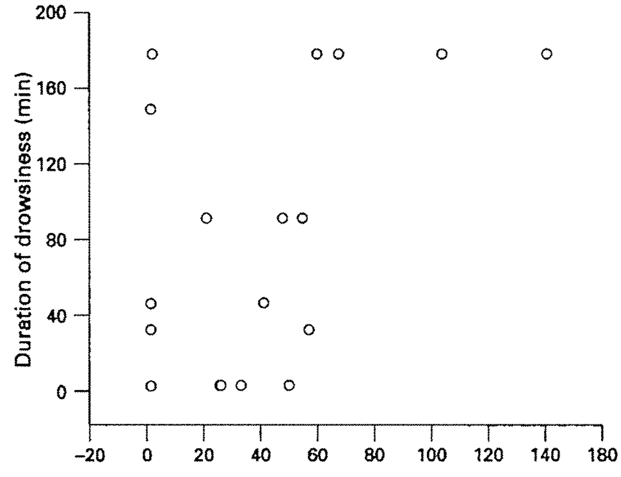

Figure 4 Correlation between duration of drowsiness and total amount of carbon dioxide used during laparoscopic cholecystectomy. $r = 0.61$, $P < 0.01$.

Postoperative drowsiness lasted 31 (61) min in the retractor group and 82 (76) min in the CPP group (ns). There was a correlation between duration of drowsiness and total amount of carbon dioxide used ($r = 0.61$, $P < 0.001$) (fig. 4). In those three patients who were drowsy during the recovery room period, the total amount of carbon dioxide used during laparoscopy was more than 60 litre.

Pain scores and location of the pain during the 3-h recovery room period were similar in both groups. There was no difference in the need for analgesics between groups.

In the recovery room, two patients in the retractor group and five patients in the CPP group needed droperidol for vomiting. During the next 24 h, the groups did not differ in the need for oxycodone (table 2) or ketorolac.

On the first day after operation one patient in the retractor group and seven patients in the CPP group suffered from right shoulder pain ($P < 0.05$). On the first day after operation, eight of 13 patients (62%) in the retractor group described pain in the abdomen "like tenderness after a hard muscle work-out". Pain was unpleasant but not unbearable.

During the next 24 h, one patient in the retractor group and eight patients in the CPP group suffered from vomiting ($P < 0.05$).

Patients in the retractor group were able to drink 9 (5) h after tracheal extubation. In the CPP group this value was 12 (7) h (ns). The interval from extubation to ability to void were 10 (4) h and 14 (5) h, respectively (ns). Patients were able to walk 11 (5) h after extubation in the retractor group and 18 (4) h in the CPP group ($P < 0.01$). In total, seven patients in the retractor group and one in the CPP group fulfilled the late recovery criteria[18] on the evening of the day of operation ($P < 0.05$) (table 2).

There were no perioperative surgical complications.

Discussion

In this study we have shown that postoperative recovery after laparoscopic cholecystectomy was faster and more uneventful when exogenous carbon dioxide was not used. In patients with the gasless method, the trachea was extubated earlier than in those with pneumoperitoneum. They were more often free from PONV and were able to walk earlier than patients after carbon dioxide insufflation.

Atracurium was needed more in the retractor group. This was probably because of the additional need for total relaxation of the abdominal muscles when the abdominal wall was lifted upwards with a force of 10–15 kg. Distension of the abdominal muscles might be painful and explain the similar need for peroperative alfentanil in the two groups. With the conventional method, the need for alfentanil can be explained by the release of endogenous catecholamines.[11]

In our study the duration of drowsiness correlated with the total amount of carbon dioxide used. Exogenous carbon dioxide is absorbed into circulation from the peritoneal cavity during operation and is exhaled via the lungs; this increased end-tidal carbon dioxide concentration occurred in our conventional pressure pneumoperitoneum group up to 1 h after operation. Retention of carbon dioxide might be one reason for prolonged drowsiness. When carbon dioxide is exhaled through the lungs, increased ventilatory drive is needed. In our patients, peroperative infusion of alfentanil was needed for attenuation of the circulatory response to carbon dioxide insufflation, and ventilation was probably inhibited by the residual effects of alfentanil infusion.[19]

The degree of divergence of the small eye muscles measured with the Maddox–Wing device has been found to correlate closely with clinical recovery of patients from general anaesthesia.[16] The Maddox–Wing tests in our patients returned earlier to the baseline level after the retractor method. Because there was a positive correlation between total carbon dioxide used during operation and changes in the Maddox–Wing test, it is probable that the slower recovery of divergence of eye muscles was attributed to the insufflated carbon dioxide. Thus exogenous carbon dioxide may significantly affect progress in early recovery.

PONV occurred significantly more often in patients with carbon dioxide insufflation. Carbon dioxide is a potent vasodilator of cerebral vessels. Increased intracranial blood flow has been seen during laparoscopic procedures.[20 21] Increased intracranial pressure is known to cause nausea and vomiting[22] which may be one reason for PONV in our and in earlier studies.[13 14] Higher end-tidal carbon dioxide concentrations during the 3-h recovery room period in our pneumoperitoneum group may also reflect higher concentrations of carbon dioxide in cerebral blood contributing to the occurrence of PONV. Also, alfentanil causes nausea and vomiting.[23]

Seven patients in the pneumoperitoneum group and only one in the retractor group suffered from right shoulder pain, which is referred pain caused by distension of the right phrenic nerve. Pain in some patients may be severe enough to warrant opioids.[24] In our study, however, the retractor method did not totally abolish right shoulder pain, probably because of diaphragmatic stretching produced by the retractor.

Our patients with the gasless method fulfilled the criteria for late recovery 7 h earlier than those with carbon dioxide pneumoperitoneum. These criteria are commonly accepted for discharge home.[18] More than 50% of patients with the gasless method could be discharged home on the evening of the operation whereas only one patient with carbon dioxide insufflation fulfilled these criteria. Eight patients (62%) in the pneumoperitoneum group needed droperidol for vomiting and required an overnight stay in hospital.

In principle, patients after laparoscopic cholecystectomy can be discharged from hospital on the evening of surgery.[25] However, the use of insufflated carbon dioxide may make this impossible. We suggest that the mechanical abdominal lift method without carbon dioxide insufflation for laparoscopic cholecystectomy may be the method of choice when considering laparoscopic cholecystectomy on a day-case basis.

Haemodynamic and metabolic response to endovascular repair of infra-renal aortic aneurysms

B. R. BAXENDALE, D. M. BAKER, A. HUTCHINSON, T. A. M. CHUTER, P. W. WENHAM AND B. R. HOPKINSON

Summary

We have examined whether or not endovascular insertion of a bifurcated aorto–iliac graft resulted in greater intraoperative haemodynamic and metabolic stability than that achieved during conventional open graft placement. We studied 20 patients prospectively during surgery for asymptomatic infra-renal aortic aneurysm. All patients received the same anaesthetic technique. Haemodynamic data were collected continuously using indwelling radial artery and pulmonary artery catheters, allowing calculation of mean arterial pressure (MAP), cardiac output (CO) and systemic vascular resistance (SVR). Blood samples were obtained for measurement of serum lactate concentrations. Variables were compared within each group before and after specific critical events, namely occlusion of femoral or aortic blood flow, or both, and sequential reperfusion of each lower limb. Patients undergoing open repair showed significant changes in CO, MAP and SVR related to aortic cross-clamping and lower limb reperfusion, and a significant increase in blood lactate concentration after distal tissue reperfusion. The only significant changes during endovascular repair were a transient increase in SVR secondary to application of the femoral artery clamps, and sequential decreases when each limb was reperfused. Endovascular aneurysm repair imposed significantly less intraoperative haemodynamic and metabolic stress on the patient compared with conventional open surgery. (*Br. J. Anaesth.* 1996; **77**: 581–585)

Elective repair of abdominal aortic aneurysms (AAA) by conventional surgery is associated with a mortality of 5–10%, although particular factors such as age and extent of co-existing systemic disease may place patients at much greater risk, even to the extent of denying them surgery. Myocardial infarction (MI) is responsible for 40–70% of this mortality,[1] with infarction within the 6 months preceding surgery and the presence of congestive cardiac failure representing the two most consistent preoperative predictors of perioperative cardiac morbidity. Endovascular repair of AAA is a technique developed to allow exclusion of the aneurysm from the circulation by means of a transfemoral approach. Early experiences with endovascular graft insertion have been reported from Nottingham and other centres.[2–4] This technique offers several potential advantages over conventional (open) repair, including a surgical approach via groin incisions rather than laparotomy, avoidance of retroperitoneal dissection and a much briefer period of abrupt aortic occlusion during placement of the graft. These theoretical advantages are likely to be of benefit to the patient only if they are accompanied by a reduction in the haemodynamic and metabolic stresses imposed by surgery, although the association between these intraoperative improvements and a reduction in postoperative morbidity and mortality may only become apparent by studying large numbers of patients.

We have compared specific intraoperative haemodynamic and metabolic variables in two groups of patients undergoing repair of infra-renal AAA by either open or endovascular surgical techniques.

Patients and methods

After obtaining approval from the hospital Ethics Committee, we studied 20 consecutive adult patients undergoing repair of an infra-renal AAA. Ten patients were selected for insertion of a bifurcated "Chuter" graft by the endovascular technique (endovascular group), with the other 10 patients undergoing conventional graft insertion (open group). Selection into the endovascular group was based primarily on radiographic criteria using calibrated aortic angiography and spiral computed tomograms.[5] This was to ensure that the aneurysm morphology was suitable for the technique, that is a maximum aneurysm proximal neck diameter of 2.5 cm and common iliac diameter of 1.5 cm, minimum

neck length of 1.5 cm from the origin of the more distal renal artery and relatively non-tortuous iliac artery to permit introduction of the 22-Fr delivery system. Preoperative assessment was standard in both groups, including height, weight, cardiac and pulmonary function and risk factors, hepatic and renal function, and diabetic status. All patients underwent transthoracic echocardiography and spirometry, and had measurement of arterial blood-gas tensions while breathing room air.

All patients were premedicated with temazepam 20 mg orally. A standard anaesthetic technique was used for both groups: i.v. induction with etomidate 0.3 mg kg^{-1}, maintenance with isoflurane and 66% nitrous oxide in oxygen, vecuronium to facilitate tracheal intubation and subsequent ventilation of the lungs, and repeated increments of fentanyl 1–3 μg kg^{-1} for analgesia. No regional anaesthetic technique was used during the intraoperative period. Monitoring included continuous 5-lead electrocardiogram with ST-segment analysis on lead II, and continuous inspired and expired gas analysis for measurement of oxygen, nitrous oxide, carbon dioxide and isoflurane concentrations. Direct continuous measurement of arterial pressure was undertaken via a radial artery cannula, and a pulmonary artery catheter was sited to measure central venous and pulmonary artery wedge pressures. Cardiac output (CO) and systemic vascular resistance (SVR) were calculated at 30-s intervals and displayed on a Baxter Vigilance Monitor (Model VMS) attached to the pulmonary artery catheter.

For the endovascular procedure both common femoral arteries were exposed and heparin 10 000 u. administered i.v. before making bilateral arteriotomies to gain access to the lumen. At this stage both femoral arteries were cross-clamped. A transfemoral catheter was introduced from the left femoral artery and passed over the aortic bifurcation and pulled out of the right femoral arteriotomy with the assistance of a stone retrieval basket. The delivery system comprising an inner shaft and an outer sheath containing the graft and stent was introduced via the right femoral arteriotomy. Particular care was required in deploying the top stent between the renal artery and the aneurysm neck, which was achieved by withdrawing the outer sheath while the inner shaft was stabilized in the correct position assessed by angiographic screening. Complete withdrawal of the outer sheath exposed a catheter attached to the left limb of the graft, which was subsequently sutured to the transfemoral catheter. The left graft limb was guided into the left iliac artery as the transfemoral catheter was withdrawn out of the left femoral arteriotomy. After deployment of both graft limbs, Wallstents (Schneider Ltd) were used to provide additional support. At this stage the femoral artery cross-clamps were removed sequentially and haemostasis secured.

Intravascular volume was supplemented if required with 0.9% sodium chloride solution and modified 4% gelatin solution, volumes administered being guided by reference to the pulmonary artery wedge pressure. If estimated blood loss exceeded 20% of the calculated blood volume, red cell preparations were transfused to replace further losses. Neither group received i.v. mannitol, dopamine or any specific vasoconstrictors, vasodilators or other inotropic support during surgery. The endovascular group received 300–500 ml of non-ionic contrast medium during surgery to allow digital subtraction imaging which ensured accurate deployment of the prosthesis.

Baseline haemodynamic values were obtained after general anaesthesia had been established, before any surgical intervention. Haemodynamic data were collected also throughout surgery with particular reference to a number of critical events: immediately before and after femoral artery clamping (in the endovascular group), immediately before

Table 1 Patient data (mean (range) or number of patients)

	Open group (n=10)	Endovascular group (n=10)
Age (yr)	72.9 (64–83)	68.5 (55–81)
Weight (kg)	77.5 (61–95)	77.3 (58–98)

and after aortic occlusion, and before and after reperfusion of the first and then the second limb. Blood lactate concentrations were measured in both groups at the same times, with samples obtained in sodium fluoride/potassium oxalate bottles and refrigerated until analysis. Haemodynamic variables and blood lactate concentrations were compared within each group during the course of surgery using ANOVA and Student's paired t test ($P < 0.05$). Comparison of blood lactate concentrations was also made between the groups using the Student's unpaired t test ($P < 0.05$).

Results

Patient data for the two groups are summarized in table 1. Details of the duration of surgery, aortic occlusion time, femoral artery clamp time and blood loss are shown in table 2. No patient in the endovascular group required conversion of the technique to an open procedure.

Changes in haemodynamic variables during surgery are shown in figures 1–3. On cross-clamping the aorta in the open group, there were significant increases in mean arterial pressure (MAP) from a mean value of 98 (SEM 6) to 115 (9) mm Hg, and SVR from 2413 (189) to 2660 (204) dyn s cm^{-5}, with CO decreasing from 3.8 (0.4) to 3.0 (0.5) litre min^{-1}. There were no significant changes in the endovascular group when deploying the proximal end of the stent within the aorta. However, the endovascular group demonstrated a significant increase in SVR from 2280 (196) to 2485 (240) dyn s cm^{-5} related to occlusion of blood flow through both femoral arteries. Femoral artery occlusion did not result in significant changes in MAP or CO.

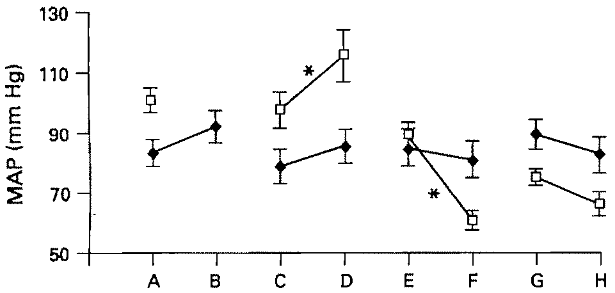

Figure 1 Intraoperative changes (mean, SEM) in mean arterial pressure (MAP) in the open (□) and endovascular (◆) groups. Point A = baseline value for each group. A→B = before and after femoral artery clamping (no data point at B in the open group); C→D = before and after aortic flow occlusion; E→F = before and after reperfusion of the first limb; G→H = before and after reperfusion of the second limb. *$P<0.05$ compared with previous datum point ("within-group comparison" using paired Student's t test).

On reperfusing the first limb, the open group demonstrated significant decreases in MAP from 89 (4) to 61 (3) mm Hg, and SVR from 2327 (146) to 1686 (153) dyn s cm^{-5}, without significant changes in CO. Reperfusion of the second limb caused a further significant decrease in SVR from 1919 (182) to 1586 (152) dyn s cm^{-5}, while MAP and CO remained relatively stable. The only significant changes in the endovascular group were a decrease in SVR from 2104 (167) to 1960 (184) dyn s cm^{-5} when reperfusing the first limb, with a more marked decrease in SVR from 2039 (227) to 1673 (209) dyn s cm^{-5} when the second limb was reperfused. Blood lactate concentrations did not change significantly in either group before reperfusion of distal tissue (fig. 4). Immediately after reperfusing the first limb in the open group, blood lactate concentrations increased from 1.6 (0.2) to 2.4 (0.4) mmol $litre^{-1}$, with a further increase from 2.2 (0.3) to 2.9 (0.4) mmol $litre^{-1}$ when the second limb was reperfused. There were no significant changes in blood lactate concentrations in the endovascular group during reperfusion of either limb.

Two patients in the open group had episodes of fast atrial fibrillation (ventricular response greater than 120 beat min^{-1}) in the first 24-h postoperative period, each requiring pharmacological intervention. There was no significant cardiac morbidity in the first 30 days after operation in the endovascular

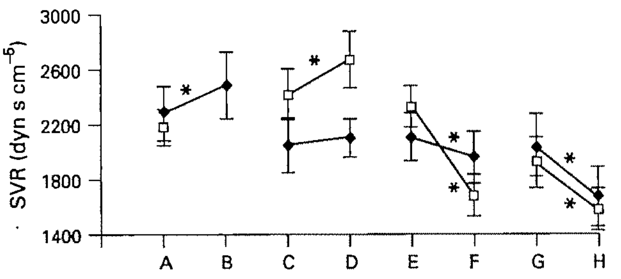

Figure 3 Intraoperative changes (mean, SEM) in systemic vascular resistance (SVR) in the open (□) and endovascular (◆) groups. Legend and X axis categories are the same as in figure 1.

group. There was no cardiac mortality in either group during the same period.

Discussion

We have demonstrated that endovascular exclusion of infra-renal AAA is associated with fewer acute haemodynamic and metabolic changes in the intraoperative period compared with conventional surgery. Cardiovascular and metabolic variables are known to alter significantly during open repair because of abrupt occlusion of blood flow via the aorta caused by cross-clamping, and again when perfusion to the distal tissues is re-established.

Previous studies examining the haemodynamic changes during open repair of AAA have identified aortic cross-clamping as one of the critical intraoperative events, producing up to a 35% decrease in cardiac index and stroke volume, a significant increase in MAP, and a 40% increase in SVR.[6 7] Similar changes were observed in patients in our open group, with SVR increasing by nearly 11%, MAP increasing by 19% and CO decreasing by 21%. The equivalent stage of surgery in the endovascular group was taken to be during deployment of the proximal end of the graft and stent within the aorta. This produced occlusion to aortic flow until the ipsilateral leg of the graft was opened, but this period of complete occlusion lasted for a mean of 9.2 min, significantly less than the 52.1 min during open procedures. Patients in the endovascular group showed greater haemodynamic stability during this period, with predictable but non-significant changes in all variables measured. Several reasons for this may be suggested, in addition to reduction in complete occlusion time. The action of aortic occlusion may have been associated with less notable changes in cardiac output because these patients had already been subjected to prior application of bilateral femoral artery clamps, after which a 22-Fr delivery system was present constantly within the distal aorta and common iliac artery, producing an increase in resistance to blood flow. At the time of proximal graft/stent deployment, we conclude that the endovascular technique resulted in a less profound increase in myocardial afterload and a less marked reduction in preload, both of which have been implicated in the changes seen with aortic cross-clamping during conventional surgery.

Patients in the endovascular group showed a significant increase in SVR secondary to femoral artery clamping during the initial stage of surgery.

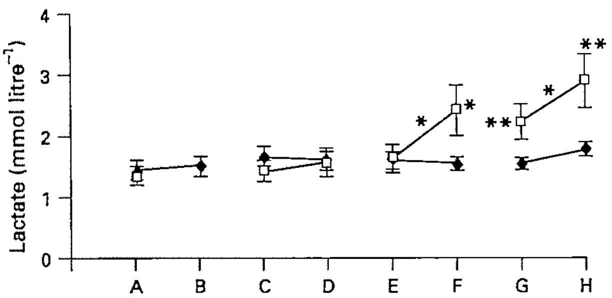

Figure 4 Intraoperative changes (mean, SEM) in blood lactate concentration in the open (□) and endovascular (◆) groups. Legend and X axis categories are the same as in figure 1. $^{**}P < 0.05$ (between-group comparison using unpaired Student's *t* test).

Although there was an associated decrease in CO and increase in MAP, neither change was statistically significant. Subsequent to femoral artery clamping, an angiographic catheter was introduced to allow intraoperative identification of the aneurysm morphology. During this stage SVR returned to baseline values, implying that femoral artery clamping produced a transient effect on the haemodynamic profile, which was relatively non-significant in clinical terms. After positioning the angiographic catheter, the wide-bore co-axial delivery system containing the graft and stents was introduced unilaterally via the femoral and common iliac artery and fed into the aorta beyond the neck of the aneurysm. This stayed in place until the prosthesis was ready for deployment. No significant haemodynamic disturbance resulted from this procedure. No comparative data from the open group were available during this period because of the differences in surgical technique.

Re-establishment of blood flow to tissues distal to an arterial clamp site has two effects: first, decrease in SVR as a result of perfusion of a maximally vasodilated vascular bed; second, return to the circulation of vasoactive metabolic products which have accumulated within the ischaemic tissue. Patients undergoing conventional surgery in our study demonstrated marked haemodynamic changes when the distal tissues were reperfused. Re-establishment of blood flow through the first graft limb produced significant decreases in MAP and SVR, with a further decrease in SVR when the second limb was reperfused. Cardiac output increased during these events, although this was not significant, presumably to compensate to some degree because of maintenance of an adequate left ventricular preload during this period.[6] There was a marked increase in blood lactate concentration in the open group on reperfusion of each limb; reperfusion of the second limb resulted in a 114% increase compared with the baseline value.

In contrast, patients in the endovascular group showed a small but significant decrease in SVR after release of the first femoral clamp, but with rapid recovery towards the pre-release value. A more marked decrease was apparent on release of the second clamp. Each occasion was associated with non-significant changes in MAP and CO. These results suggest that sequential reperfusion via each femoral artery re-opens a vascular compartment sufficient to decrease afterload significantly, but the patient is able to compensate by modest changes in CO, so preventing a clinically significant alteration in MAP. The endovascular group demonstrated no changes in blood lactate concentrations throughout surgery, implying that any "ischaemic" period did not cause a significant metabolic insult from imposed anaerobic metabolism. We suggest that the differences between the two groups related to reperfusion occurred because although the open group had apparently been subjected to a shorter overall period of tissue ischaemia, the quantity and location of tissue rendered ischaemic was significantly different. The endovascular technique used bilateral femoral artery clamps for the majority of surgery, but blood flow through internal iliac and deep femoral collaterals would have continued during this period of arterial clamping.

Haemodynamic stability during endovascular aortic surgery demonstrated in this study represents a potential improvement for patients requiring aortic aneurysm surgery. A significant proportion of this patient population have associated cardiovascular disease, notably previous myocardial infarct (40–50%), congestive cardiac failure (10–15%), ischaemic heart disease (20–30%) or hypertension (50–60%).[8 9] Although debate continues on the combination of preoperative factors associated most reliably with perioperative cardiac morbidity or mortality,[10] it seems reasonable to suggest that a more stable intraoperative haemodynamic profile without evidence of ischaemic metabolic insult may be beneficial during surgery of this type. The Chuter graft/stent system used in this study uses self-expanding modified Gianturco Z-stents, and requires neither deliberate haemodynamic manipulation by the anaesthetist nor balloon inflation at the time of proximal graft fixation, in contrast with other endovascular systems.[4 11] Although the association between improved intraoperative haemodynamic stability and a reduction in significant perioperative cardiac events is intuitive, this study and others to date include insufficient numbers to make firm conclusions.[12] This will rely on larger scale, prospective, randomized, controlled studies being conducted, stating clearly the type of endovascular system being evaluated, with details of preoperative assessment of the patient and perioperative haemodynamic management.[13] This is of paramount importance if the technique is to be considered for patients regarded as representing too high a risk for conventional surgical intervention,[4 14] especially as there is a reported failure rate of approximately 20% in centres experienced with the technique, the consequences of which usually require surgery to be converted to a more extensive procedure or even open repair.[3 4]

Comparison of caudal bupivacaine and diamorphine with caudal bupivacaine alone for repair of hypospadias

A. A. KELLEHER, A. BLACK, S. PENMAN AND R. HOWARD

Summary

Forty-five boys undergoing repair of hypospadias were allocated randomly to one of two groups. After induction of anaesthesia, 22 patients received 0.25% caudal bupivacaine 0.5 ml kg^{-1} and diamorphine 30 μg kg^{-1} and the remaining 23 patients received 0.25% caudal bupivacaine 0.5 ml kg^{-1} alone. Pain scores (Children's Hospital of Eastern Ontario Pain Scale), sedation scores, ventilatory frequency, analgesic requirements and associated side effects were recorded for the first 24 h after operation. The two groups were indistinguishable in age, weight and duration of surgery. There was a statistically significant reduction in early pain scores. There was also a statistically significant increase in the time to first passage of urine in those boys in the diamorphine group who were not catheterized during operation. (*Br. J. Anaesth.* 1996; **77**: 586–590)

Key words

Surgery, urological. Anaesthetics local, bupivacaine. Analgesics opioid, diamorphine. Anaesthetic techniques, regional, caudal.

Adequate postoperative analgesia in children is a vital part of perioperative care. Regional techniques such as caudally administered local anaesthetics have long been used in conjunction with general anaesthesia to provide intraoperative and postoperative analgesia. More recently several studies have examined the effects of adding morphine or fentanyl to caudally administered local anaesthetic, some of which appeared to show an improvement in postoperative analgesia. However, at least one case was associated with unacceptable side effects.[1] The aim of this study was to assess the potential benefits and complications associated with adding diamorphine to caudally administered bupivacaine in boys undergoing repair of hypospadias under general anaesthesia.

Patients and methods

After obtaining hospital Ethics Committee approval, informed parental consent was obtained from 45 ASA I and II boys, aged 6–88 months, undergoing repair of hypospadias.

Patients were prescribed premedication with atropine 40 μg kg^{-1} orally and either trimeprazine 3 mg kg^{-1} or temazepam 0.5 mg kg^{-1} orally. EMLA cream was applied to potential venous access sites. Anaesthesia was induced with either thiopentone 5 mg kg^{-1} i.v. or halothane and nitrous oxide in oxygen. Neuromuscular block was produced with atracurium 0.5 mg kg^{-1} and the trachea intubated.

Each child was then allocated randomly to receive one of two possible caudal injections, either 0.25% bupivacaine 0.5 ml kg^{-1} and diamorphine 30 μg kg^{-1}, or 0.25% bupivacaine 0.5 ml kg^{-1} alone. Addition of diamorphine increased the volume of the injectate by 0.03 ml kg^{-1}. The composition of the caudal solution was known only to an anaesthetist who subsequently played no part in the postoperative assessment of the patient. Anaesthesia and normocapnia were maintained by intermittent positive pressure ventilation with halothane and nitrous oxide in oxygen. Intraoperative monitoring included arterial oxygen saturation, ECG, non-invasive arterial pressure monitoring, end-tidal carbon dioxide concentration and nasopharyngeal temperature. Duration of surgery from completion of induction to antagonism of neuromuscular block was recorded for each patient.

After operation, on arrival in recovery, each child received oxygen 4 litre via a face mask and monitoring was continued in the form of pulse oximetry, ECG and non-invasive arterial pressure measurements. Each child was assessed on arrival in recovery, every 15 min for the first hour, at 2 h and then every 2 h for the remainder of the first 24 h. Subsequently, all children were nursed on the same ward and all assessments were carried out by staff nurses unaware of the composition of the injectate given, and trained in the scoring systems used. Monitoring included heart rate, arterial pressure and temperature measurement. Supplementary oxygen was not continued on the ward and arterial oxygen saturation was not assessed.

Each child was prescribed codeine phosphate 1 mg kg^{-1} i.m. and paracetamol 12.5 mg kg^{-1} orally to be given at the discretion of the nursing staff. Additional postoperative observations included

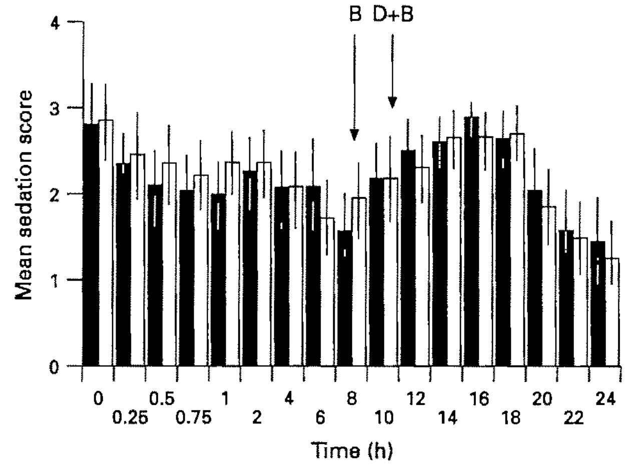

Figure 2 Mean postoperative sedation scores for patients receiving either diamorphine and bupivacaine (D + B) (□) or bupivacaine (B) alone (■) (median (95% confidence intervals)). Arrows indicate the median time to first dose of codeine phosphate in the two groups.

heart rate and non-invasive arterial pressure measurement.

Postoperative assessment comprised scoring for pain and sedation. Ventilatory frequency was also recorded, as were the occurrence of nausea and vomiting, pruritus or urinary retention. The pain score used was the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) (table 1). This assigns scores for crying, facial expression, verbal response, touching the wound and torso, and leg position.

The sedation score graded the degree of sedation from awake to unrousable (table 2).

Patient data and duration of operation in each group were compared using the chi-square test. The remaining data, including pain scores, analgesic requirements and incidence of side effects, were analysed using one-way analysis of variance (ANOVA) with Bonferroni's type I error rate correction for multiple tests of significance. Data analysis was performed using SPSS windows version 6.0. $P < 0.05$ was considered statistically significant.

Results

The two groups were similar in age and weight; mean age in the diamorphine group was 31.36 months and in the bupivacaine alone group, 26.18 months (table 3). Mean weights were 13.34 kg and 12.96 kg, respectively.

There was no significant difference between the two groups in mean duration of surgery, which was 90.9 min in the diamorphine group and 80 min in the bupivacaine alone group.

There were no failed blocks in either group. However, there were significant differences in early pain scores with lower scores in the diamorphine group (fig. 1). The difference in scores at times 0, 15 and 30 min were significant ($P < 0.05$). In the bupivacaine alone group, after initially decreasing, pain scores started to increase again after 4–6 h. Median time to first analgesia (either codeine phosphate or paracetamol) in this group was 8.55 h and thereafter pain scores showed a steady decline. In the diamorphine group there was a smaller peak in pain scores

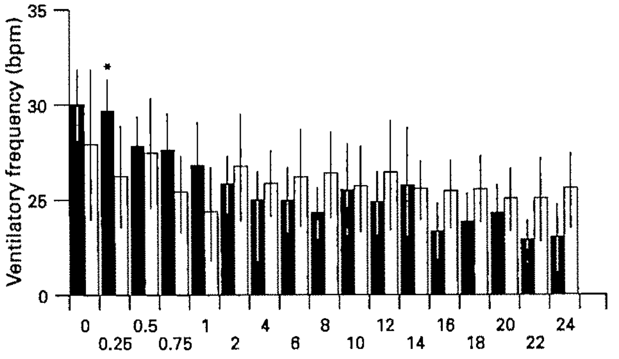

Figure 3 Postoperative ventilatory frequencies for patients receiving either diamorphine and bupivacaine (□) or bupivacaine alone (■) (median (95% confidence intervals)). *$P < 0.05$ (one-way ANOVA).

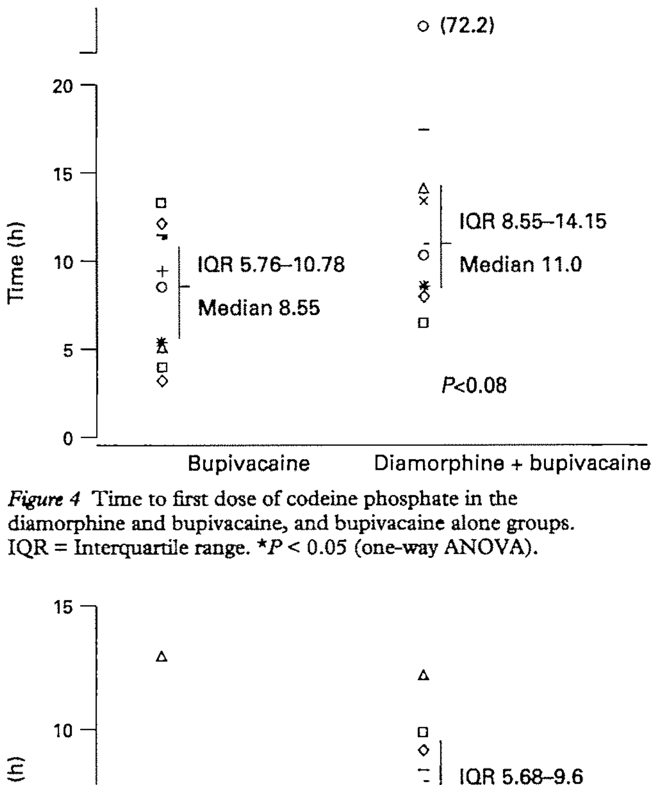

Figure 4 Time to first dose of codeine phosphate in the diamorphine and bupivacaine, and bupivacaine alone groups. IQR = Interquartile range. *$P < 0.05$ (one-way ANOVA).

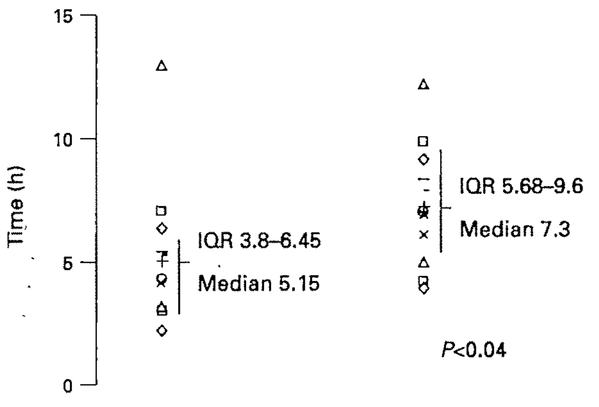

Figure 5 Time to first passage of urine in the diamorphine and bupivacaine, and bupivacaine alone groups. IQR = Interquartile range. *$P < 0.05$ (one-way ANOVA).

at 12 h, the median time to first analgesia was 10.45 h and subsequently pain scores remained relatively constant for the remainder of the first 24 h.

There was no significant difference between the two groups in the degree of sedation, although early scores were slightly higher in the diamorphine group (fig. 2). As may be expected, sedation scores in both groups were high in the immediate postoperative period, then declined during the day, followed by an increase in the evening as the children fell asleep. The first dose of codeine in both groups (median 8.55 h in the bupivacaine alone group and 11 h in the diamorphine group) was associated with an increase in sedation score.

Early postoperative ventilatory frequencies were higher in the bupivacaine alone group, and were significant at 15 min (fig. 3). There were no cases of clinically significant respiratory depression in either group.

Thirteen patients in the diamorphine group and 12 in the bupivacaine alone group did not require codeine phosphate after operation. Of those patients who did, the time to the first dose of codeine was longer in the diamorphine group, although this was not significant (fig. 4). Four patients in the diamorphine group and eight in the bupivacaine alone group received no paracetamol after operation; in those patients who did, the time to first dose was not significantly different between the two groups.

There was an increase in the incidence of nausea and vomiting in the diamorphine group (13.6% compared with 4.3% in the bupivacaine alone group) but this was not significant. There was no incidence of pruritus in either group.

Nine patients in the diamorphine group were electively catheterized during operation for surgical reasons and 10 patients in the bupivacaine alone group. The time to first passage of urine in those patients not catheterized was significantly longer in the diamorphine group, from a median of 5.4 h to 7.6 h after operation ($P < 0.04$) (fig. 5).

Discussion

Caudally administered bupivacaine has long been known to provide good postoperative analgesia with minimal morbidity in children undergoing urogenital surgery.[2–4] More recently, the addition of morphine 50 $\mu g\ kg^{-1}$ to the injected local anaesthetic has been demonstrated to increase the duration and intensity of analgesia without a significant increase in side effects.[5–7] However, at least one of these studies may be criticized in that the volume of bupivacaine given (0.75 $ml\ kg^{-1}$) for orchidopexy may have been inadequate, rendering the local anaesthetic alone group at a disadvantage.[8] Fentanyl 1 $\mu g\ kg^{-1}$ has also been added to caudally administered local anaesthetic but without any improvement in the duration or quality of analgesia after circumcision.[9 10] However, Lejus and colleagues showed that extradural fentanyl 2 $\mu g\ kg^{-1}$ followed by a fentanyl infusion provided a similar level of analgesia as extradural morphine 0.75 $mg\ kg^{-1}$ with a further bolus at 24 h, but as might be expected with a more highly lipid soluble drug, there was a lower incidence of side effects.[11] We could find no study in which diamorphine had been added to caudally administered local anaesthetic in children, although it has been used extensively, and shown to be beneficial in extradural anaesthesia in adults.[12–14]

Diamorphine is 2–3 times as potent and approximately 200 times more lipid soluble than morphine (the olive oil/water partition coefficient of diamorphine is 0.2 compared with 0.016 for morphine)[15] and therefore may cross from the extradural space into the subarachnoid space to bind to spinal opioid receptors much faster than morphine. This results in a more rapid onset of analgesia, usually within 10–15 min compared with 30–60 min with morphine.[16] Consequently, side effects, including rostral spread resulting in late respiratory depression, are less likely.[11,14,17] Because of this increased lipid solubility, diamorphine also diffuses out of the extradural space into surrounding blood vessels faster than morphine, resulting in higher plasma concentrations.[18,19] Inevitably, some of the analgesia and side effects provided by diamorphine may be as a result of systemic absorption rather than a local action on spinal opioid receptors; this leads to a shorter duration of action compared with a relatively non-lipid soluble drug such as morphine. However, it has be shown previously in adults that diamorphine administered extradurally provides a better quality of analgesia than that administered i.m.[14] which implies that the site of action, at least in part, is at the level of the spinal receptor.

The early postoperative pain scores and ventilatory frequency were significantly lower in the diamorphine group. There was no significant difference in the degree of sedation between the two groups, thus the difference in early pain scores could not be attributed solely to increased sedation in the diamorphine group. However, the CHEOPS score is a very sensitive pain assessment tool, whereas sedation score is relatively insensitive, thus it may be that administration of extradural diamorphine, in addition to providing analgesia, led to subtle changes in behaviour resulting in lower pain scores without a comparable increase in sedation score.

Extradural opioids are associated with well recognized side effects, including itching, urinary retention, nausea and vomiting, and respiratory depression, the majority of which may be related to rostral spread.[20] In our study, pruritus did not occur in either group; this may not be surprising as the incidence of pruritus after extradural morphine has been quoted variously as 1–100%.[17,21–23] Nausea and vomiting were more common in the group receiving diamorphine than the bupivacaine alone group, but this was not statistically significant and was low compared with a reported incidence of 50% with extradural morphine.[23] There were no cases of respiratory depression in either group; this may be a reflection of the relatively small size of the study as extradural opioid-induced respiratory depression is comparatively rare with an incidence of 0.2– 0.33% in adult patients receiving extradural morphine.[24,25] In patients receiving extradural diamorphine the incidence is likely to be even lower because of its increased lipid solubility. The time to first passage of urine was significantly longer in those children receiving extradural diamorphine ($P < 0.05$) who were not catheterized during operation, however, no child required intervention with naloxone or catheterization for urinary retention.

In summary, we found that all children in both groups had adequate postoperative analgesia, but the addition of diamorphine $30\ \mu g\ kg^{-1}$ to the caudal injection resulted in a significant reduction in early pain scores. Opioid-induced side effects were few, and only increased time to first passage of urine was statistically significant. We did not encounter any serious side effects such as respiratory depression; this may be related to the small size of the study, the rarity of such complications with extradural opioids and the high lipid solubility of diamorphine.

Effect of hypothermia on rectal mucosal perfusion in infants undergoing cardiopulmonary bypass

P. D. BOOKER, D. P. PROSSER AND R. FRANKS

Summary

We have examined the effect of profound hypothermia on gut mucosal perfusion in 20 infants, aged 1.4–45 weeks, requiring cardiopulmonary bypass (CPB). After induction of anaesthesia, a laser Doppler probe was inserted 8 cm into the patient's rectum to allow monitoring of rectal mucosal perfusion ("flux") throughout operation. Steady-state observation periods (5 min with no change in temperature or mean arterial pressure (MAP)) were achieved after 10 min on CPB at 35 °C, after CPB-induced cooling to 15–25 °C, immediately before rewarming and after rewarming to 35 °C. Throughout these periods flow rate was 100 ml kg^{-1} min^{-1}, packed cell volume was kept constant and Pa_{CO_2} maintained at 5.3 ± 0.5 kPa. No vasoactive drugs were used. Initial warm and rewarm MAP values (46 mm Hg) were significantly lower ($P = 0.008$) than during the cold CPB periods (63 and 64 mm Hg). Mean flux in the first cold period (152) was significantly lower ($P = 0.001$) than that in the first warm CPB period (211). Post-rewarm flux (127) was significantly lower than all other CPB flux values ($P = 0.004$). We conclude that although hypothermia significantly reduced mucosal blood flow, rewarming produced even greater reductions in mucosal perfusion that may prove crucial in the development of mucosal hypoxia. (*Br. J. Anaesth.* 1996; **77**: 591–596)

Key words
Heart, cardiopulmonary bypass. Measurement techniques, flowmetry. Gastrointestinal tract, mucosal perfusion. Infants. Hypothermia. Surgery, cardiovascular.

Splanchnic perfusion during cardiopulmonary bypass (CPB) may be jeopardized by vasoconstriction secondary to hypocapnia[1] or to increased concentrations of angiotensin II,[2–5] vasopressin[6] or thromboxane.[7 8] Haemodilution,[9] hypotension[10] and microvessel occlusion, secondary to platelet and leucocyte aggregation,[11] may also reduce oxygen delivery to the gut during CPB. Furthermore, animal[8 12 13] and adult clinical studies[14–17] have confirmed that transient gut mucosal ischaemia may occur during or after CPB. A sufficient reduction in gut mucosal blood flow to induce mucosal hypoxia can cause mucosal barrier breakdown and allow bacterial translocation,[18] as the integrity of the intercellular "tight" junctions is an ATP-dependent process.[19] The incidence of post-CPB gut dysfunction[20 21] and endotoxaemia during CPB[22 23] show a positive correlation with increasing CPB time in adults. Translocation of bacteria and endotoxins from the gut lumen into the portal and systemic circulations is usually self-limiting but may cause sepsis, multiple organ failure (MOF), or both.[24–27]

The incidence of MOF in infants and children undergoing CPB (1.6–3.5%)[28–30] is apparently much higher than that in adults (0.37%).[27 31 32] Although differences in diagnostic criteria or pathophysiology, or both, could account for this disparity, the major dissimilarities between adult and paediatric CPB techniques may be equally important. Profound hypothermia is used in paediatric cardiac surgery to protect vital organs during periods of reduced flow CPB or circulatory arrest. Although the potential for hypothermic CPB to cause gut mucosal hypoxia may be mitigated by the reduction in cellular metabolic rate, hypothermia also increases the affinity of haemoglobin for oxygen and may reduce gut mucosal blood flow.[12 33–35] We studied infants undergoing CPB-induced profound hypothermia and, using laser Doppler flowmetry (LDF), determined how rectal mucosal blood flow changed with temperature, maintaining all other factors constant.

Patients and methods

With local Ethics Committee approval and written, informed parental consent, we studied 20 infants, aged 1.4–45 weeks, requiring profound hypothermia during CPB for elective or urgent cardiac surgery. Infants <2.5 kg in weight or with coarctation of the aorta were excluded. No premedication was used. Anaesthesia was induced with thiopentone 4 mg kg^{-1} and neuromuscular block was produced with vecuronium 0.2 mg kg^{-1} h^{-1}. Anaesthesia was maintained with i.v. infusions of midazolam 240 µg kg^{-1} h^{-1} and diamorphine 24 µg kg^{-1} h^{-1}, supplemented with 0.25% isoflurane in oxygen or air, or both, before CPB.

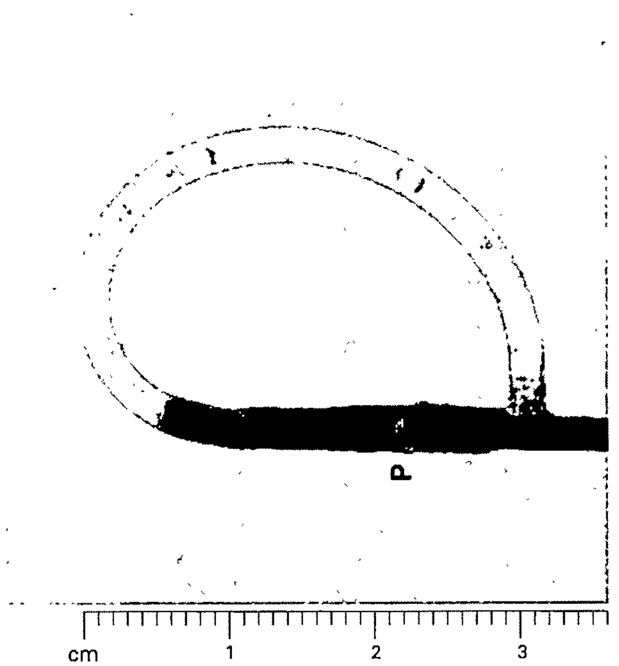

Figure 1 Laser Doppler probe with attached silastic ring. The proximal 10 cm of glass fibre cable had been thickened to provide sufficient rigidity to insert the probe 8 cm into the rectum. The probe's optical prism is located at point P.

A central venous catheter was inserted, a femoral artery cannulated for monitoring of systemic arterial pressure and temperature probes placed in the mid-oesophagus, rectum and nasopharynx. A laser Doppler probe (Moor Instruments Ltd) was inserted 8 cm into the patient's rectum, the probe's special design ensuring that its optical prism lay against the mucosa (fig.1). The probe was connected to a MBF3/D monitor (Moor Instruments Ltd) and computer; later analysis of recordings was made using Moorsoft data interpretation software (Moor Instruments Ltd). The hollow fibre D701 oxygenator (Dideco) used for CPB was primed with a warmed mixture of blood and crystalloid such that the packed cell volume (PCV) 10 min after initiation of CPB was 25 ± 5% and blood and core temperatures 35 ± 0.5°C.

When the patient had been established on non-pulsatile CPB at a flow rate of 100 ml kg^{-1} min^{-1} for 10 min and nasopharyngeal and rectal temperatures were constant at 35 ± 0.5°C, baseline measurements of femoral mean arterial pressure (MAP) and rectal mucosal flux were recorded for another 5 min ("warm-1"). Patients were then cooled on CPB to 15–25°C, depending on the anticipated duration of low flow or circulatory arrest required. The rate of cooling and rewarming was controlled to approximately 1°C min^{-1}. All measurements were repeated during another three "steady-state" 5-min periods: immediately before initiation of low flow ("cold-1"), 10 min after resumption of full flow ("cold-2") and after rewarming to 35°C ("warm-2"). "Steady state" was defined as a period when nasopharyngeal and rectal temperatures did not vary by >0.1°C and MAP did not vary by >2%. Arterial blood-gas tensions, PCV and ionic calcium (Ca^{2+}) concentrations were measured immediately before and after each period. PCV was maintained constant at 25–30 and Ca^{2+} concentration and arterial base deficit were kept within normal limits, although no drugs were given during or within 10 min of any study period. Maintenance of a constant Pa_{O_2} (20 ± 5 kPa) throughout CPB was aided by the use of an in-line Pa_{O_2} monitor (Polystan), and a capnograph (Datex Ltd), attached to the gas outlet port of the oxygenator, helped maintain a constant Pa_{CO_2} (5.3 ± 0.5 kPa, temperature uncorrected, i.e. alpha-stat regulation[36]), together with intermittent arterial blood-gas measurements. All patients maintained MAP at 30–80 mm Hg with a CPB flow rate of 100 ml kg^{-1} min^{-1}, without the use of vasoactive drugs. Inotropic support was given as required to aid weaning from CPB, when the warm-2 readings were complete.

Comparisons between mean flux and mean MAP obtained during the initial warm CPB period and other flux and MAP values were analysed using the Wilcoxon matched pairs signed rank test and exact two-tailed tests (SPSS). Kendall's tau-*b* correlation coefficient was used to examine the relationships between MAP and flux and between CPB time and flux.

Results

Median age of the patients was 16.5 (range 1.4–45) weeks and median weight 5.3 (2.9-7.9) kg (table 1). Patients were cooled to a median nasopharyngeal temperature of 17.9 (14.5–24.6) °C during CPB for periods of 21–132 min. Median CPB time was 122 (102–355) min.

Mean flux values were compared with the mean flux obtained during the first normothermic CPB period (warm-1) (table 2, fig. 2). All CPB data were measured while cardiac output (pump flow rate) was controlled and while the patient was not subject to the effects of vasoactive drugs. Mean cold-1 flux was significantly lower than mean warm-1 flux (P = 0.001). Mean cold-2 flux was not significantly different from mean cold-1 flux (P = 0.12). Mean warm-2 flux was significantly lower than mean warm-1 flux (P = 0.001), mean cold-1 flux (P = 0.004) and cold-2 flux (P = 0.001). Mean flux values before and after CPB were also recorded and compared with mean warm-1 flux, although non-CPB data were obtained during periods when cardiac output was uncontrolled and vasoactive drugs were being used.

MAP increased significantly on cooling (P = 0.001), returning to baseline values on rewarming (table 3, fig. 2). There were no significant differences between MAP during the warm-1 and warm-2 periods (P = 0.91) or between the cold-1 and cold-2 periods (P = 0.98). Table 4 shows the correlations between flux and MAP at different periods. There were no significant correlations between MAP and flux at any time other than at warm-1 (r = 0.33; P = 0.04). Table 5 shows that there were no significant correlations between CPB time and flux.

Discussion

We have demonstrated that rectal mucosal perfusion or "flux", measured using LDF, was reduced significantly secondary to CPB-induced core cooling to

14–24 °C compared with flux during normothermic CPB at the same flow rate. Further reductions in flux were seen during and after rewarming, although ventricular ejection sometimes produced pulsatile flow during this period. Pulsatile flow would be expected to increase rather than decrease mucosal perfusion,[2 5] compared with non-pulsatile flow which was invariable during the hypothermia period. Furthermore, changes in flux at different temperatures did not correlate with changes in MAP (table 4) and, therefore, reflect variable shunting of blood away from the mucosa.

Experimental animal work[8 13 37] has shown that gut mucosal ischaemia may occur during normothermic CPB despite maintenance of pre-CPB superior mesenteric arterial (SMA) flow rates. Recent animal work has suggested that overall gut blood flow and oxygen consumption may increase progressively during normothermic CPB but are associated with a decrease in mucosal blood flow in the stomach, ileum and rectum.[13] This diversion of blood away from the gut mucosa is thought to be caused by CPB-induced release of vasoactive substances that affect regional blood flow at the macro- or microcirculatory levels, or both.[38] Vasoconstrictors known to be released during CPB in adults include vasopressin,[6] catecholamines,[4 39 40] angiotensin II[2–5] and thromboxane A_2 and B_2.[7 8 41]

Experimental CPB studies using animal models have demonstrated either a reduction,[34] no change[12 35] or an increase[42] in SMA flow during hypothermic (25 °C) CPB. These inconsistent results may be explained by the use of different methodologies, different baseline references and varying perfusion flow rates, and Pa_{CO_2} control. Nevertheless, it would seem from these studies that shunting of blood away from the mucosa is unlikely to be occurring at the arteriolar regulatory level. The decrease in mucosal flux during profound hypothermia, compared with the initial warm CPB value, therefore, must reflect either arteriovenous shunting at the sub-mucosal level or redistribution of blood from the mucosa to the muscularis and serosa. Blood distribution within the gut wall, regulated by pre-capillary sphincter tone, is thought to be governed by local tissue oxygen tension.[43] Thus gut mucosa, which has a high metabolic rate, normally receives 65–92% of total gut blood flow.[44 45] This theory of pre-capillary sphincter regulation, although compatible with the decrease in flux during hypothermia, does not explain the decrease in flux seen during rewarming. We postulate that normal local regulation of pre-capillary sphincter tone was overwhelmed by high concentrations of circulating vasoconstrictors, as demonstrated during normothermic CPB in adults (see above).

Laser Doppler flowmetry (LDF) provides a direct measure of tissue blood flow by using the fact that when laser light is reflected off a moving red blood cell, it undergoes a Doppler frequency shift, the amount of shift being dependent on the speed of the moving object. The laser light is delivered to the tissue surface via a single glass fibre, another fibre being used to collect a portion of the back-scattered light. This photodetector signal is then amplified and the signal-to-noise ratio improved by eliminating noise that is outside the bandwidth of the Doppler frequencies. The analogue signal is then converted into a digital signal for spectral analysis, which is primarily a measure of the average Doppler frequency. The output from a LDF is referred to as "flux", which is a measure of the number of red blood cells flowing through a unit volume of tissue per unit time.

There are problems in using LDF to measure tissue perfusion. First, the technique generates only arbitrary units of measure; however, gut mucosal flux values have been shown experimentally to correlate linearly with changes in gut mucosal blood flow measured using other techniques, over a wide range of flow rates.[46–48] Second, the probe tends to be position-sensitive, although this is not a problem when making successive measurements over a relatively short time period in paralysed patients. Finally, to draw any meaningful conclusions from flux data, it has to be assumed that the tissue measurement volume, at most 6 mm,[3 49] is representative of a larger region of tissue, although fortunately, rectal mucosa has a relatively homogeneous vascular anatomy. Although it cannot be assumed that rectal mucosal blood flow is representative of mucosal blood flow in other areas of the gut, recent animal work has suggested that rectal mucosal perfusion decreases during CPB in a similar manner to that of gastric and ileal mucosa, as measured tonometrically.[13]

Haemodilution results in a reduced density of red blood cells reflecting light back to the monitoring probe, causing a decrease in flux levels with no change in "perfusion". Similarly, a decrease in mean MAP during CPB, compared with levels before CPB, may result theoretically in an increase in mean red cell transit time at the capillary level, further tending to reduce flux values. Thus a reduction in flux during the initial warm CPB period compared with the value before CPB was not unexpected. Thereafter, however, PCV was maintained at a constant level and changes in flux during CPB cannot be attributed to changes in PCV. MAP values changed significantly with temperature, although they did not correlate with flux other than at the initial warm-1 period (table 4, fig. 2). We found no correlation between flux values and duration of CPB (table 5).

Our results contrast with those of Ohri and colleagues, who found no significant difference in jejunal mucosal flux at 28 °C during CPB in dogs compared with baseline readings obtained before CPB.[12] After rewarming, they measured a 70% increase in flux and a simultaneous decrease in jejunal mucosal pH_i from 7.42 to 7.12. These latter results agree with tonometric pH_i data from other experimental and clinical studies in adults and confirm that mucosal hypoxia is most likely to occur during the rewarming phase.[15 50 51] Although a significant correlation between pH_i and blood flow may occur under some conditions,[50 52] pH_i relates to blood flow only insofar as it relates to the adequacy of tissue oxygenation.[53]

Lactate concentrations in skeletal muscle and plasma have been shown, in adult patients during

CPB, to increase after rewarming, suggesting that a shift towards anaerobic cellular metabolism may occur even during normothermic full flow CPB.[54 55] Profound hypothermia and low flow perfusion are likely to exacerbate this tendency. Gut mucosa becomes hypoxic during rewarming not only because of diversion of blood to other parts of the gut but also because of increased oxygen consumption.[12] Increased mucosal oxygen consumption would be expected as the cellular metabolic rate increases with increasing temperature, but hypoxia may also be exacerbated by an oxygen debt being incurred during cooling. CPB-induced hypothermia immediately decreases mucosal oxygen delivery because of decreased blood flow, haemodilution, hypotension and the increased affinity of haemoglobin for oxygen, while tissue cooling and reductions in cellular metabolism occurred more slowly. Although increased tissue requirements for oxygen during rewarming may be met to some extent by increased oxygen extraction,[12 56] experimental work[52] suggests that blood flow is the major factor limiting intestinal oxygen consumption.[52] We have found no evidence that capillary recruitment or precapillary sphincter vasodilatation occurs after rewarming from profound hypothermia, rather the reverse.

In conclusion, our finding of reduced rectal mucosal flux during hypothermia is probably of less clinical relevance than that of decreased flux during and after rewarming, a period when the likelihood of mucosal hypoxia is highest. We recommend that strategies for improving gut perfusion, such as supranormal CPB flow rates or administration of dopexamine[57 58] or epoprostenol,[59] should be directed at the rewarming phase, which represents a particularly critical time for the continued maintenance of normal mucosal barrier function.

Gut mucosal perfusion in neonates undergoing cardiopulmonary bypass

P.D. BOOKER, H. ROMER AND R. FRANKS

Summary

We studied gut mucosal perfusion in 24 neonates requiring cardiopulmonary bypass (CPB). Group A patients (n = 12) had obstruction to their aorta such that gut perfusion before operation was dependent on flow through a ductus arteriosus (DA). Group B neonates were of similar age and size and required a similar duration of CPB, but did not have a DA. An orogastric tonometer allowed intermittent calculations of gastric intramucosal pH (pH_i), and rectal mucosal perfusion ("flux") was monitored using laser Doppler flowmetry. Measurements of arterial base deficit, and lactate and pyruvate concentrations were made intermittently. Before CPB, mean femoral arterial pressure (MAP) and base deficit in group A were not significantly different from those in group B. However, mean flux before CPB was significantly lower and the lactate/pyruvate (L/P) ratio was significantly higher in group A compared with group B. Mean pH_i was below normal (<7.26) throughout the operative period in group A, although it remained normal (>7.33) in group B. After corrective surgery, both during warm CPB and after CPB, we found no significant difference in MAP, L/P ratio or base deficit between the groups, but both flux and pH_i were significantly lower in group A compared with group B. We conclude that neonates requiring aortic arch surgery may be at particular risk of gut mucosal hypoxia both before and after operation. (*Br. J. Anaesth.* 1996; **77**: 597–602)

Key words
Measurement techniques, flowmetry. Measurement techniques, tonometry. Gastrointestinal tract, mucosal perfusion. Neonate. Heart, cardiopulmonary bypass. Surgery, cardiovascular.

Splanchnic perfusion during cardiopulmonary bypass (CPB) may be jeopardized by vasoconstriction secondary to hypocapnia[1] or to increased concentrations of angiotensin II,[2] vasopressin,[3] thromboxane,[4] endothelin-1[5] and catecholamines.[3 6] Haemodilution,[7] hypotension[8] and microvessel occlusion secondary to platelet, leucocyte or erythrocyte aggregation,[9] may also reduce oxygen delivery to the gut during CPB. Animal[10 11] and adult[12 13] studies have confirmed that transient gut mucosal ischaemia may occur during and after CPB. A sufficient reduction in gut mucosal blood flow to induce mucosal hypoxia can cause mucosal barrier breakdown and allow bacterial translocation,[14] as the integrity of the intercellular "tight" junctions is an ATP-dependent process.[15] Translocation of bacteria and endotoxins from the gut lumen into the portal and systemic circulations is usually self-limiting but may cause sepsis or multiple organ failure, or both.[16] However, bacterial and endotoxin translocation may not be necessary for distant organ injury after gut ischaemia–reperfusion.[17] The reperfused gut may cause oxidant-induced mast cell activation and priming of circulating neutrophils, resulting in pulmonary injury secondary to neutrophil sequestration.[18]

We postulated that neonates with coarctation, or other aortic arch anomalies affecting descending aortic blood flow, may be at particular risk of developing splanchnic ischaemia in the perioperative period. We have compared gut mucosal perfusion in neonates with ductus arteriosus (DA)-dependent circulations with a control group with normal aortic arch anatomy; patients were of a similar mean age and weight, and CPB times were comparable. We used a tonometric technique to assess gastric mucosal perfusion[19] and laser Doppler flowmetry to monitor rectal mucosal perfusion.[20]

Patients and methods

With local Ethics Committee approval and written, informed parental consent, we studied 12 neonates, > 2.0 kg in weight, aged 3–15 days, requiring CPB for repair of an cardiac anomaly, together with either a coarctation or interrupted aortic arch. Another 12 neonates with normal aortic arch anatomy (with no DA), requiring CPB for cardiac surgery, were also studied (table 1). Patients requiring preoperative vasoactive drugs, other than prostaglandins, were excluded. None of the neonates had significant fetal distress *in utero*. There was no significant difference between mean age, weight or CPB times in the two groups of patients, but mean aortic clamp time in the

Table 2 Age, weight, oxygen saturation (sat.) before cardiopulmonary bypass (pre-CPB), and CPB and aortic clamp (AC) times in the two groups patients (mean (SD or range)

	Group A	Group B	*P*
Age (days)	8.7 (3–15)	17.1 (4–57)	0.28
Weight (kg)	3.3 (0.4)	3.4 (0.8)	0.85
Pre-CPB oxygen sat. (%)	88.8 (3.0)	81.5 (3.5)	0.001
CPB time (min)	169 (86)	202 (90)	0.42
AC time (min)	62 (13)	77 (15)	0.01

control group B was significantly longer than in group A (table 2).

No premedication was used. Anaesthesia was induced with thiopentone 4 mg kg^{-1} and neuromuscular block was produced with vecuronium 0.2 mg kg^{-1}·h^{-1}. Anaesthesia was maintained with i.v. infusions of midazolam 240 μg kg^{-1} h^{-1} and diamorphine 24 μg kg^{-1} h^{-1}, supplemented with 0.25% isoflurane in oxygen or air, or both, before CPB. A central venous catheter was inserted and a femoral artery cannulated for monitoring of systemic arterial pressure. A urinary catheter and nasopharyngeal and oesophageal temperature probes were inserted and a peripheral tissue oxygen saturation probe was taped in place.

A laser Doppler probe (Moor Instruments Ltd) was inserted 7 cm into the patient's rectum, the probe's special design ensuring that its optical prism lay against the mucosa.[20] The probe was connected to a MBF3/D monitor (Moor Instruments Ltd) and computer; later analysis of recordings was made using Moorsoft data interpretation software (Moor Instruments Ltd). A Trip sigmoid tonometer (Tonometrics, Inc., MA, USA) was inserted orally into the patient's stomach. Correct positioning of the tonometer was aided by the sight of a small bulging of the anterior abdominal wall as it was gently advanced, later confirmed by chest x-ray obtained after operation. Saline 0.9% (2.5 ml) was then introduced anaerobically into the tonometer balloon.

After the chest was opened, but before surgical manipulation of the great vessels, baseline recordings of rectal mucosal flux and femoral mean arterial pressure (MAP) were made over a 5-min period. A sample of arterial blood was obtained for measurement of Pa_{O_2}, Pa_{CO_2}, PCV and base deficit. Ionic calcium (Ca^{2+}), bicarbonate, lactate and pyruvate concentrations were measured and, subsequently, the lactate/pyruvate (L/P) ratio was calculated. $P\text{CO}_2$ of the saline in the tonometer balloon was determined using a Ciba-Corning 865 analyser. Gastric intramucosal pH (pH_i) was calculated using the Henderson–Hasselbalch equation and time correction factors as supplied by Tonometrics, Inc. The inspired oxygen concentration before CPB was adjusted such that peripheral oxygen saturation was 75–90% in all patients, although group A patients had a significantly higher mean saturation than group B patients (see table 2).

The hollow fibre D701 oxygenator (Dideco) used for CPB was primed with warmed blood and crystalloid such that blood and core temperatures 10 min after initiation of CPB were 34 ± 0.5 °C and PCV was 25 ± 5%. When the patient had been established on non-pulsatile CPB at a flow rate of 100 ml kg^{-1} min^{-1} for 10 min and nasopharyngeal temperature varied by <0.1 °C min^{-1}, another arterial blood sample was obtained for measurements of PCV, base deficit and bicarbonate, lactate and pyruvate concentrations. MAP and rectal mucosal flux were recorded for another 5 min before the patient was cooled during CPB to 15–25 °C, depending on the anticipated duration of low flow or circulatory arrest required. The rate of cooling and rewarming was controlled to approximately 1 °C min^{-1}. Throughout CPB, PCV was maintained at 25 ± 5% and Ca^{2+} concentration and base deficit were kept within normal limits, although no drugs were given within 15 min of any study period. Intermittent arterial blood-gas measurement was used to maintain a constant Pa_{O_2} (20 ± 5 kPa) throughout CPB, aided by the use of an in-line Pa_{O_2} monitor (Polystan). Similarly, a capnograph (Datex Ltd), attached to the gas outlet port of the oxygenator helped maintain a constant Pa_{CO_2} (5.3 ± 0.5 kPa, temperature uncorrected, i.e. alpha-stat regulation).[21] No vasoactive drugs were required in any patient to maintain MAP at 30–80 mm Hg during warm CPB using a flow rate of 100 ml kg^{-1} min^{-1}. When the patient was rewarmed on CPB and stabilized at 35 ± 0.1 °C for 5 min, another set of blood and tonometer samples, flux and haemodynamic readings were obtained over another 5 min. Inotropic support was given as required to aid weaning from CPB when the rewarm readings were complete. A final set of readings and blood samples were obtained just before transfer to the ICU, usually about 1 h after CPB.

Comparisons between mean flux, mean pH, mean MAP, mean base deficit and mean L/P ratio obtained at each period in the two groups were

analysed using the Wilcoxon test and SPSS exact test (SPSS UK Ltd). Kendall's tau-*b* rank correlation coefficient was used to assess associations between MAP, base deficit, flux, pH_i and L/P ratios at every period.

Results

Mean flux before CPB in group A (154) was significantly lower than that in group B (275) (P = 0.03) (table 3, fig. 1). Although mean pH_i before CPB in group A (7.25) was lower than that in group B (7.34), this difference was not statistically significant. Mean L/P ratio before CPB was significantly higher in group A (16.8) than that in group B (11.4) (P = 0.05), although there were no statistically significant differences between the groups in MAP or base deficit before CPB.

Mean flux (158) and mean pH_i (7.23) in group A were lower than the mean values in group B (236 and 7.41, respectively) during the initial warm CPB period before corrective surgery. However, these differences were not significant, probably because it was not possible in every patient to obtain warm, stable temperatures during CPB for at least 30 min before commencement of core cooling. There were no significant differences between the two groups in mean L/P ratios, MAP or base deficit measured after rewarming on CPB after corrective surgery (table 4). However, mean flux in group B (183) was significantly higher (P = 0.01) than that in group A (106) at this time. In addition, mean gastric pH_i in group A (7.21) was significantly lower (P = 0.04) than that in group B, which remained normal (7.37).

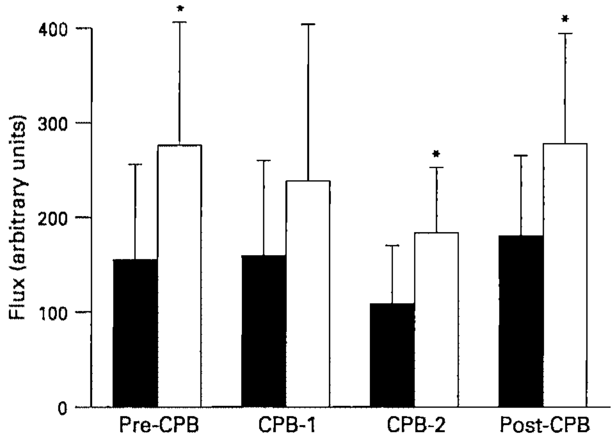

Figure 1 Mean (SD) rectal mucosal perfusion ("flux") in the two groups of patients at each observation period. CPB= Cardiopulmonary bypass. CPB-1 = warm CPB before corrective surgery; CPB-2 = warm CPB after corrective surgery. Group A (■) patients had aortic arch obstruction with ductus-dependent circulations; group B (□) patients had normal aortic arch anatomy. *P < 0.05.

Table 6 Significant correlations between arterial base deficit (BD), gastric pH_i, and lactate/pyruvate (L/P) ratios (all patients). There were no other significant correlations between any other measured variables. r = correlation coefficient, P = level of significance. CPB= Cardiopulmonary bypass; Warm CPB-2 = after corrective surgery but still requiring CPB

	Pre-CPB BD	Warm CPB-2 BD	Post-CPB BD	Post-CPB pH_i
Pre-CPB pH_i	r=−0.33 P=0.04			
Warm CPB-2 pH_i		r=−0.39 P=0.03		
Warm CPB-2 L/P		r=0.41 P=0.02		
Post-CPB L/P			r=0.37 P=0.03	r=−0.43 P=0.02
Post-CPB BD				r=−0.49 P=0.004

Two patients in group A and one patient in group B did not survive after CPB. To enable successful weaning from CPB, all patients received enoximone 10 μg kg^{-1} min^{-1} and either dobutamine or adrenaline; we found no significant differences between the two groups in the mean dose of dobutamine or adrenaline required (table 5). In addition, for the purposes of statistical comparison and on the basis of data from an ongoing study, we assumed adrenaline 1 μg kg^{-1} min^{-1} produced an inotropic effect equivalent to dobutamine 20 μg kg^{-1} min^{-1}. There was no significant difference between the "combined" inotrope requirements in the two groups. Mean pH_i in group A (7.07) was significantly lower than that in group B (7.36) after CPB (P = 0.0004) (table 4). Mean flux in group A patients, although slightly higher than the mean pre-CPB value, remained significantly lower than that in group B (P = 0.04). There were no significant differences in mean L/P ratios, MAP or base deficit between the two groups after CPB.

Gastric pH_i showed a significant correlation with base deficit both before and after CPB and with L/P ratios after CPB. Significant correlations between arterial base deficit and L/P ratios were found both at warm CPB after corrective surgery and after CPB (table 6, fig. 2).

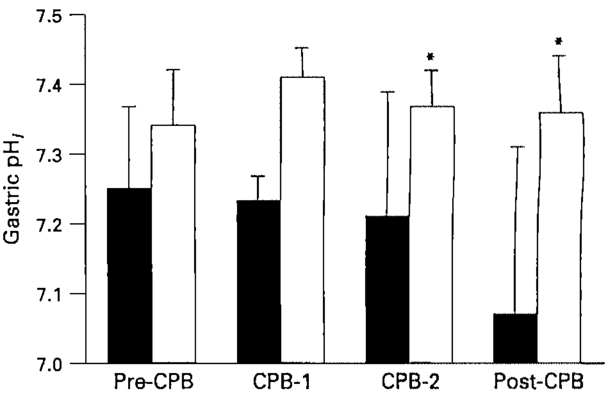

Figure 2 Mean (SD) gastric pH_i in the two groups of patients at each observation period. CPB = Cardiopulmonary bypass. CPB-1 = warm CPB before corrective surgery; CPB-2 = warm CPB after corrective surgery. Group A (■) patients had aortic arch obstruction with ductus-dependent circulations; group B (□) patients had normal aortic arch anatomy. $^*P < 0.05$.

Discussion

We have shown that neonates with aortic arch anomalies (group A) may have periods of gut mucosal ischaemia not only before, but also shortly after corrective surgery. Mean gastric intramucosal pH (pH_i) was <7.26 in group A patients, before, during and after surgery, whereas pH_i remained >7.33 throughout the operative period in our control group B patients with normal aortic arch anatomy. We believe, on the basis of these results, other neonatal data we have collected (unpublished) and adult studies[13 22] that a pH_i value <7.33 is below normal and indicates mucosal hypoxia. In addition, rectal mucosal perfusion ("flux") was significantly lower in group A than that in group B both before and after corrective surgery. The significant difference in gastric pH_i and rectal mucosal flux between the two groups of neonates after surgery suggests that despite anatomical correction of the aortic obstruction and a resulting increase in total blood flow to the gut, early post-surgical mucosal perfusion in group A patients remained below normal.

The requirement for saline to be introduced into the tonometer balloon for at least 30 min before sampling implied that the number of observations was reduced during the initial warm CPB (before surgery) period (table 3). Statistical analysis of this comparative data may therefore underestimate the real difference between the two groups at this time. Measurement of tonometer saline $P\text{CO}_2$ during the other periods was after an equilibration time of >45 min, to allow accurate calculation of pH_i. The potential problems and assumptions that underlie the use of laser Doppler flowmetry (LDF) to measure rectal mucosal blood flow have been reported previously.[20]

Notwithstanding evidence that prostaglandin E_1, administered before CPB only to group A patients, may increase gut mucosal blood flow,[23] ultrasound studies of neonatal mesenteric arterial flow have indicated that the presence of a ductus arteriosus (DA) may lead to compromised splanchnic perfusion.[24 25] Although necrotizing enterocolitis has been reported as a complication of hypoplastic aortic arch,[26] we are not aware of any previous studies that have examined the relationship between DA-dependent perfusion, which is peculiar to this age group, and gut ischaemia. Nevertheless, the preoperative difference in both mucosal pH_i and flux between our two groups of patients was not unexpected.

We have confirmed our previous finding that rectal mucosal flux is decreased after rewarming following CPB-induced hypothermia.[20] In group B patients, with normal aortic arch anatomy, flux during CPB after rewarming was significantly lower than flux before CPB ($P = 0.01$). However, the reduction in mucosal perfusion did not result in an abnormal gastric pH_i in this group of patients, suggesting that although mucosal blood flow had been reduced, it had not decreased sufficiently to cause mucosal hypoxia. In contrast, rewarm flux in group A was not only significantly lower than that in group B, but was associated with gastric intramucosal acidosis. These data are compatible with the premise that when mucosal blood flow decreases to below the critical level required to maintain mucosal cell homeostasis, pH_i decreases to below normal values, indicating mucosal hypoxia. One hour after weaning from CPB, pH_i in group A decreased to 7.07, despite a small increase in rectal mucosal flux, confirming data from an adult study which showed that pH_i values after CPB do not necessarily correlate with global splanchnic perfusion.[27] Nevertheless, the flux value of 179 after CPB in group A patients compares with our "normal" flux values of 250–300 (values taken from this study, previous published work[20] and other unpublished data). This finding suggests that although gut mucosal blood flow had improved (by about 16%) after surgery, this increase had not been sufficient to return values to "normal".

CPB-induced impairment of macro- or microcirculatory vasoregulation, or both, has been suggested as a cause of heterogeneous distribution of gut blood flow after CPB,[27] although our data for group B patients do not support this. The relatively low flux after CPB in group A patients may have been a result of local vascular endothelial release of the potent long-lasting vasoconstrictor endothelin-1, which is known to increase in response to hypoxia or reduction in regional perfusion pressure.[28 29] Alternatively, the more severe gut mucosal ischaemia–reperfusion injury experienced by group A compared with group B patients may have caused an increase in local nitric oxide inhibition[18] or eicosanoid release.[4 18] In addition, there is evidence that reperfusion injury can cause severe disruption of the mucosal microcirculation. Boros, Takaichi and Hatanaka[9] have shown, in an animal model, that reperfusion of ischaemic gut mucosa can lead to capillary block caused by erythrocyte plugging, possibly secondary to perivascular oedema and capillary compression.

In addition to below-normal mucosal blood flow, another possible cause of mucosal hypoxia after CPB is that of increased cellular oxygen consumption secondary to reperfusion injury[30] or use of inotropic drugs.[31] Our two groups of patients required equipotent amounts of inotropic support (table 5). Data from an ongoing study (unpublished) suggests that adrenaline, given in a dose of $>1\ \mu g\ kg^{-1}\ min^{-1}$, produces a higher mean systemic vascular resistance than dobutamine when given in an equipotent inotropic dose. We therefore compared the dose rates of adrenaline and dobutamine separately in the two groups of patients, but found no significant difference. It would seem, therefore, that the vasoconstrictor effect of high-dose adrenaline, although unquantified in this study, was unlikely to have been the main determinant of mucosal hypoxia after CPB in group A patients. However, these data do not preclude the possibility that an increase in local endothelin-1 concentrations in group A patients would have potentiated the splanchnic vasoconstrictor effects of high-dose adrenaline.[32]

Base deficit[33] and L/P ratios[34] are thought to be useful global indices of cellular oxygenation. L/P values >10 are indicative of tissue hypoxia; the higher the value, the greater the magnitude of the oxygen debt. Although lactate generation *per se* does not cause acidaemia, increased lactate production as a result of development of anaerobic metabolism is associated with degradation of high-energy phosphates, leading to increased production of hydrogen ions and carbon dioxide. Reperfusion of ischaemic tissue would be expected therefore to wash out both accumulated lactate and hydrogen ions, causing an increase in both L/P ratio and base deficit. Although the preoperative L/P ratio in group A was significantly higher than that in group B, hyperlactataemia in the former group was not associated with significant acidaemia. This suggests that, despite better peripheral tissue oxygen saturation than group B, tissue hypoxia in group A was occurring, although it was not severe or extensive. Hypothermic CPB may decrease both hepatic lactate clearance and pyruvate metabolism such that the L/P ratio remains unchanged.[34 35] However, in all of our patients, L/P ratios increased and remained abnormally high during CPB, probably because of the lactate and citrate load associated with a blood prime, and lactate washout with reperfusion after periods of low flow. An imbalance between regional oxygen delivery and tissue oxygen consumption during rewarming causes hyperlactataemia and our finding of similar high L/P values after CPB in both groups of patients suggests that hypoxia in tissues other than the gut may occur in all neonates after CPB. We found significant correlations between base deficit and L/P ratios after surgery and between pH_i and base deficit before and after surgery. However, the non-specific indices of tissue hypoxia, L/P ratio and base deficit, were generally unhelpful in identifying those patients most at risk of gut mucosal hypoxia.

We have shown that neonates requiring aortic arch surgery are at risk of below-normal gut mucosal perfusion and hypoxia, not only before and during corrective surgery, but also after operation, despite resultant normal aortic arch perfusion. Although gastric and rectal mucosal perfusion cannot necessarily be related to ileal or colonic perfusion, we believe that further studies are required to determine if strategies that may improve gut perfusion, such as administration of dopexamine, prevent or ameliorate the gut mucosal hypoxia we have observed in neonates with aortic arch anomalies.

Effects of dopamine on oxygen consumption and gastric mucosal blood flow during cardiopulmonary bypass in humans

W. KARZAI, M. GÜNNICKER, G. SCHARBERT, U. M. VORGRIMLER-KARZAI AND H.-J. PRIEBE

Summary

We investigated the effects of flow rate and dopamine on systemic oxygen delivery (DO_2), oxygen consumption ($\dot{V}O_2$) and gastric mucosal microcirculatory blood flow (gMCF), measured by laser Doppler flowmetry in 12 patients undergoing mild hypothermic (34 °C) cardiopulmonary bypass (CPB). The first intervention comprised increasing CPB flow rates from 2.4 to 3.0 litre min^{-1} m^{-2}, and the second intervention administering dopamine 6 μg kg^{-1} min^{-1}. Measurements were made before and 10 min after the start of one of the two interventions. The heart remained in cardioplegic arrest throughout the study. There were no significant differences in variables between the two baseline measurements preceding the interventions. The increase in CPB flow rate increased DO_2 and gMCF without affecting $\dot{V}O_2$. At constant flow rate, dopamine also increased gMCF with no change in $\dot{V}O_2$, DO_2 or mean arterial pressure. Our data suggested that dopamine had no flow-independent effect on $\dot{V}O_2$ and that it increased gMCF during constant flow hypothermic CPB. (*Br. J. Anaesth.* 1996; **77**: 603–606)

Keywords

Oxygen, consumption. Blood, flow. Gastrointestinal tract, mucosal perfusion. Heart, cardiopulmonary bypass. Surgery, cardiovascular. Pharmacology, dopamine.

We have shown previously that in patients undergoing cardiopulmonary bypass (CPB), dobutamine caused a flow-independent increase in oxygen consumption ($\dot{V}O_2$) without affecting gastric mucosal blood flow.[1] In common with dobutamine, dopamine increased $\dot{V}O_2$ in healthy volunteers with an intact circulation.[2] Unlike dobutamine, dopamine has been shown to increase splanchic[3] and gastric[3] mucosal blood flow in animals and humans. As gut mucosal ischaemia has been reported during cardiac surgery, and to correlate with postoperative morbidity,[5–7] administration of dopamine during cardiac surgery may be a means of ameliorating intraoperative splanchnic hypoperfusion in susceptible patients. However, the ability of dopamine to increase splanchnic blood flow has been challenged recently.[8,9] In pigs, dopamine did not increase total gastric blood flow during CPB.[8] However, dopamine may increase mucosal blood flow without affecting total gastric blood flow.

Therefore, the aims of this study were to investigate the effects of dopamine on $\dot{V}O_2$ and on gastric microcirculatory blood flow during constant flow CPB in patients undergoing cardiac surgery. We hypothesized that dopamine would be comparable with dobutamine in its flow-independent effects on $\dot{V}O_2$ but would differ in its effect on gastric microcirculatory blood flow. As we and others have shown, CPB provides a unique opportunity to study global and regional effects of drugs during constant flow.[1,10,11]

Patients and methods

After obtaining approval from the Ethics Committee of Essen University, and informed consent, we studied 12 patients requiring CPB for coronary artery bypass grafting. All patients received flunitrazepam 2 mg approximately 1 h before arriving in the operating room. Under local anaesthesia, a left radial arterial cannula and a flow-directed pulmonary artery catheter were inserted. Anaesthesia was induced with etomidate 0.15-0.30 mg kg^{-1}, pancuronium 0.1 mg kg^{-1} and fentanyl 5–7 μg kg^{-1}, and maintained with 0.4–0.6 vol% isoflurance and 50% nitrous oxide in oxygen. Before CPB, additional fentanyl 0.25 mg, pancuronium 2 mg and flunitrazepam 0.2 mg were administered as needed. Fentanyl 0.25 mg and pancuronium 4 mg were added to the CPB prime, and 0.4 vol% isoflurane, added to the oxygenator air flow, was continued throughout the bypass period. Non-pulsatile pump flow (Stöckert, Munich, Germany) at a standard flow rate of 2.4 litre min^{-1} m^{-2} was maintained during extracorporeal circulation. Oxygenation was provided by a Cobe CML membrane oxygenator (Laboratories GmbH, Heimstetten, Germany). The asanguineous prime contained lactated Ringer's solution 100 ml, 10% hydroxyethylstarch 500 ml, 20% mannitol 100 ml and 8.4% sodium bicarbonate 100 ml. During CPB, blood temperature was maintained at 34 °C and packed cell volume was kept

above 20% by transfusion of autologous packed red cells before bypass. Measurements were made after CPB had commenced, the aorta cross-clamped, the heart in cardioplegic arrest and after rectal and nasopharyngeal temperatures were within 0.8 °C of each other.

Gastric mucosal microcirculatory blood flow was studied using laser Doppler flowmetry (LDF) (MBF 3D, Moors Instruments Ltd, Devon, UK). The measurement probe, a fibreoptic wire, was inserted through the lumen of a nasogastric tube. The correct position of the nasogastric tube was confirmed by auscultation and aspiration of gastric contents. The correct position of the probe was verified by observing typical pulse synchronous oscillations. The frequency band used throughout the investigation was 14.9 kHz and the last 2 min of each period were averaged for the measurements. LDF uses the size and amount of the frequency shift caused by back-scattered laser beam to calculate microcirculatory flow.[12] LDF has been used experimentally to measure intestinal mucosal blood flow, and has been found to correlate with mucosal blood flow, as measured by standard techniques.[13] In addition to gastric microcirculatory blood flow, skin microcirculatory blood flow was studied by placing a second probe on the forehead of the patient.

Initial measurements were made at a flow rate of 2.4 litre min^{-1} m^{-2} (baseline 1). Flow was then increased to 3.0 litre min^{-1} m^{-2} (intervention 1), and repeat measurements were made 10 min later. Flow was then returned to and maintained at 2.4 litre min^{-1} m^{-2}, and measurements were repeated 5 min later (baseline 2). Subsequently, with no change in flow, dopamine was started at a rate of 6 μg kg^{-1} min^{-1} (intervention 2), and repeat measurements were made 10 min later. At each of these times, blood samples were obtained from sampling ports of the CPB cannulae for measurement of blood-gas tensions, and electrolyte and glucose concentrations, and haemodynamic variables were recorded. Blood-gas tensions were measured immediately at 37 °C. Total body oxygen delivery (DO_2) and $\dot{V}O_2$ were calculated according to standard formulae.

Non-parametric analysis of variance (Friedman) was used to test for differences between times. The Wilcoxon signed rank test, corrected for multiple comparisons (Bonferroni), was used to test for differences between each baseline and subsequent intervention, and between the two baseline values. Statistical significance was based on $P < 0.05$. Results are presented as mean (SD). The statistical program used was SPSS version 6.0 on an Accel (486DX33) Notebook computer (Accel Computers, Rockville, MD, USA).

Results

Patient data are summarized in table 1. The increase in flow rate from 2.4 to 3.0 litre min^{-1} m^{-2} increased DO_2 (approximately 20%) and gastric mucosal microcirculatory blood flow (gMCF) (table 2). Skin microcirculatory blood flow (sMCF), $\dot{V}O_2$ and mean arterial pressure (MAP) did not change significantly.

At unchanged flow rate, dopamine (table 2) increased gMCF ($P < 0.01$). There were no changes

in DO_2, $\dot{V}O_2$, sMCF or MAP during this intervention.

Blood glucose concentrations increased throughout the study ($P < 0.05$) unrelated to the individual intervention. Potassium and haemoglobin concentrations, and body temperature did not change significantly (table 3).

Discussion

The principal findings of this study were: (1) at constant flow, dopamine did not increase $\dot{V}O_2$; (2) at constant flow, dopamine increased gastric mucosal blood flow; and (3) increasing flow rates increased gastric mucosal blood flow.

Our finding that dopamine increased mucosal blood flow is consistent with previous studies. Dopamine receptors have been identified in the human gastric mucosa.[14] When injected locally into the gastric submucosa, dopamine increased gastric mucosal blood flow, as assessed by laser Doppler flowmetry.[4] Furthermore, in the rat, dopamine exhibited a protective role in the stomach.[15] Our study demonstrated that dopamine, administered i.v. at clinically relevant doses, may increase gastric microcirculatory blood flow in humans during CPB, supporting the role of dopaminergic receptors in regulating gastric mucosal blood flow in humans.

In contrast with the increases in gastric microcirculatory blood flow during both increase in flow and dopamine infusion, skin microcirculatory blood flow did not increase during each intervention. Differences in baseline vasomotor tone or vascular reactivity between gastric mucosal and cutaneous vasculature, or both, may explain the different regional flow responses. To what extent differences in flow response are caused by redistribution of flow between regional circulations on the basis of a steal phenomenon cannot be determined by this investigation.

In two previus studies using a similar design, we found that during constant flow CPB, chronic pretreatment with beta adrenoceptor antagonists decreased $\dot{V}O_2$[10] and dobutamine increased $\dot{V}O_2$.[1] These findings suggest a flow-independent effect of catecholamines on $\dot{V}O_2$ during CPB. In contrast with our previous findings with dobutamine, dopamine did not increase $\dot{V}O_2$ during constant flow CPB. Whereas dobutamine 5–10 $\mu g\ kg^{-1}\ min^{-1}$ increased $\dot{V}O_2$ or energy expenditure in normal volunteers by 22–30%,[16 17] comparable doses of dopamine increased $\dot{V}O_2$ or energy expenditure by only 6–10%.[2 18 19] Thus dopamine appears to increase $\dot{V}O_2$ to a lesser extent than dobutamine. In these studies, both dopamine and dobutamine increased heart rate, stroke volume, cardiac output and, most likely, myocardial oxygen consumption. When the heart is in cardioplegic arrest and unable to respond mechanically to catecholamine stimulations (as in this study), catecholamines are likely to produce a smaller increase in $\dot{V}O_2$. In accordance with this hypothesis, dobutamine, administered in comparable doses, caused a 22–33% increase in $\dot{V}O_2$ in healthy volunteers[2 19] but only an 11% increase during CPB.[1] Conversely, the small 6–10% increase in $\dot{V}O_2$ during administration of dopamine in the presence of an intact circulation[2 19] would explain the lack of an increase in $\dot{V}O_2$ during constant flow CPB in this study.

However, our results may only apply to nonpulsatile flow conditions. In the presence of pulsatile flow the absolute and relative effects of dopamine on gastric and cutaneous microcirculations may differ.

Increasing flow rate increased gastric microcirculatory blood flow. As $\dot{V}O_2$ did not increase during this intervention, hypoperfusion is unlikely to have occurred at the lower flow rate. Although increasing flow rates may increase the likelihood of damage to blood components, our findings suggest that increasing flow rates may be a means of increasing gastric microcirculatory blood flow in patients at risk of splanchnic hypoperfusion.

Laser Doppler flowmetry has been used previously to measure mucosal microcirculatory blood flow in animals[20] and humans.[13] Whereas in the absence of CPB, mechanical heart activity and ventilatory excursions transmitted to the very sensitive measurement probe via the oesophagus do, at times, produce artefacts, with the heart in cardioplegic arrest during CPB such artefacts do not occur. Laser Doppler flowmetry may not be reliable when there are acute changes in haemoglobin concentration.[20] However, haemoglobin concentration did not change through our study.

Randomization of the sequence of interventions (i.e. flow variation and dopamine infusion) might have been preferable. However, as there are no data on the clearance of dopamine during hypothermia we chose not to randomize the sequence of interventions. The similar values before flow intervention and before dopamine infusion are evidence of stability, and of return to baseline conditions after flow intervention. In addition, in three patients in whom the duration of CPB allowed a repeat measurement 10 min after discontinuation of infusion of dopamine, the laser signal returned to near baseline values.

In conclusion, our data suggest that both increasing CPB flow rates and infusing dopamine during constant flow CPB did not affect $\dot{V}O_2$ but increased gastric microcirculatory blood flow. Patients at risk of gastric mucosal ischaemia may thus benefit from dopamine during CPB.

Effects of rocuronium and vecuronium on intracranial pressure, mean arterial pressure and heart rate in neurosurgical patients

W. M. SCHRAMM, K. STRASSER, A. BARTUNEK, H. GILLY AND C. K. SPISS

Summary

We have evaluated the effects of a single bolus dose of rocuronium 0.6 mg kg^{-1} (group 1, $n = 10$) or vecuronium 0.1 mg kg^{-1} (group 2, $n = 10$) on intracranial pressure (ICP), mean arterial pressure (MAP), cerebral perfusion pressure (CPP) and heart rate (HR) in 20 neurosurgical patients undergoing mechanical ventilation of the lungs during continuous sedation with sufentanil and midazolam. Before and after neuromuscular block using twice the ED_{90} of the blockers, ICP, MAP, CPP and HR were recorded continuously for 15 min. Treatment caused no significant changes in ICP, CPP or MAP and there was no evidence of histamine release. Mean maximum block in the rocuronium group was slightly less than that in the vecuronium group (95.9 (3.1) % *vs* 100%; ns) The difference between the two groups in onset time (rocuronium 142 (62) s, vecuronium 192 (64) s; $P = 0.04$) was significant. Patients in the rocuronium group showed a slight (7 (4) %) but significant ($P = 0.003$) increase in heart rate. (*Br. J. Anaesth.* 1996; **77**: 607–611)

Key words
Neuromuscular block, rocuronium. Neuromuscular block, vecuronium. Brain, intracranial pressure. Surgery, neurological. Cardiovascular system, effects. Heart, heart rate. Arterial pressure, drug effects.

For neurosurgery the use of drugs which do not increase or preferentially decrease intracranial pressure (ICP) is preferred. For emergency neurosurgery, rapid sequence intubation is often performed as fasting conditions in patients with subarachnoid haemorrhages, severe head injury or intracerebral bleeding are often unknown. Suxamethonium is often used to facilitate tracheal intubation because of its rapid onset, but it has the disadvantage of increasing intracranial pressure.[1] Other non-depolarizing agents such as vecuronium[1 2] and atracurium dibesylate[1 3–5] have no direct effect on ICP; however, their onset of action is considered too long for rapid sequence intubation. Rocuronium is a non-depolarizing neuromuscular blocking agent with a faster onset than all currently available non-depolarizing agents, approaching that of suxamethonium.[6 7]

There are no previous studies of the effects of rocuronium on cerebral dynamics. Because of the rapid onset of action of rocuronium,[8] we have compared the effects of rocuronium with those of vecuronium on ICP, mean arterial pressure (MAP), cerebral perfusion pressure (CPP) (= MAP − ICP) and heart rate (HR) in neurosurgical patients.

Patients and methods

After approval from the local Ethics Committee, we studied 20 ASA I–III patients, aged 18–65 yr. Patients known or suspected of having neuromuscular disorders, metabolic diseases, impaired renal function or impaired hepatic function were excluded. As osteoclastical trepanation interferes with the normal relationship between MAP and ICP, such patients were also excluded from this study. Five patients did not meet the inclusion criteria and these were replaced in order to have a total of 10 evaluable patients in each group. The investigation was performed in the neurosurgical intensive care unit, on postoperative or conservatively treated patients (table 1), after a stabilization period of at least 6 h without neuromuscular block. The lungs of all patients were ventilated in a volume-controlled mode with an air–oxygen mixture ($F_{I_{O_2}}$ = 0.3–0.4) and received, at least 6 h before the start of the study, continuous sedation with sufentanil 1–3 $\mu g\ kg^{-1}\ h^{-1}$ and midazolam 0.05–0.15 mg $kg^{-1}\ h^{-1}$ until at least the end of the study. An extradural probe (Gaeltec, Gaeltec Ltd, Scotland) or an intraventricular catheter (Cordis, Cordis Corporation, USA) was *in situ* for ICP measurements. Temperature (36–37 °C) and ventilation (end-tidal carbon dioxide concentration 4–4.5 kPa) were kept constant throughout the study.

In the intensive care unit, an arterial cannula, neuromuscular block monitoring equipment (Myotest MK II, Biometer Odense, Denmark) and an end-tidal carbon dioxide sensor were attached.

Neuromuscular block was monitored by supramaximal single twitch stimulation of the ulnar nerve at the wrist (single twitches of 0.2 ms duration at 0.1 Hz). Evoked responses were quantified mechanomyographically and recorded with a constant preload of 200–400 g on the adductor pollicis muscle to determine maximal neuromuscular response and onset time (time from administration of the neuromuscular blocking agent to 95% effect). HR, invasive MAP, end-tidal carbon dioxide, ICP and single twitch responses were allowed to stabilize for at least 10 min. Thereafter baseline variables (time T0: ICP_{T0}, MAP_{T0}, HR_{T0}, CPP_{T0}) and arterial blood samples were obtained for measurement of baseline Pa_{CO_2}. Patients in study group 1 received a single bolus dose of rocuronium 0.6 mg kg^{-1} and patients in study group 2 a single bolus dose of vecuronium 0.1 mg kg^{-1} i.v. As rocuronium is approximately six times less potent than vecuronium,[9–11] both doses represent twice the ED_{90}. HR, MAP, end-tidal carbon dioxide and ICP were recorded every minute for 15 min (time T1–T15) after administration of the neuromuscular blocking agent. Changes in ICP ($\Delta ICP_{Ti} = ICP_{Ti} - ICP_{T0}$), HR ($\Delta HR_{Ti} = HR_{Ti} - HR_{T0}$), MAP ($\Delta MAP_{Ti} = MAP_{Ti} - MAP_{T0}$) and CPP ($\Delta CPP_{Ti} = CPP_{TI} - CPP_{T0}$) were calculated for 15 min by subtracting the respective baseline values in both groups. Possible histamine-related reactions such as skin rashes, bronchospasms or severe (±20%) haemodynamic changes were recorded also.

Non-parametric analysis of variance (Friedman) was performed for HR, MAP, ICP and CPP in both the rocuronium and vecuronium groups followed by the multiple comparison Wilcoxon–Wilcox[12] if the Friedman test showed significance. Comparison of baseline variables (ICP_{T0}, MAP_{T0}, CPP_{T0}, HR_{T0}, Pa_{CO_2}) and neuromuscular variables in both groups was performed using the Mann–Whitney–Wilcoxon test. Results were considered statistically significant at $P < 0.05$.

Results

Characteristics of the 20 patients in the two groups are shown in table 2. Baseline variables did not differ significantly between the two groups. The time course of ΔICP, ΔCPP, ΔMAP and ΔHR during the 15-min study period is shown in figures 1 and 2. In the rocuronium group, the change in ICP from baseline varied from −3 to +4 mm Hg and in the vecuronium group from −4 to +2 mm Hg. There were no significant changes in ICP, MAP and CPP in each group even though MAP decreased slightly (4%) in the rocuronium group. Patients in the rocuronium group showed a slight (+7 (4) %) but significant ($P = 0.003$) increase in HR which peaked 5 min after drug administration and decreased thereafter to baseline values. HR did not change in patients in the vecuronium group. No patient had histamine-related symptoms or adverse clinical events. Mean maximum block in the rocuronium group was slightly lower than that in the vecuronium group (95.9 (3.1) % vs 100%; ns). The difference between the two groups in onset time (rocuronium 142 (62) s, vecuronium 192 (64) s; $P = 0.04$) was significant (table 2).

Discussion

In this study ICP was measured after administration of rocuronium 0.6 mg kg^{-1} or vecuronium 0.1 mg kg^{-1} in adult neurosurgical patients undergoing mechanical ventilation and continuous sedation with sufentanil and midazolam. To avoid any impact of concomitant neuromuscular block during the study, only intermediate-acting neuromuscular blocking agents were used for tracheal intubation during the pre-study period. In this study we attempted to control and minimize confounding factors that could influence ICP. External stimuli such as noise, touch and tracheal suction which might alter ICP were either avoided or held constant during the study. Reliable monitoring of ICP with either an intraventricular or extradural probe was achieved as measurements were performed only after a stabilization interval of at least 6 h. Recording of ICP during surgery could have been confounded by surgical manipulation. ICP was measured extradurally in 12 and intraventricularly in eight patients. Although it has been shown that extradural pressure correlates closely with intraventricular pressure over a wide range in animals and in clinical practice,[13] we decided to include approximately the same number of patients with ICP measured extradurally and intraventricularly. As our study was undertaken in both six patients with extradural ICP measurement and four patients with intraventricular ICP measurement, a possible impact of measurement technique was excluded. However, both are accepted methods of ICP measurement and this study aimed to detect changes from baseline rather than absolute values. The non-parametric statistical analysis of choice to detect only changes in ICP from the baseline in a time span (figs 1, 2) was therefore the Friedman test.

We used sufentanil and midazolam for sedation.

There is controversy on the effects of sufentanil on ICP but recent studies have shown that sufentanil exerts minimal influence on ICP.[14] In patients sedated adequately with sufentanil, concomitant haemodynamic changes[15] are critical for adequate CPP, therefore, the infusion rate of sedating drugs remained unchanged before and during the study.

There was no significant change from baseline in MAP in the two groups during the 15-min study. The rocuronium group showed a transient increase in HR (fig. 1) which peaked 5 min after administration of the neuromuscular blocking agent. The fact that patients were stable before the beginning of the study might have contributed to the marked cardiovascular stability noted in this study. Increases in HR from baseline, probably because of a vagal blocking effect, did not exceed 7% and MAP did not decrease by more than 4% in the rocuronium group. These changes were not clinically important. Our results concur with a report on dose-related HR increases associated with rocuronium in humans.[16,17] As the drug possesses no ganglionic blocking effect or histamine-releasing properties,[18,19] a substantial decrease in MAP was unlikely. CPP is calculated from MAP and ICP, which were not influenced by either blocker and therefore CPP was not impaired.

A reduction in cerebral perfusion and venous blood return caused by coughing or poor synchronization with the ventilator results in increased cerebral oedema. In neurosurgical patients, neuromuscular block is important to avoid brisk bucking, straining and coughing during laryngoscopy and tracheal intubation. In neurological patients with severe head injuries or subarachnoid haemorrhages who are restless and demonstrate difficulty in artificial ventilation in spite of sedatives and analgesics, neuromuscular block may be the treatment of choice to prevent an increase in ICP.[20,21]

It is known that tubocurarine may increase ICP[22] by ganglionic block which may also produce arterial hypotension. If an increase in ICP occurs concomitantly with a decrease in MAP, a substantial decrease in CPP occurs. In patients with disturbed autoregulation, increased MAP after administration of pancuronium could be a disadvantage. Atracurium has the potential to release histamine, but in humans as in animals,[4,23] atracurium has been shown to have minimal effect on ICP. Vecuronium does not induce histamine release nor does it change MAP or HR. In patients with brain tumours, vecuronium had minimal effects on ICP,[2,24] which was consistent with our results. From the point of view of direct cerebral effects, non-depolarizing neuromuscular agents, such as pancuronium,[3,25] vecuronium[1,2,24] and atracurium, that do not increase ICP, are appropriate for use during neurosurgical procedures and for intubation. Good-to-excellent intubating conditions should exist to limit the increase in ICP which may be caused by intubation. The use of suxamethonium to facilitate tracheal intubation in neurosurgical patients has been associated with an increase in ICP for 4–6 min.[1,26] The mechanism of this effect has been ascribed to transient EEG desynchronization secondary to muscle fasciculation and concomitant increase in cerebral blood flow and cerebral blood volume[27–31] and to a transient increase in intra-abdominal pressure caused by muscle fasciculations leading to increased central venous pressure and intracerebral venous pressure.[32] Thus the increase in ICP is thought to be specific for depolarizing neuromuscular blocking agents. The use of suxamethonium therefore has been declining in clinical neuroanaesthetic practice, with the exception of emergency situations, such as the patient with a full stomach in whom rapid sequence induction is recommended.

Rocuronium is the first non-depolarizing neuromuscular blocking agent with a rapid onset (approaching that of suxamethonium) and good-to-excellent intubating conditions.[6,7] The results of our study suggest that rocuronium may be used for neurosurgical patients without the risks associated with suxamethonium.

Acknowledgement

We thank Organon Teknika, Belgium, for generous support and for supplying rocuronium, and Massimo Margeritella for helping with neuromuscular monitoring.

Interactions between suxamethonium and mivacurium or atracurium

K. S. KIM, D. J. NA AND S. U. CHON

Summary

We have compared the dose–response relationships of suxamethonium, mivacurium and atracurium and examined the interactions of suxamethonium with mivacurium or atracurium in humans by isobolographic analysis. We studied 100 adult patients during fentanyl and thiopentone anaesthesia. Neuromuscular function was monitored using a Myograph 2000 (Biometer Co., Odense, Denmark). The dose–response curves were determined by probit analysis. Isobolographic and fractional analyses were used to assess quantitatively the combined effect of equipotent doses of suxamethonium, mivacurium and atracurium and to define the type of interaction between suxamethonium and mivacurium or atracurium. The ED_{50} values for suxamethonium, mivacurium and atracurium were 198.8 (95% confidence interval 190.7–206.9), 48.6 (45.4–51.8) and 202.1 (197.9–206.2) mg kg^{-1}, respectively. Isobolographic and fractional analyses of the suxamethonium–mivacurium and suxamethonium–atracurium combinations demonstrated antagonistic interactions. (*Br. J. Anaesth.* 1996; **77**: 612–616)

Mivacurium is a new, short-acting, non-depolarizing neuromuscular blocking agent of the benzylisoquinoline type.[1 2] It is hydrolysed by plasma cholinesterase *in vitro* at 70–88% the rate of suxamethonium.[3–5] Atracurium has an intermediate duration of action because of its chemical elimination by the Hofmann mechanism.[6] The effects of the interaction between suxamethonium and non-depolarizing neuromuscular blocking agents depend on the order of administration and doses used.[7–12] The interaction between non-depolarizing neuromuscular blocking agents by isobolographic analysis has been reported.[13–15] However, none of the data from these studies was subjected to interaction analysis.

In this study, we have compared the dose–response relationships for suxamethonium, mivacurium and atracurium and examined the interactions of suxamethonium with mivacurium or atracurium in humans by isobolographic analysis.

Patients and methods

After obtaining hospital Ethics Committee approval and informed consent, we studied 100 patients, ASA I or II, aged 17–59 yr, undergoing elective surgical procedures. No patient had any disease or metabolic abnormality known to alter neuromuscular transmission or was receiving any drug known or suspected of interfering with neuromuscular function.

Anaesthesia was induced with fentanyl 4–5 μg kg^{-1} and thiopentone 5 mg kg^{-1} i.v., without premedication, and maintained with a continuous infusion of thiopentone 10–15 mg kg^{-1} h^{-1} and intermittent boluses of fentanyl 1–2 μg kg^{-1}. Ventilation was adjusted to maintain normocapnia (end-tidal carbon dioxide partial pressure 4.8–5.3 kPa) via a face mask without tracheal intubation. Halogenated anaesthetics or nitrous oxide were not used.

The ulnar nerve was stimulated at the wrist with square-wave supramaximal stimuli of 0.2 ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz every 10 s, using a Myotest DBS peripheral nerve stimulator (Biometer Co., Odense, Denmark). The resultant contraction of the adductor pollicis was recorded using a force displacement transducer and neuromuscular function analyser (Myograph 2000, Biometer Co., Odense, Denmark). Preload tension of the thumb was maintained at 300 g throughout the investigation. The first twitch (T1) of the TOF was considered the twitch height.

After stable recording of neuromuscular transmission had been established for a minimum of 30 min, patients were allocated randomly to receive suxamethonium, mivacurium, atracurium, suxamethonium and mivacurium or atracurium combination. The following predetermined doses of drugs were administered to subgroups of 20 patients: suxamethonium 150, 250 and 350 μg kg^{-1}; mivacurium 30, 50 and 70 μg kg^{-1}; atracurium 150, 200 and 250

μg kg^{-1}; suxamethonium and mivacurium, respectively, 198 and 48.6 μg kg^{-1}, 247.5 and 60.8 μg kg^{-1}, 297 and 72.9 μg kg^{-1}; suxamethonium and atracurium, respectively, 198 and 202 μg kg^{-1}, 247.5 and 243.5 μg kg^{-1}, 297 and 285 μg kg^{-1}. Studies of the single-drug groups were concluded first, so that doses of the combination could be planned. From the dose–response curves of the neuromuscular agents administered alone, we determined the respective effective doses resulting in 50% reduction of twitch tension (ED$_{50}$). Subsequently, dose–response curves were obtained by administration of the following drug combinations in a constant dose ratio based on the ED$_{50}$ values of the single agent. For the suxamethonium–mivacurium combination, the following combinations were administered: 1 × ED$_{50}$ suxamethonium + 1 × ED$_{50}$ mivacurium; 1.25 × ED$_{50}$ suxamethonium + 1.25 × ED$_{50}$ mivacurium; and 1.5 × ED$_{50}$ suxamethonium + 1.5 × ED$_{50}$ mivacurium. Similar dose ratio combinations were used for the suxamethonium–atracurium combination.

All drugs were given over 5 s into a rapidly flowing i.v. infusion. In the combination group, drugs were injected simultaneously into two separate i.v. cannulae inserted in one arm. The neuromuscular response was recorded as maximum depression of T1, expressed as a percentage of the control value, in the arm opposite to that cannulated. When the maximum effect of the selected dose was reached (that is, when no further decrease in evoked response to three consecutive stimuli occurred), the study was terminated and anaesthesia continued as appropriate for surgery.

The percentage values for twitch depression in each group were transformed to probits and plotted against the logarithm of the dose.[16] Regression lines were compared using analysis of covariance. ED$_{50}$ values were calculated from the log–probit regression lines for each group. Using analysis of variance, we compared age, weight and height between the different groups. Unless otherwise specified, the results are expressed as mean (95% confidence intervals) and were considered significant when $P < 0.05$.

Isobolographic analysis[17 18] was used to define the type of interaction between suxamethonium and mivacurium or atracurium. This analysis has the advantage of being independent of the slopes of the dose–response curves, that is parallelism does not have to be established. It has been used to confirm the interactions between non-depolarizing neuromuscular blocking agents[14 15] and between other drugs.[19–21] If the ED$_{50}$ of a combination falls on the theoretical additive line, the effect of the drug mixture is additive. Points to the left of the theoretical additive line would be consistent with a synergistic interaction, whereas points to the right of the line would indicate an antagonistic interaction. Confidence intervals for each point were calculated from the variances of each component alone and were evaluated for statistical significance using the unpaired Student's *t* test.

Fractional analysis[22] was based on the expression of the component doses of the two agents of the combination as fractions of the doses that produce the same effect when given separately. Values near 1 indicate additive interaction, values greater than 1 imply antagonism and values less than 1 indicate synergism. This analysis was also used to confirm the interaction between non-depolarizing neuromuscular blocking agents.[14 15]

Results

Patient characteristics are shown in table 1; they did not differ between groups. The calculated ED$_{50}$ values for twitch depression were 198.8 (95% confidence interval 190.7–206.9), 48.6 (45.4–51.8) and 202.1 (197.9–206.2) μg kg^{-1} for suxamethonium, mivacurium and atracurium, respectively. The dose–response curves are shown in figures 1 and 2. The regression lines for suxamethonium, mivacurium, atracurium and the combinations did not deviate from parallelism. The slopes for suxamethonium alone, mivacurium alone, suxamethonium combined with mivacurium, and mivacurium combined with suxamethonium were, respectively, 5.4 (5.0–5.8), 3.2 (2.7–3.7), 7.2 (6.9–7.5) and 6.3 (5.8–6.8) (fig. 1). The slopes for suxamethonium alone, atracurium alone, suxamethonium combined with atracurium, and atracurium combined with suxamethonium

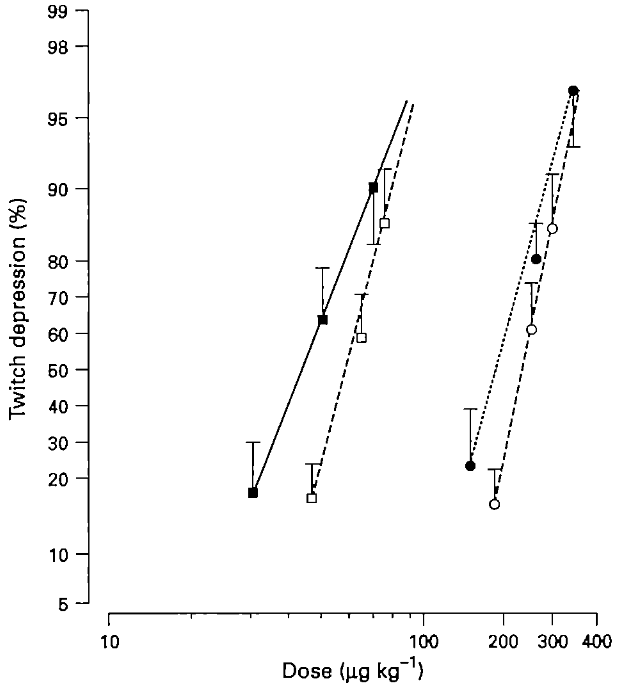

Figure 1 Log dose–probit plot for twitch depression for mivacurium with (□) or without (■) suxamethonium, and suxamethonium with (○) or without (●) mivacurium. Individual points represent mean (95% confidence intervals) twitch depression (% control) with each dose.

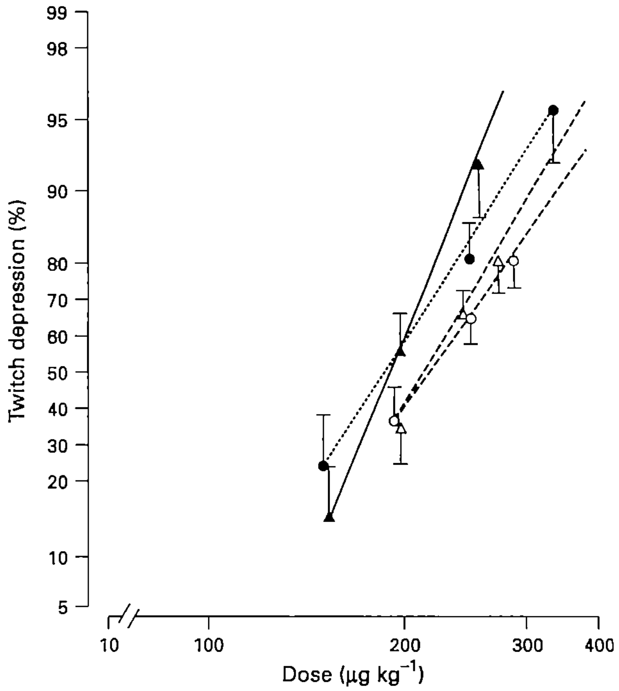

Figure 2 Log dose-probit plot for twitch depression for atracurium with (△) or without (▲) suxamethonium, and suxamethonium with (○) or without (●) atracurium. Individual points represent mean (95% confidence intervals) twitch depression (% control) with each dose.

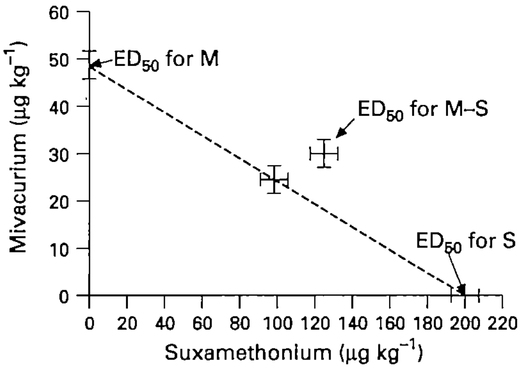

Figure 3 First-twitch ED_{50} isobologram for the interaction of mivacurium (M) and suxamethonium (S). The broken line connecting the single-drug ED_{50} points is the theoretical additive line; the point on this line is the theoretical additive point (95% confidence intervals). The experimentally determined ED_{50} dose (95% confidence intervals) of the mivacurium–suxamethonium (M–S) combination showed significant antagonistic effect ($P < 0.0005$).

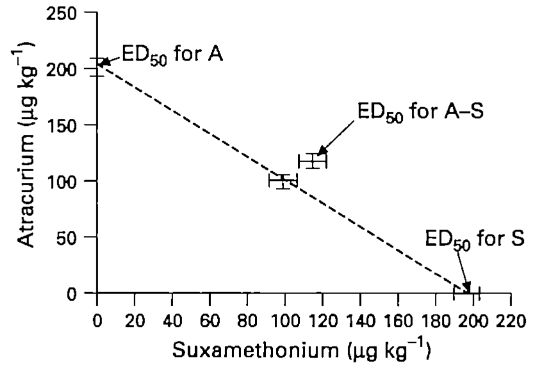

Figure 4 First-twitch ED_{50} isobologram for the interaction of atracurium (A) and suxamethonium (S). The broken line connecting the single-drug ED_{50} points is the theoretical additive line; the point on this line is the theoretical additive point (95% confidence intervals). The experimentally determined ED_{50} dose (95% confidence intervals) of the atracurium–suxamethonium (A–S) combination showed significant antagonistic effect ($P < 0.0005$).

were, respectively, 5.4 (5.0–5.8), 6.5 (6.2–6.8), 5.3 (5.1–5.5) and 5.7 (5.2–6.1) (fig. 2). The slopes and intercepts of the combined drugs were significantly different from those of the single drugs ($P < 0.05$).

Isobolographic analyses demonstrated antagonistic interactions with respect to the neuromuscular blocking activity of the suxamethonium and mivacurium or atracurium combinations (figs 3, 4). Fractional analyses of these interactions also demonstrated antagonism (tables 2, 3). The ED_{50} isobologram for the suxamethonium–mivacurium interaction is shown in figure 3. The experimentally determined ED_{50} value for the combination was 123.3 (119.2–127.4) $\mu g\ kg^{-1}$ for suxamethonium and 30.2 (28.6–31.8) $\mu g\ kg^{-1}$ for mivacurium. The theoretical additive ED_{50} value was calculated as 99.4 (91.3–107.5) $\mu g\ kg^{-1}$ for suxamethonium and 24.3 (21.2–27.4) $\mu g\ kg^{-1}$ for mivacurium. The confidence intervals of these points did not overlap and the result of Student's *t* test for potency ratio was significant ($P < 0.0005$).

The ED_{50} isobologram for the suxamethonium–atracurium interaction is presented in figure 4. The experimentally determined ED_{50} value for the combination was 117.3 (110.2–124.4) $\mu g\ kg^{-1}$ for suxamethonium and 119.2 (115.1–123.3) $\mu g\ kg^{-1}$ for atracurium. The theoretical additive ED_{50} value was calculated as 99.4 (91.3–107.5) $\mu g\ kg^{-1}$ for suxamethonium and 101 (96.8–105.2) $\mu g\ kg^{-1}$ for atracurium. The confidence intervals of these points did not overlap and the result of Student's *t* test for potency ratio was significant ($P < 0.0005$).

Discussion

We have found that isobolographic analyses demonstrated that the combination of suxamethonium and mivacurium or atracurium exerted greater antagonistic effects than those seen with either agent administered alone. Fractional analyses of these interactions also demonstrated antagonistic interactions, that is the effect of the combination was precisely that expected from the dose–response relations of the individual agents.

Suxamethonium was administered before or after non-depolarizing neuromuscular blocker in previous studies,[7–12] however, in this study suxamethonium and mivacurium or atracurium were administered simultaneously for isobolographic analysis. Potentiation of the effects of atracurium[8] and tubocurarine[10] was reported by prior administration of suxamethonium. In contrast, Walts and Dilien[7] noted the opposite for tubocurarine. Previous administration of suxamethonium had only minor effects on the following mivacurium block.[11 12] Pretreatment with mivacurium had a marked antagonistic effect on the development of subsequent depolarizing block produced by suxamethonium.[11] Small doses of suxamethonium might antagonize the partial block seen during recovery from atracurium, but larger doses usually enhanced the block.[9]

Szalados, Donati and Bevan[23] reported that small doses (0.15–0.25 mg kg^{-1}) of suxamethonium were associated with more twitch augmentation than higher doses. This was probably because twitch height was the algebraic sum of neuromuscular block and twitch augmentation. The large increases in twitch height observed with small doses suggested that twitch augmentation predominated with small doses, and block was more prominent if large doses were given. In this study the doses of suxamethonium (150, 250 and 350 $\mu g\ kg^{-1}$) were similarly small as those of twitch augmentation.

Traditionally, mivacurium or atracurium produce mainly competitive block of postsynaptic receptors. Such a block might be overcome by increasing the concentration of agonist usually, in clinical practice, by administration of neostigmine. However, suxamethonium also acted as an agonist and interacted with the same postsynaptic receptors, leading to the opening of ionic channels and depolarization of the membrane. In turn, this may initiate a muscle action potential and contraction. We interpreted our results collectively as the combination of suxamethonium and mivacurium or atracurium acted as the competitive antagonism at postsynaptic receptors.

Both mivacurium and suxamethonium are metabolized by plasma cholinesterase, suggesting that potentiation of block should occur in combination. However, recovery of twitch height during mivacurium block was even slightly shortened after suxamethonium in a patient with normal cholinesterase activity.[12] We also found that the antagonistic action of the combination of mivacurium and suxamethonium was similar to that of the combination of suxamethonium and atracurium which was not metabolized by plasma cholinesterase (figs 3, 4).

In this study, the ED_{50} value for suxamethonium (198.8 $\mu g\ kg^{-1}$) was similar to that reported by Smith, Donati and Bevan[24] (210 (190–230) $\mu g\ kg^{-1}$ during opioid–thiopentone–nitrous oxide anaesthesia). Naguib and colleagues[11] reported that the ED_{50} for suxamethonium was 86 $\mu g\ kg^{-1}$ by the single-dose technique during 1 MAC isoflurane anaesthesia, and Miller and colleagues[25] reported 88 $\mu g\ kg^{-1}$ by the cumulative dose technique during 1.25 MAC of isoflurane anaesthesia. Isoflurane may have potentiated neuromuscular block in these studies. We used the single-dose technique as the cumulative dose technique underestimated the potency of suxamethonium.[24]

The dose–response relationship of mivacurium and atracurium was estimated by means of the single-dose technique rather than by the cumulative method commonly used with neuromuscular blocking agents of long duration of action.[26] The possibility of higher ED_{50} and ED_{95} values of short-acting neuromuscular blocking agents generated by the cumulative method relative to the single-dose technique has been discussed by Gibson and colleagues.[27 28] We also used the single-dose technique for mivacurium and atracurium. Diefenbach and colleagues[29] reported that the ED_{50} of mivacurium was 48 $\mu g\ kg^{-1}$ during nitrous oxide and fentanyl anaesthesia, and this was similar to our result. Sokoll and colleagues[30] reported the ED_{50} of atracurium during nitrous oxide and fentanyl anaesthesia as 120 $\mu g\ kg^{-1}$. Naguib and colleagues[14] calculated an ED_{50} of 50.5 $\mu g\ kg^{-1}$ during isoflurane anaesthesia. Isoflurane potentiated neuromuscular block, but Sokoll and colleagues[30] used no inhalation agent. The only methodological difference between the study of Sokoll and colleagues and ours was the use of nitrous oxide for maintenance of anaesthesia. This raises the possibility of an interaction between nitrous oxide and atracurium.

We conclude that the interaction of suxamethonium and mivacurium or atracurium combination was the result of antagonistic action at the neuromuscular junction.

Midlatency auditory evoked potentials as indicators of perceptual processing during general anaesthesia

N. A. M. DE BEER, J. C. VAN HOOFF, C. H. M. BRUNIA, P. J. M. CLUITMANS, H. H. M. KORSTEN AND J. E. W. BENEKEN

Summary

We tested the hypothesis that midlatency auditory evoked potentials (MLAEP) can predict the occurrence of long latency AEP components (LLAEP), which are taken as evidence for perceptual processing. Forty-one patients undergoing cardiac surgery were anaesthetized with propofol and alfentanil. During several periods of surgery we recorded LLAEP. Peak-to-peak amplitude measures were used to determine if a particular LLAEP recording trace contained a recognizable waveform. Both before and after each LLAEP recording epoch, MLAEP and the spontaneous electroencephalogram (EEG) were recorded. Peak latencies and amplitudes of brainstem peak V and midlatency peaks Na, Pa, Nb, Pb and Nc, characteristic frequencies from the spontaneous EEG, mean arterial pressure (MAP) and nasopharyngeal temperature (*T*) were compared between recording epochs with and without clear LLAEP waveforms. These variables were also used in a discriminant analysis to predict the occurrence of an LLAEP waveform. Pa and Nb latencies were significantly shorter both before and after recording epochs in which an LLAEP waveform occurred, compared with epochs in which no LLAEP waveform occurred. Using a combination of up to six EEG, MLAEP, MAP and *T* measures, it was possible to predict the occurrence or absence of an LLAEP waveform with a sensitivity of 89% and specificity of 86%. We conclude that MLAEP components provide information on the possibility of perceptual processing during general anaesthesia, and thus may be relevant for monitoring depth of anaesthesia. (*Br. J. Anaesth.* 1996; **77**: 617–624)

Key words
Brain, evoked potentials. Monitoring, evoked potentials. Anaesthesia, depth.

Many studies on intraoperative memories suggest that auditory information processing may persist during general anaesthesia,[1] but there is still no standardized method for determining during operation whether or not an auditory stimulus is actually perceived. The availability of such a method is an essential prerequisite for monitoring anaesthetic depth. Auditory evoked potentials (AEP) provide a method for monitoring the transmission and processing of auditory stimuli from the cochlea to the cortex. The AEP consists of a series of waves that are characterized by their latency (the time of occurrence after sound onset) and amplitude. Brainstem auditory evoked potentials (BAEP), consisting of waves I–VII, occur within 10 ms after stimulus presentation, and reflect activation of the acoustic nerve and brainstem auditory structures. Midlatency AEP components (MLAEP) occur between 10 and 100 ms after sound onset. MLAEP components are termed N0, P0, Na, Pa, Nb, Pb and Nc, and are thought to be generated in thalamic and cortical auditory structures. MLAEP components are followed by long latency AEP components (LLAEP) which reflect activation of the association areas of the cerebral cortex. LLAEP components P1, N1 and P2 reflect the more cognitive aspects of information processing.[2] (No general agreement exists over the exact boundary to use between midlatency and long latency components. Theoretically, P1 and N1 are identical to Pb and Nc. In this article, labels P1 and N1 were used to indicate components elicited in an oddball paradigm, while labels Pb and Nc were used to indicate components elicited by clicks.)

Thornton has shown that BAEP components increase in latency with increased levels of volatile agents, whereas they remain unaffected by i.v. anaesthetics.[3] Latency and amplitude of MLAEP components have been found to show dose-related changes with general anaesthetics that were highly similar for inhalation and i.v. agents.[3 4] In addition, the decrease in Nb and Pb amplitude induced by anaesthesia was found to be reversed by surgical stimulation.[5] These results suggest that MLAEP components are related to responsiveness of the auditory pathways. However, their occurrence is

insufficient evidence that the presented stimulus is actually perceived.[6] The purpose of this study was to investigate the relationship between MLAEP components and auditory perception. Evidence of such a relationship would provide further support for the usefulness of the MLAEP for routine monitoring of perceptual processing during anaesthesia.

Previous research on this relationship has focused on the isolated forearm technique (IFT) and implicit memory. In a study by Thornton and colleagues,[7] it was shown that responsiveness, as indicated by IFT, was associated with shorter latencies of MLAEP peak Nb. IFT measures the ability of a patient to respond to verbal commands during anaesthesia. Absence of a response may indicate unconsciousness, but it is also possible that the patient wanted to respond, but was unable. Furthermore, it may be difficult to distinguish general movements from a purposeful response to command. Another limitation is that this technique can only be used for a short period of time, to prevent ischaemia in the isolated arm. In a study by Schwender and co-workers,[8] Pa latency was 100% sensitive and 77% specific in predicting implicit memory for material presented during the intraoperative period. Although this supports the notion that MLAEP measures reflect some degree of perceptual processing, the results of implicit memory tests are not determined exclusively by the effects of anaesthesia on perceptual processing but also on memory processes. In addition, the results of implicit memory tests may also be affected by intermediate processes between the time of stimulus administration and the time of testing.

To circumvent these disadvantages of the IFT and implicit memory tests, we focused on LLAEP components as a possible way of obtaining evidence for perceptual processing. The N1 and P2 components, occurring approximately 100 to 200 ms after a stimulus, are associated with early discrimination processes. Their amplitudes are influenced not only by the physical features of the stimuli, but also by the subject's attention.[9] The P3 component is a task-related component, most typically elicited by an infrequent stimulus presented against a background of frequent, standard stimuli (the so-called oddball task). This component, which has a latency of 250–600 ms, reflects controlled stimulus processing and target detection, presumably associated with conscious awareness of the presented stimulus.[10] Evidently, recording of LLAEP components in addition to MLAEP components would create the possibility of relating early cortical MLAEP changes resulting from anaesthesia to variations in levels of perceptual and cognitive processing.

In this study, MLAEP and LLAEP were recorded during several periods of cardiac surgery with propofol–alfentanil anaesthesia. Our hypothesis was that MLAEP measures can predict the occurrence of LLAEP components (specifically the P1-N1-P2 complex), which is taken as the earliest evidence of perceptual processing. The predictive value of MLAEP measures was compared with that of mean arterial pressure, nasopharyngeal temperature and several spectral EEG measures.

Patients and methods

The study was performed at the Catharina Hospital, Eindhoven, and was approved by the local medical Ethics Committee. Informed consent was obtained from 41 patients (34 male) undergoing cardiac surgery. Mean age of the patients was 59 (range 38–74) yr. Two patients underwent aortic valve replacement and the others underwent coronary artery bypass grafting. Patients were premedicated approximately 2 h before surgery with morphine 10 mg s.c. Total i.v. anaesthesia was used with propofol and alfentanil. Anaesthesia was induced with a loading dose of propofol 2 mg kg^{-1} and alfentanil 100 $\mu g\ kg^{-1}$, given over 12 min; after this, anaesthesia was continued with infusion rates of propofol of 8 mg $kg^{-1}\ h^{-1}$ and alfentanil 4 $\mu g\ kg^{-1}\ min^{-1}$ for 10 min, then propofol 6 mg $kg^{-1}\ h^{-1}$ and alfentanil 3 $\mu g\ kg^{-1}\ min^{-1}$ for 10 min and finally propofol 4 mg $kg^{-1}\ h^{-1}$ and alfentanil 2 $\mu g\ kg^{-1}\ min^{-1}$ for maintenance. Pancuronium 8 mg was used to facilitate tracheal intubation. Additional pancuronium 8 mg was given at the start of cardiopulmonary bypass (CPB). The lungs were ventilated mechanically with air and oxygen to maintain end-tidal carbon dioxide pressure at 4 kPa. Oxygen saturation was monitored continuously. Increases in arterial pressure were counteracted with nitroglycerin or ketensine and decreases with administration of i.v. fluids, calcium or inotropic drugs, together with reduced doses of propofol and alfentanil. During CPB moderate hypothermia to 32 °C was used.

RECORDING PROCEDURE

Baseline recordings for both MLAEP and LLAEP were obtained on the morning of operation before patients were premedicated. During surgery MLAEP and LLAEP recordings were obtained during the following periods: before CPB (approximately 30 min after first incision); at the start of CPB; during CPB; at the end of CPB; and approximately 10 min after CPB.

In the event that surgery was too short to complete all recording series, period 3 was excluded. MLAEP and LLAEP were recorded successively during each of the above periods, as presented schematically in figure 1, because MLAEP components are typically evoked by presentation of auditory clicks, while LLAEP components are best elicited by tones with a much lower presentation rate. In addition, different filter settings are needed for these two types of AEP components, for which we used different EEG amplifiers. The total recording time in each recording period was limited to 22 min, as indicated in figure 1; typically it was about 15 min. The exact moment and duration of each recording epoch was dependent on the absence of disturbances caused by electrosurgery or the bypass pump.

An IBM-compatible 486 personal computer provided with a LabMaster analogue-to-digital (A/D) and digital-to-analogue (D/A) converter (Scientific Solutions, Solon OH) was used for presentation of MLAEP and LLAEP stimuli, control of the oddball task and acquisition of all neurophysiological signals, as described in the next sections.

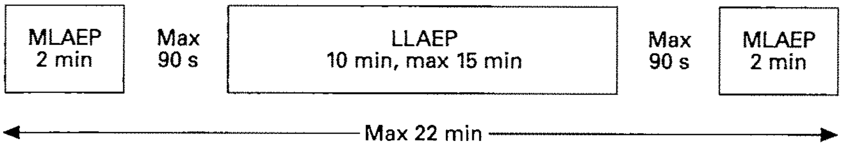

Figure 1 Schematic representation of MLAEP and LLAEP recording epochs.

LLAEP RECORDING AND PROCESSING

LLAEP were recorded during passive auditory oddball tasks. For baseline measurements, patients were instructed to ignore the stimuli. No specific instructions were given for the intraoperative recordings, because it was assumed that during anaesthesia patients would not be able to direct their attention towards any of the stimuli. Two tones of different pitch were presented binaurally through Nicolet Tip-10 insert earphones. The tones were 100-ms bursts of a digitally stored sine wave of 70 dB sound pressure level (SpL), with rise and fall times of 10 ms. Eighty percent of the stimuli were "standard" 1000-Hz tones, and 20% were "deviant" 2000-Hz tones. The inter-stimulus interval was 1044 ms. During two intraoperative oddball tasks (periods 1 and 4) five one-syllable words were presented repeatedly inter-mixed with the two types of tones. In these tasks the words had a probability of 0.15, compared with 0.70 for the standard tones and 0.15 for the deviant tones. After operation these words were tested for (covert) recognition, which will be reported in detail elsewhere (van Hooff and colleagues, in preparation). In the preoperative period, a total of 200 stimuli were presented. During surgery, 400–600 stimuli were presented because of a poorer signal-to-noise ratio.

For LLAEP processing, the raw electroencephalogram (EEG) was recorded from silver–silver chloride electrodes placed at Fz, Cz, Pz and two lateral positions C5 and C6, located midway between T3–C3 and T4–C4, respectively. Linked pre-auricular points served as reference. Recording and averaging were performed as described previously,[11] with the exception of filtering and artefact detection. In this study, the EEG signals were digitally filtered using a 33-point finite- impulse response bandpass filter with −3 dB cut-off frequencies of 2.7 and 8 Hz. The criteria for detecting an artefact were the occurrence of spikes greater than 110 μV, drift greater than 80 μV in a single trial or a difference in DC level in successive 250-ms epochs larger than 60 μV. The mean number of trials composing LLAEP in response to frequent tones, infrequent tones and words after artefact detection were 364 (SD 85), 87 (23) and 73 (14), respectively.

Peak amplitudes were determined for each individual waveform as being the most positive (for P1 and P2) and most negative (for N1) values in selected time windows based on the grand averages. P1 amplitudes were determined relative to the 200-ms pre-stimulus baseline, and N1 and P2 were determined with respect to their preceding peak (P1N1 and N1P2, respectively). P3 was not recognizable as a clear peak during anaesthesia and was therefore not quantified. Criteria for peak amplitudes were specified and used to judge whether or not a clear P1-N1-P2 complex could be distinguished in individual intraoperative recordings. Because LLAEP components were most clearly visible at Cz and because the recordings to frequent stimuli had the best signal-to-noise ratio, this was done for the Cz electrode position and the LLAEP to frequent tones only. When P1N1 and N1P2 amplitudes were larger than their median amplitudes (1.46 μV and 1.73 μV, respectively) and the correlation with an overall average waveform obtained by averaging all intraoperative LLAEP was larger than 0.55 (calculated over the first 800 ms of the response after tone-onset), then the recording was judged to be a clear LLAEP response, that is containing a recognizable P1-N1-P2 complex. The purpose of this assessment was to test if the presence of a clear LLAEP response could be predicted from the MLAEP.

MLAEP RECORDING AND PROCESSING

For MLAEP processing the raw EEG was recorded from Cz–A1 and Cz–A2, each referenced to Fpz. Recording and filtering of the EEG was performed as described previously.[12] Clicks were delivered with random inter-stimulus intervals, according to a Poisson distribution, with an average stimulation rate of 80 clicks s^{-1}. An important implication of using this distribution for random presentation of stimuli is that the effects of interfering stimuli are distributed equally over the entire sweep, independent of sweep length.[13 14] This results in a smoothing of the effect of interfering stimuli. We chose a sweep length of 270 ms for averaging of the MLAEP in this study to ensure that component Nc could be detected if present. Automatic detection of artefacts[12] was used to exclude sweeps containing artefacts from the averaging process. The MLAEP was not used in further processing if, because of the occurrence of artefacts, the total number of sweeps in the resulting average was lower than 3000 (corresponding to a net recording time of 38 s). From the resulting averages the latency and amplitude of brainstem peak V and of midlatency peaks Na, Pa, Nb, Pb and Nc were determined. Brainstem peak V was used to check if a response was actually present: if peak V could not be determined, the entire MLAEP waveform was not used in further processing.

PROCESSING OF THE SPONTANEOUS EEG

The raw EEG recorded for MLAEP averaging was also used for spectral analysis, using the CCSA software package developed in our group.[15] Before calculation of the spectra, the EEG was digitally low-pass filtered, using a 69-point moving average filter with a −3 dB cut-off frequency of 32 Hz. Spectra were calculated from 8-s epochs using 2-s overlapping of epochs, and applying a Blackman time window to prevent spectral leakage. Detection and rejection of epochs from the filtered EEG that contained artefacts was done with the same algorithm as was used for detecting artefacts in the MLAEP. If the occurrence of artefacts caused the total number of remaining epochs for a specific recording to be lower than six (corresponding to a net recording time of 38 s), that recording was not used in further processing. The features derived from the calculated spectra were median frequency, 95% spectral edge frequency and peak power frequency, and percentage delta (0–4 Hz), theta (4–8 Hz), alpha (8–14 Hz) and beta (>14 Hz) power. The resulting spectral features for each recording were averaged so that one set of EEG features remained for each set of MLAEP features.

Because the raw EEG was high-pass filtered at 5 Hz to enhance the quality of the MLAEP recordings, the calculated spectral features are higher than values reported in the literature as being necessary for surgical anaesthesia,[16 17] especially for median and peak power frequency. Percentage delta power is lower in our study.

RECORDING OF ARTERIAL PRESSURE AND TEMPERATURE

The values of mean arterial pressure (MAP) and nasopharyngeal temperature (*T*) were measured at the start and end of each MLAEP recording epoch. To avoid large physiological changes during the recordings, limits of acceptability were defined for the changes in MAP and *T*. When the difference in MAP and *T* values at the start and end of an MLAEP recording epoch exceeded the thresholds, as indicated in the first row of table 1, this MLAEP recording was excluded from further analysis. If neither MAP or *T* exceeded these thresholds, then for each MLAEP recording the average of MAP and *T* values obtained at the start and end of this recording epoch were calculated for inclusion in further analyses. When the differences in these average MAP and *T* values for the MLAEP recordings before and after each LLAEP recording epoch exceeded the thresholds, as indicated in the second row of table 1, then this set of MLAEP and LLAEP recordings was excluded from further analysis. This criterion implies that sets of MLAEP and LLAEP recordings for which there were no MAP or *T* values available, either before or after the LLAEP recording epoch, were also excluded from further analysis.

Table 1 Thresholds for mean arterial pressure (MAP) and nasopharyngeal temperature (*T*) for inclusion in the analysis. The threshold for changes in MAP was based on the maximally allowed range for MAP during CPB (40–70 mm Hg). The thresholds for changes in *T* were based on a maximally allowed cooling and rewarming rate of 0.5 °C min^{-1}

	MAP (mm Hg)	*T* (°C)
Maximally allowed difference between values obtained at start and end of MLAEP recording epoch	30	1
Maximally allowed difference between values obtained before and after LLAEP recording epoch	30	5

Systolic and diastolic arterial pressures were not included in the analysis, because during bypass no observations for these variables were available. Heart rate was also not included, partly because during CPB heart rate is zero, and partly because several patients were paced after CPB. This implies that heart rate contains no relevant information in these situations.

STATISTICAL ANALYSIS

MLAEP and EEG measures, MAP and *T* (all recorded both before and after each LLAEP recording epoch) were tested for differences between recording epochs in which an LLAEP occurred and epochs in which no LLAEP occurred. We used Wilcoxon's rank sum test for this comparison because of the low number of observations in the group consisting of recording epochs in which a reliable LLAEP occurred.

Predicting the occurrence of an LLAEP

Discriminant analysis was used to examine if it is possible to predict the occurrence of an LLAEP waveform in a specific recording epoch. Based on observations of MAP, *T* and MLAEP, and EEG features, a discriminant function was estimated that optimally separates the group of recording epochs in which an LLAEP occurred from the group of recording epochs in which no LLAEP occurred. Estimation of the optimal discriminant function was performed several times, using different sets of features, to compare the predictive power of the various available features. First, it attempted to predict the occurrence of an LLAEP using only the observations for MAP and *T* obtained at the start of each recording epoch. More variables were included for estimation of the discriminant function in subsequent analysis cycles. These added variables were the measures derived from the EEG (median, spectral edge and peak power frequency, and percentages of delta, theta, alpha and beta power) in the second cycle, the measures derived from the MLAEP (latencies and amplitudes of peaks V, Na, Pa, Nb, Pb and Nc) in the third cycle, and finally all MLAEP and EEG derived measures in the fourth cycle. These four cycles were repeated to include also the observations of the variables obtained at the end of each recording epoch.

In each cycle the discriminant analysis calculated the best linear combination of features from the total available data set by stepwise selection of variables. To prevent the resulting discriminant function from becoming difficult to interpret, we limited the number of variables to be included in the discriminant function to six in each cycle. The performance of the resulting discriminant function was tested after each cycle to see if its predictions agreed with the actual occurrence of an LLAEP waveform.

Table 2 Number of LLAEP recordings during the various periods of surgery. After selection=number of LLAEP recordings remaining after selecting those recordings for which both before and after the recording epoch, observations for MAP, *T*, MLAEP and EEG measures were present

	No. recordings		After selection	
	Total	Clear LLAEP	Total	Clear LLAEP
Total	176	44	52	9
Before CPB	35	19	8	3
At start of CPB	34	6	10	2
During CPB	33	—	11	—
At the end of CPB	34	11	4	1
After CPB	40	8	19	3

Because in this study we had only a limited amount of data available, we used the leave-one-out method for cross validation. This implies that when we have n data points, the discriminant function was calculated from $n-1$ data points and subsequently tested on the one remaining datum point. This was repeated n times so that each datum point was used once for testing. Performance was assessed in terms of sensitivity, specificity and accuracy. Sensitivity was defined as the fraction of epochs for which the occurrence of an LLAEP was predicted correctly by the discriminant function. Specificity was defined as the percentage of epochs for which the absence of an LLAEP was predicted correctly. Accuracy was defined as the percentage of epochs for which the occurrence or absence of an LLAEP was predicted correctly.

Results

In total, 176 LLAEP recordings were obtained during the 41 operations, of which 44 were judged as containing a clear LLAEP waveform (25%). Most of these clear LLAEP were recorded in the period before CPB, suggesting that perceptual processing occurred predominantly during this period. In table 2 the total number of LLAEP recordings obtained during the various periods of surgery are summarized. Table 2 also summarizes the number of recordings in each period of surgery for which both before and after the recording epoch complete observations for MLAEP, EEG, MAP and *T* were available. Of these remaining recordings, nine recording epochs obtained in nine different patients contained a clear LLAEP.

Examples of baseline and intraoperative LLAEP waveforms are presented in figure 2. Compared with preoperative LLAEP, intraoperative recordings were delayed and more positive going. N1, typical of preoperative recordings, decreased to or below prestimulus baseline levels during anaesthesia. A P3 response was generally absent in individual LLAEP traces. A more detailed description of the LLAEP results is presented elsewhere (van Hooff and colleagues, submitted). Examples of baseline and intraoperative MLAEP waveforms are presented in figure 3. Compared with baseline MLAEP waveforms, intraoperative MLAEP recordings showed longer latencies and smaller amplitudes. Compared with baseline EEG measures, intraoperative EEG

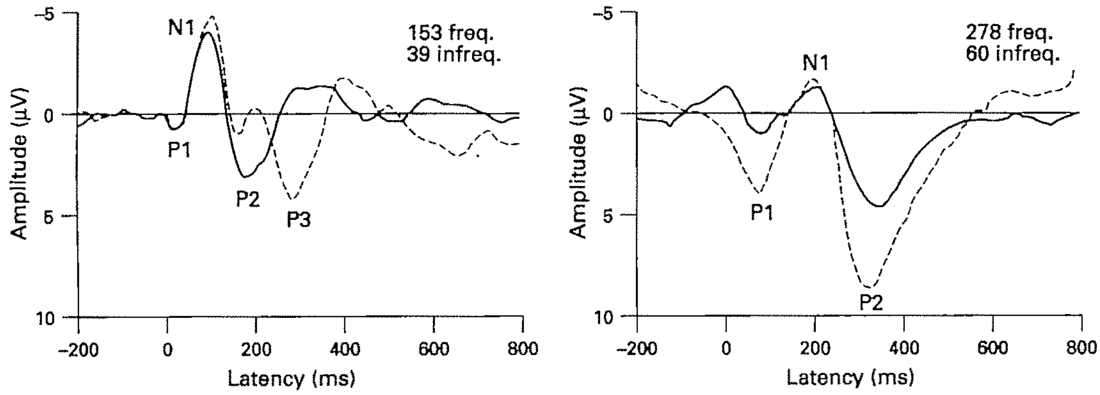

Figure 2 Examples of baseline (left) and intraoperative (right) LLAEP waveforms. Solid lines = responses to frequent stimuli, broken lines = responses to infrequent stimuli. Negativity is plotted upwards by convention.

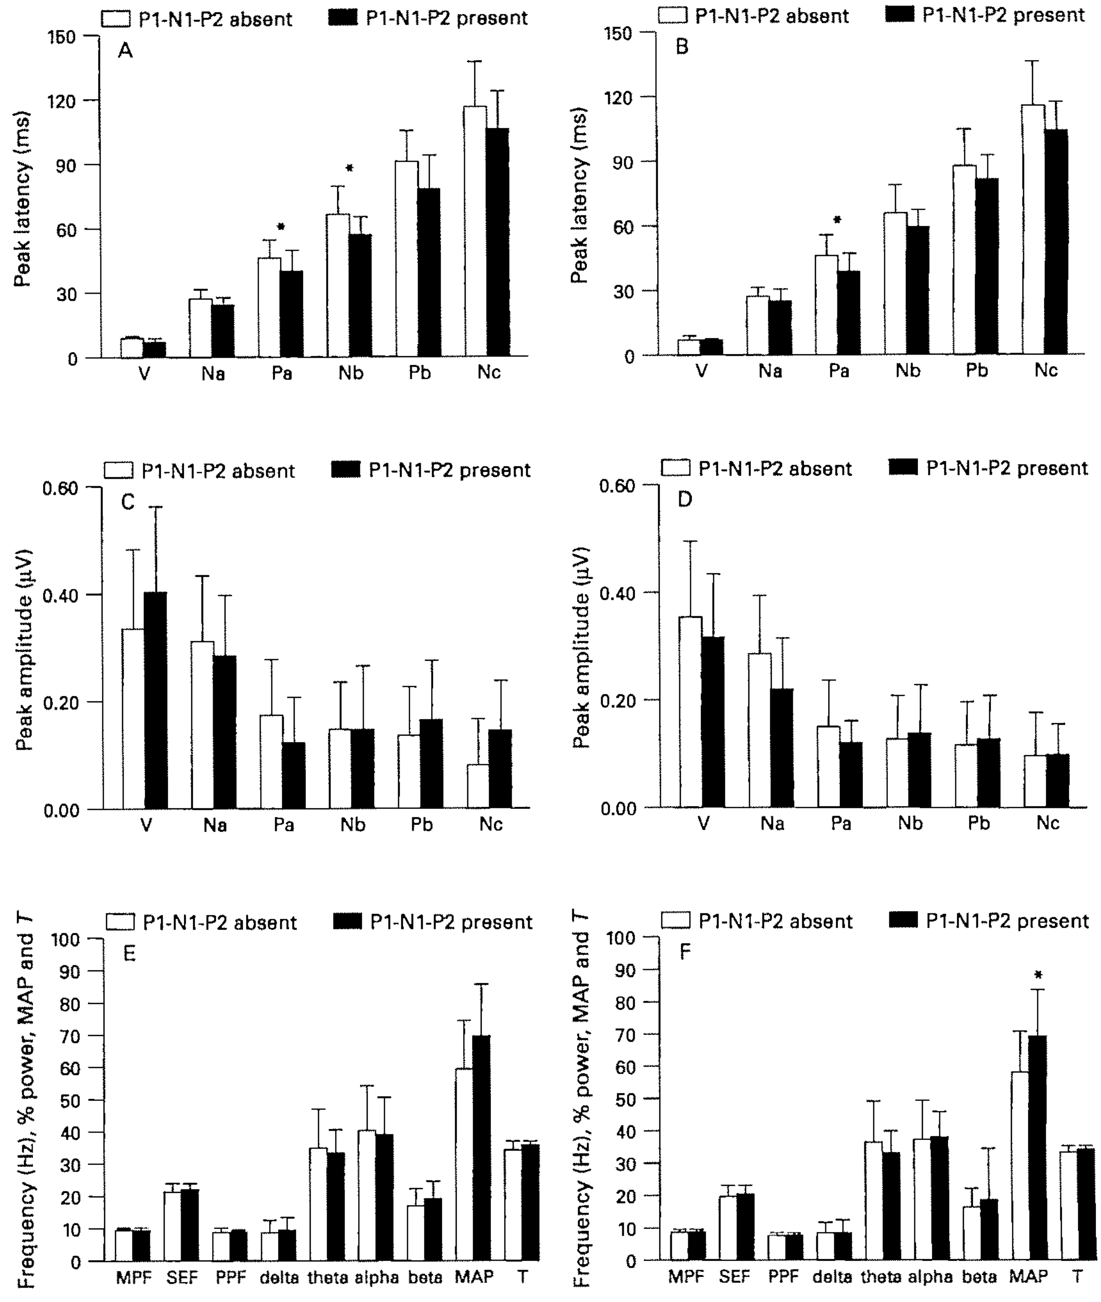

Figure 4 Mean (SD) values for MLAEP and EEG measures, mean arterial blood pressure (MAP) and nasopharyngeal temperature (T). Left column (A, C, E): MLAEP and EEG measures obtained before LLAEP recording epochs. Right column (B, D, F): MLAEP and EEG measures obtained after LLAEP recording epoch. First row (A, B): MLAEP peak latencies. Second row (C, D): MLAEP peak amplitudes. Third row (E, F): EEG spectral features, MAP and T.
$^*P < 0.05$ between recording periods (Wilcoxon rank sum tests).

measures showed a decrease in median, spectral edge and peak power frequencies, an increase in percentage delta and theta power, and a decrease in percentage beta power.

Mean (SD) values for MLAEP and EEG features, mean arterial pressure and nasopharyngeal temperature obtained before and after LLAEP recording epochs are presented in figure 4. Latencies of MLAEP peaks Pa and Nb were significantly shorter ($P = 0.050$ and $P = 0.045$, respectively) at the start of LLAEP recording epochs in which a clear LLAEP occurred, in comparison with recording epochs in which no clear LLAEP occurred. Latency of MLAEP peak Pa was significantly shorter ($P = 0.020$) at the end of LLAEP recording epochs in which a clear LLAEP occurred, compared with recording epochs in which no clear LLAEP occurred. Mean arterial pressure was significantly higher ($P = 0.042$) at the end of LLAEP recording epochs in which a clear LLAEP occurred, in comparison with recording epochs in which no clear LLAEP occurred.

The variables used in the discriminant function and its performance in predicting the occurrence of an LLAEP are summarized in Table 3. Adding only EEG features to the discriminant function did not improve the performance of the discriminant function beyond the performance of using only mean arterial pressure. Adding features from the MLAEP to the discriminant function improved specificity,

Table 3 Performance in terms of sensitivity, specificity and accuracy of different combinations of types of measured variables to predict the occurrence of an LLAEP. The first column indicates the group of variables available to the discriminant analysis, the second column indicates which of these variables were actually selected, in order of importance

Variable group	Variables used in discriminant function	Sens. (%)	Spec. (%)	Acc. (%)
Obtained before LLAEP recording epoch				
MAP + *T*	MAP	67	54	56
MAP + *T* + EEG	MAP	67	54	56
MAP + *T* + MLAEP	Lat Nb, MAP, amp V, amp Pb, amp Nc	67	74	73
MAP + *T* + MLAEP + EEG	Lat Nb, beta, amp Nc, amp V, MAP, sef	78	84	83
Obtained before (b) or after (a) LLAEP recording epoch				
MAP + *T*	MAP (a)	56	63	62
MAP + *T* + EEG	MAP (a)	56	63	62
MAP + *T* + MLAEP	Lat Pa (a), amp Nc (b), MAP (a), amp V (b), amp V (a), lat V (b)	78	81	81
MAP + *T* + MLAEP + EEG	lat Pa (a), beta (b), amp V (b) amp V (a), amp Nc (b), sef (b)	89	86	87

that is correct prediction of absence of an LLAEP waveform. Adding features from both the MLAEP and EEG improved sensitivity and specificity. Using MLAEP and EEG measures obtained both at the start and end of LLAEP recording epochs mainly improved sensitivity, that is correct prediction of the presence of an LLAEP waveform compared with using only variables obtained at the start of LLAEP recording periods.

Discussion

The hypothesis underlying this study was that MLAEP measures can predict the occurrence of LLAEP components during general anaesthesia. Our basic assumption was that the occurrence of LLAEP components can be taken as the earliest evidence for perceptual processing. It has been demonstrated that the N1 and P2 components reflect some level of perception[9 18] and that P3 reflects controlled stimulus processing and target detection.[10 19] These LLAEP components have in common that they are sensitive to the subject's psychological state, that is their amplitude and latency vary with attention, sleep or anaesthesia.[11 20–22] A study by Jessop and colleagues[23] showed a correlation between amnesia and presence or absence of P3.

When using an inter-stimulus interval of 1 s, and presenting a minimum of 200 stimuli (160 frequent and 40 infrequent stimuli), LLAEP recording during anaesthesia would require at least 3 min. Therefore, LLAEP themselves cannot be used for monitoring purposes, because rapid fluctuations in anaesthetic state cannot be detected. Instead, LLAEP can be used as a reference measure, providing information on whether or not auditory information processing actually occurs. If measures more suitable for monitoring, such as MLAEP components or spectral EEG measures, were to appear to be predictive with respect to the occurrence of LLAEP, this would be strong evidence for the use of these measures. It has been suggested that recording of MLAEP components also has the drawback that a relatively long acquisition time is needed.[24] A study by van de Velde, Cluitmans and Declerck[25] showed, however, that using random presentation of auditory stimuli, as was used in this study, may result in the acquisition of acceptable MLAEP waveforms within 40–60 s.

OCCURRENCE OF LLAEP WAVEFORMS

In agreement with our previous study,[11] P3 was not observed in individual intraoperative recordings, indicating that it is not likely that patients had awareness for the stimuli. Anaesthetic concentrations of fentanyl–isoflurane also suppressed the occurrence of a P3 response.[26] To date, only Plourde and colleagues[22] claimed to have observed a P3 subcomponent (P3a) during some periods of cardiac surgery during sufentanil anaesthesia. Although P3 is promoted frequently as being a promising measure to detect intraoperative awareness, it seems too easily abolished by surgical anaesthesia. Therefore, the presence of earlier LLAEP components, reflecting early perceptual processes (presumably automatically), was taken as a reference measure in this study. A clear P1-N1-P2 complex was present in 25% of intraoperative recordings. At first sight, this seems only a small proportion of all intraoperative recordings. However, these clear LLAEP were recorded in 28 of 41 patients, indicating that in 68% of all patients auditory processing persisted during some period of surgery.

Unfortunately, not all LLAEP obtained were preceded and followed by MLAEP and EEG recordings within the imposed time limit of 90 s. This was because of the restrictions imposed by external disturbances (e.g. electrosurgery), sudden changes during operation (e.g. onset of CPB) and anaesthetic or surgical intervention (e.g. defibrillation). Additionally, considerable effort was made to avoid large physiological changes during each series of recordings. After application of criteria to ensure the continuity of nasopharyngeal temperature and mean arterial pressure, 52 recording epochs, each comprising a series of MLAEP, LLAEP and MLAEP recordings as indicated in figure 1, remained for further analysis. From these 52 recordings, nine were judged as containing a clear LLAEP waveform (17%).

PREDICTIVE VALUE OF MLAEP AND EEG MEASURES

Pa and Nb latencies were shorter and MAP was higher when they were recorded close to LLAEP recording epochs comprising a clear LLAEP waveform than when they were recorded close to LLAEP recording epochs comprising no reliable LLAEP waveform (see fig. 4). This suggests a possible relationship between these measures and the presence of LLAEP components, that is the ability of higher level processing. This suggestion is supported by earlier observations of Thornton and colleagues[7] and Schwender and colleagues,[8] as described above. The predictive quality of Pa and Nb latencies in addition to MAP can further be derived from the fact that one or the other was always selected first in the discriminant functions. Because both variables are highly correlated they were not selected simultaneously by the discriminant analysis. MLAEP amplitudes, spectral EEG measures and nasopharyngeal temperature were not significantly different, whether or not the nearby LLAEP recording epochs comprised a clear LLAEP waveform. Nevertheless, discriminant analysis revealed that some of these variables in combination had predictive value with respect to the occurrence of clear LLAEP waveforms.

The results of our study indicate that both MLAEP and EEG measures may be used for predicting the occurrence of perceptual processing during anaesthesia. We found an accuracy of 87% in predicting the occurrence of an LLAEP waveform within a limited period of time, using MLAEP and EEG measures obtained at the start and end of that period of time. Accuracy was still 83% when only data obtained before the actual occurrence of an LLAEP waveform were used for this prediction.

In summary, we used LLAEP components for assessment of perceptual processing. The advantages of this technique are that it may also be used during longer periods of surgery, and that perceptual processing is assessed at the time it occurs. However, the long acquisition time needed for obtaining the LLAEP makes it unsuitable for routine monitoring. The results of our study provide additional support for the notion that the MLAEP and (to a lesser extent) the EEG may be used for routine monitoring of perceptual processing during anaesthesia. This may improve the conventional assessment of the risk of awareness based on clinical signs such as arterial pressure and heart rate.

Effect of racemic mixture and the (S+)-isomer of ketamine on temporal and spatial summation of pain

L. ARENDT-NIELSEN, J. NIELSEN, S. PETERSEN-FELIX, T. W. SCHNIDER AND A. M. ZBINDEN

Summary

We have compared the analgesic efficacy of the racemic mixture and the stereoisomer (S+) of the NMDA antagonist ketamine. In a double-blind, three-way crossover, placebo-controlled study, we assessed the following: pain evoked by small/large area pressure stimuli, pain detection threshold and pain ratings to small/large area of heat stimuli, pain detection threshold and pain rating to heat stimuli of brief/long duration, summation pain threshold and pain ratings to repeated heat/electrical stimuli, side effects and reaction time. Plasma concentrations of 350 ng ml^{-1} for ketamine (racemic) and 180 ng ml^{-1} for ketamine (S+) were tried. We found that ketamine (racemic) prolonged the reaction time more than ketamine (S+). Both drugs affected pain caused by repeated stimuli or stimuli of long duration equally or more than a single stimulus of short duration. They also affected pain evoked from large areas equally or more than pain evoked from small areas. The (S+)-isomer was approximately twice as potent as the racemic mixture of ketamine in inhibiting central summation. (*Br. J. Anaesth.* 1996; **77**: 625–631)

Key words
Anaesthetics i.v., ketamine. Pain, mechanism. Pain, experimental. Pharmacokinetics, stereoisomers. Pharmacokinetics, ketamine.

Several studies have indicated that anaesthetic agents are less effective in blocking pain caused by repeated/prolonged stimuli than pain caused by a single stimulus, and less effective in blocking stimuli covering large areas than stimuli covering small areas.[1–5] Increased pain caused by repetition is termed temporal summation and increased pain as a result of activation of a large area is termed spatial summation.

Wind-up (increased and prolonged firing after repeated stimulation) in animal dorsal horn neurones[6–8] is probably the mechanism underlying temporal summation in humans. The mechanism behind spatial summation is less clear but is presumably a result of convergence on central neurones. Techniques to investigate wind-up are needed to assess the effect of different anaesthetic drugs on this mechanism in humans. Psychophysical and electrophysiological techniques have been established to assess temporal[9–11] and spatial[12] summation in humans.

Animal experiments have shown that NMDA antagonists inhibit wind-up.[12 13] In human studies, NMDA antagonists (ketamine, dextromethorphan) were found to attenuate temporal summation.[10 14] Unfortunately, few NMDA antagonists are available for human use and the existing drugs have severe psychomimetic side effects. Commercially available ketamine is a racemic mixture. In animal experiments the stereoisomer, ketamine (S+), has proved to be 2–3 times more potent but less psychoactive than the (R−)-isomer.[15] In a human study the (S+)-isomer was four times more potent than the (R−)-isomer for management of postoperative pain.[16] Therefore, the (S+)-isomer offers clinically useful advantages if an equipotential dose causes less side effects than the racemic mixture.

The aim of this double-blind, placebo-controlled human study was to use psychophysical techniques to determine the analgesic potency of ketamine (racemic) and ketamine (S+) on temporal and spatial summation and to compare potency and side effects.

Subjects and methods

We studied 12 paid, healthy students (mean age 27.1 (range 23–41) yr). Mean weight was 69.8 kg (range 58–86 kg). Informed consent according to the Helsinki Declaration was obtained and the study was approved by the Regional Scientific Ethics Committee, Bern.

I.v. infusion of NaCl–glucose was started before testing. Pulse oximetry (Sp_{O_2}), ECG and non-invasive arterial pressure were monitored during the study. Skin temperature at the lateral aspect of the

forearm was measured by a medical precision thermometer (Therm 3480-6, Holzkirchen, Deutschland). Mean reaction time to five 1000-Hz tone stimuli was determined.

STIMULATION AND THRESHOLDS

Heat stimulation

The heat stimulator had a circular contact surface with a diameter of 20 mm (314 mm^2). This surface consisted of a thin copper foil placed on top of a thermofoil (Minco Products, Inc.), being a resistive heating element in principle (fig. 1). As the mass of the heating element was low, rapid increases in temperature were obtained (30 °C s^{-1}). The thermofoil was maintained at a constant baseline temperature (35 °C) by adjusting the current passing through the element. Temperature was calibrated by the medical precision thermometer. To obtain active cooling of the skin after each stimulation, a relatively large aluminium block was placed behind the thermofoil. This block was maintained at a constant temperature of 10 °C by a Peltier device and cooling water. This resulted in a skin cooling rate of up to 15 °C s^{-1}. Five identical heat stimulators were controlled individually and the areas activated by one, two, three, four and five thermodes were 314 mm^2, 628 mm^2, 942 mm^2, 1256 mm^2 and 1570 mm^2, respectively. The circular thermodes were placed on a line with a centre-to-centre distance of 50 mm. Heat pulses were delivered to the lateral aspect of the forearm without preparing the skin in any way. The inter-stimulus time was distributed randomly between 15 and 20 s.

Spatial summation

This stimulation procedure investigated if the drugs affected small and large areas in a similar way. Spatial summation was investigated by detection of the thermal pain threshold to one and five thermodes (314 and 1570 mm^2, respectively). The heat pain detection threshold was determined as the point where thermal sensation became painful. Peak temperature was increased automatically in steps of 0.5 °C until the threshold was reached. The stimulus was increased by 8 °C s^{-1} and maintained at the peak temperature for 2 s.

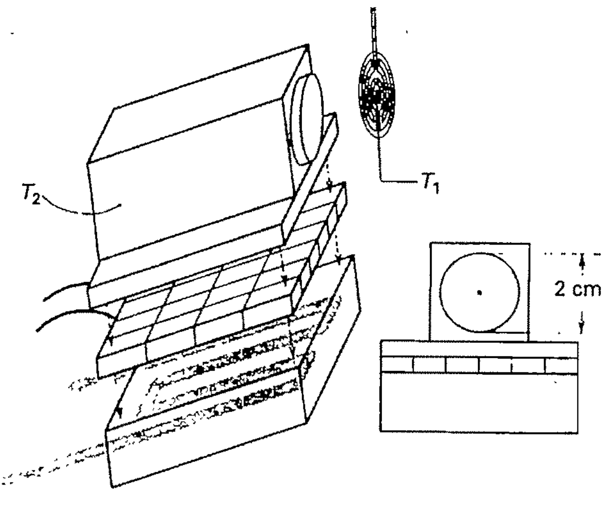

Figure 1 Schematic drawing of the thermal stimulator used in this study. The heat foil is maintained at a baseline temperature of, for example 35 °C (*T1*). The heat foil is glued (by thermal conductive glue) to an aluminium block maintained at a temperature of 10 °C (*T2*). This controlled cooling temperature is obtained by a Peltier device which is again cooled by water.

Temporal summation

This stimulation procedure determined if the drugs affected single and repeated stimuli in the same way, and short and long duration stimuli in a similar way. Temporal summation was investigated using a single thermode (314 mm^2) and five pulses delivered at 0.66 Hz (rise time 30 °C s^{-1}). The heat summation pain threshold was determined as the temperature at which the subject reported the pain to increase during the course of five stimuli.[11] Temperature was increased automatically in steps of 0.5 °C until the summation threshold was reached.

Another method of investigating temporal summation was to change the duration of the heat pulse. Volunteers were stimulated with one and five thermodes at a supra-threshold temperature of 50 °C in two ways: (1) 50 °C of one thermode was reached at 8 °C s^{-1} and then immediately returned to baseline. Pain intensity was rated on a VAS scale; (2) 50 °C of one and five thermodes was reached at 8 °C s^{-1} and maintained for 2 s and then returned to baseline. Pain intensity was rated on a VAS scale.

Electrical stimulation

This stimulation procedure examined if the drugs affected single and repeated stimuli in a similar manner. A constant current, computer-controlled stimulator (Aalborg University, Denmark) was used for percutaneous electrical stimulation of the sural nerve using a electrode with two silver–silver chloride electrodes separated by 20 mm (13L20, Dantec, Denmark). Five constant current 1-ms pulses supplied rectangularly at 200 Hz were defined as a "single stimulus". When this single stimulus was repeated five times at 2 Hz, it was defined as "repeated stimuli". The electrical summation pain threshold to repeated stimuli was determined as the point at which the subject felt an increasing sensation during the five stimuli[11] eventually resulting in pain. The intensity was increased in steps of 1 mA until the summation threshold was reached. At least 10 s elapsed between individual stimuli. The VAS rating to 1.2 times the baseline summation pain threshold was determined.

Pressure stimulation

This stimulation procedure investigated if the drugs affected small and large areas in a similar way. Pressure was applied using an electronic pressure algometer (Somedic AB, Stockholm, Sweden). Pressure pain detection and tolerance thresholds were determined using two different probe areas

(6.0 mm and 10.8 mm diameter, 28 mm^2 and 92 mm^2, respectively) applied at the second and third finger pulps of the left and right hand. Pressure was increased with a fixed rate of 50 kPa s^{-1} corresponding to 1.4 N s^{-1} and 4.6 N s^{-1} for the small and large areas, respectively. Ten to 15 s elapsed between stimuli.

MEDICATION

Volunteers received ketamine (racemic), ketamine (S+) or placebo (saline) in a randomized, double-blind, crossover design. Ketamine (racemic and S+) was administered by a target-controlled infusion system. This consisted of a computer connected to a Harvard 22 (Harvard Apparatus, South Natick, MA, USA) infusion pump with a serial interface. The pharmacokinetic variables for ketamine reported by Domino and co-workers[17] were programmed into the software Stanpump (Stanpump is available at no charge from the author, Steven L. Shafer, MD, Anesthesiology Service (112A), Pavamc, 3801 Miranda Ave, Palo Alto, CA 94304, or from the WWW at URL: http:@pkpd.icon.palo-alto.med.va.gov.). Stanpump attempts to maintain a constant plasma concentration by simulation. The programmed pump variables do not consider any stereoselective differences in ketamine pharmacokinetics. Pseudo-steady-state concentrations of 350 ng ml^{-1} and 180 ng ml^{-1} were targeted for racemic and ketamine (S+), respectively.

GENERAL CONDITION AND SIDE EFFECTS

Before the tests, subjects were asked if they felt calm/agitated (0 = very calm, 10 = very agitated), well/bad (0 = very well, 10 = very bad), and had side effects such as dreams (0 = no dreams, 10 = dreams all the time), and if dreams (0 = very pleasant dreams, 10 = very unpleasant dreams), or hallucinations (0 = none, 10 = much). The general condition and side effects were rated on a 10-cm electronic rating scale. Dreams were explained as experiences having a connection to reality and hallucinations without connection to reality.

STUDY DESIGN

All subjects attended three times, each attendance separated by 1 week.

Each time a trial test series was performed before recording of a baseline test series.

A test series lasted approximately 20–25 min and included recording of the following:

- Side effect rating
- Reaction time
- Skin temperature
- Heat pain detection threshold to 314 and 1570 mm^2 (8 °C s^{-1}, 2 s duration at peak temperature)
- VAS rating to 50°C at 314 and 1570 mm^2 (8°C s^{-1}, 2 s duration at 50 °C)
- VAS rating to 50°C at 314 mm^2 (2°C s^{-1}, 8°C s^{-1})
- Heat summation pain threshold (0.66 Hz, 30 °C s^{-1}, 314 mm^2)
- Electrical summation pain threshold (2 Hz)
- VAS rating to 1.2 × the initial electrical pain summation threshold
- Pressure pain detection and tolerance thresholds (28 and 92 mm^2)

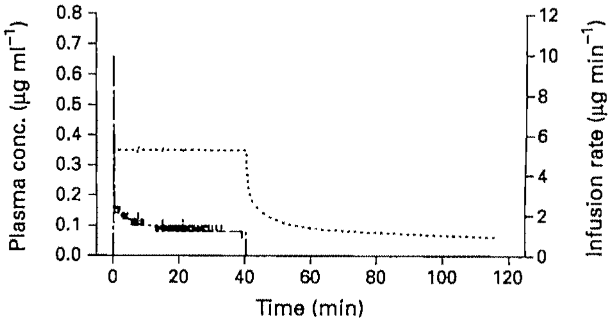

Figure 2 Infusion rates used by the "Stanpump" to obtain the estimated target plasma concentration (dotted line) of 350 ng ml^{-1} for ketamine (racemic).

After the baseline series the target-controlled infusion was started and equilibration for 15 min was allowed to ensure constant plasma and CNS concentrations (fig. 2). A test series was then performed. Thereafter, the infusion was stopped, and a final test series was performed 60 min after the infusion was terminated. At this last test series the predicted plasma concentration (Stanpump) declined to only 6–8 ng ml^{-1} for racemic ketamine and 3–4 ng ml^{-1} for ketamine S+.

STATISTICAL ANALYSIS

For each measurement (temperature, heat, pain threshold, etc.), the variance between drugs (racemic ketamine, (S+)-ketamine, placebo) and the conditions (before, during and after infusion) were tested using a two-factor ANOVA for repeated measures. In the event of interaction between drug and condition, multiple pairwise comparisons of the measures (e.g. heat, pain threshold before *vs* after ketamine) were performed with the Student–Newman–Keuls method for corrections of repeated measures. In cases where data for different measurements (e.g. small and large stimulation areas) were pooled, Student's *t* test was used for comparison. $P < 0.05$ was regarded as significant.

Results

GENERAL CONDITION AND SIDE EFFECTS

One volunteer was able to participate in only two of the sessions and was withdrawn from the rest of the experiment. During the three sessions, no differences in "general feelings" (table 1) were reported before, during or after infusion. The amounts of infused ketamine (racemic) and ketamine (S+) were 59.75 (5.29) mg and 29.22 (2.55) mg, respectively.

The reaction times (table 2) to auditory stimuli were increased ($P < 0.001$–0.002) by approximately 100 and 50 ms after infusion of ketamine (racemic) and ketamine (S+), respectively. These changes were significant ($P < 0.001$–0.003) compared with placebo. Ketamine (racemic) showed a significantly

prolonged reaction time ($P < 0.02$) compared with ketamine (S+).

The approximately 0.1-s increase in reaction time for ketamine affected the thresholds only marginally. The slowing in reaction time caused maximally a 5-kPa increase in pressure thresholds, and 0.2 °C and 0.8 °C increases in thresholds to slow and fast temperature rise times. As skin temperature at the same time was decreased by approximately 1 °C, the influence was limited.

PRESSURE PAIN DETECTION AND TOLERANCE THRESHOLDS (TABLE 3)

For the small probe (28 mm^2), increases ($P <$ 0.006–0.004) in pain detection and pain tolerance thresholds were obtained after infusion of ketamine (racemic) (374 and 164 kPa) and ketamine (S+) (315 and 207 kPa).

For the large probe (92 mm^2), increases ($P <$ 0.002–0.008) in pain detection and pain tolerance thresholds were obtained after infusion of ketamine (racemic) (244 and 129 kPa) and ketamine (S+) (146 and 104 kPa). A difference ($P <$ 0.002–0.03) from placebo was found for all tolerance thresholds except for the ketamine (S+) tolerance threshold. An increase ($P < 0.01$) in the pain detection threshold was found after infusion of ketamine (racemic) compared with infusion of ketamine (S+).

The active drugs affected the large area to the same degree as the small area. When threshold determinations for the small and large probes were pooled, the pain detection thresholds increased ($P < 0.004$) more than the tolerance thresholds for both drugs.

HEAT PAIN DETECTION THRESHOLDS TO ONE AND FIVE THERMODES (TABLE 4)

For one thermode (314 mm^2), an increase in heat pain threshold (2.7 °C) was obtained after infusion of ketamine (racemic) ($P < 0.001$) and ketamine (S+) ($P < 0.004$, 2.1 °C). These changes were significant compared with placebo ($P < 0.002$, $P < 0.003$). For simultaneous activation of five thermodes (1570 mm^2), increases ($P <$ 0.001–0.002) in the thresholds after ketamine (racemic) (3.6 °C) and ketamine (S+) (2.4 °C) were found compared with baseline and placebo, respectively. No differences were found between threshold changes for one and five thermodes. When threshold determinations for both drugs were pooled, a trend ($P > 0.08$) towards a larger increase in the five probe threshold than in the one probe threshold was found. Infusion of ketamine (racemic) increased significantly the threshold to five probes ($P < 0.002$) more than ketamine (S+).

VAS RATING TO ONE AND FIVE THERMODES (TABLE 4)

A decrease in the VAS ratings to one thermode (50 °C, 8 °C s^{-1}, 2 s duration) was found after infusion of ketamine (racemic) and ketamine (S+) compared with baseline ($P <$ 0.001–0.002) and placebo ($P <$ 0.01–0.02), showing no difference between drugs.

A decrease in VAS ratings to five thermodes (50 °C, 8 °C s^{-1}, 2 s duration) was found after infusion of ketamine (racemic) and ketamine (S+) compared with baseline ($P <$ 0.001–0.003) and placebo ($P <$ 0.001–0.006), with no difference between drugs. There were no differences between VAS rating changes for one and five thermodes. If the heat pain thresholds and the VAS ratings to one and five thermodes for the two drugs were pooled statistically, measurements related to the five probe stimulation were changed significantly ($P < 0.02$) more than the one probe measurement.

VAS RATING TO ONE THERMODE USING DIFFERENT RISE TIMES (TABLE 4)

A decrease in VAS ratings to one thermode (50 °C, $2\,°C\ s^{-1}$) was found after infusions of ketamine (racemic) and ketamine (S+) compared with baseline ($P < 0.001$–0.002) and placebo ($P < 0.008$–0.01), with no difference between drugs.

A decrease in VAS ratings to one thermodes (50 °C, $8\,°C\ s^{-1}$) was found after infusions of ketamine (racemic) and ketamine (S+) compared with baseline ($P < 0.002$–0.006) and placebo ($P < 0.001$–0.008), with no difference active drugs.

A similar effect of the thresholds to $2\,°C\ s^{-1}$ and $8\,°C\ s^{-1}$ was found for the drugs.

VAS RATING TO ONE THERMODE USING DIFFERENT DURATIONS (TABLE 4)

The VAS rating to one thermode (50 °C and $8\,°C\ s^{-1}$) was compared between the session where the temperature decrease immediately after 50 °C was reached (0 s duration), and the session where temperature was maintained at 50 °C for 2 s (2-s duration). The VAS score of the long duration stimulus was approximately two times higher than the VAS score of the short stimulus, but the changes provoked by the drugs were not different.

When data from both drug studies were pooled, VAS of the stimuli of long duration (50°, $2\,°C\ s^{-1}$, 2 s duration) was changed significantly ($P < 0.004$) more than for the stimuli of short duration (50°, $8\,°C\ s^{-1}$ threshold, 0 s duration).

HEAT SUMMATION PAIN THRESHOLD (TABLE 4)

Increases in the summation threshold were found after infusion of ketamine (racemic) ($P < 0.001$, 2.9 °C) and ketamine (S+) ($P < 0.001$, 1.9 °C), and these increases were significant compared with placebo ($P < 0.001$, $P < 0.001$, respectively).

ELECTRICAL SUMMATION PAIN THRESHOLD (TABLE 4)

Increases in the summation threshold were found after infusion of ketamine (racemic) ($P < 0.003$, 1.4 mA) and ketamine (S+) ($P < 0.003$, 1.2 mA), and these increases were significant compared with placebo ($P < 0.005$).

VAS RATING TO REPEATED ELECTRICAL STIMULI (TABLE 4)

The VAS ratings to repeated, electrical stimuli were reduced by ketamine (racemic) ($P < 0.002$) and ketamine (S+) ($P < 0.02$) and these decreases were significant compared with placebo ($P < 0.004$–0.04).

Discussion

Our study suggests that ketamine (racemic) and ketamine (S+) had potent analgesic effects compared with placebo on various pain modalities involving spatial and temporal summation aspects. No systematic differences in the analgesic effect of ketamine (racemic) and ketamine (S+) on summation were detected, indicating a potency for the (S+)-isomer of twice that of the racemic mixture. Both drugs attenuated repeated heat and electrical stimuli, pain from large areas more than pain evoked from small areas, and long duration heat stimuli more than short duration stimuli. Ketamine (racemic) prolonged the reaction time significantly more than ketamine (S+) indicating a different degree of sedation or impairment of motor performance.

KETAMINE (RACEMIC) *VS* KETAMINE (S+)

A dose ratio (1:2) has been found using depression of the auditory evoked potentials[18] or the hypnotic effect[19] as variables. These studies did not evaluate analgesic effects. Our study suggests that the chosen target concentration (assumed to be close to actual plasma concentrations) of ketamine (S+) of 180 ng ml^{-1} inhibited central summation equally as 350 ng ml^{-1} of ketamine (racemic). However, true potency comparisons require dose–response curves for both the racemic mixture and the (S+)-isomer. In a recent clinical study the (S+)-isomer was found to be four times more potent than the (R−)-isomer for management of postoperative orofacial pain.[16]

NMDA antagonists are reported to prevent wind-up in a wide dynamic range of neurones as a result of long-lasting C-fibre stimulation.[12 13 20] Interestingly, these drugs do not reduce the response to short-lasting C-fibre stimulation.[12] For the management of acute pain states possibly inducing wind-up and hyperexcitability (e.g. trauma and surgical procedures), ketamine (S+) seems to be a suitable drug for further clinical study.

TEMPORAL SUMMATION

For a long time temporal summation has been considered as an important mechanism for pathophysiological pain.[6 7] We have recently shown that extradurally administered analgesics (bupivacaine) have substantially less effect on stimuli with long duration than on stimuli with short duration.[4 5] This indicated that temporal summation may be an important factor for the lack of effectiveness of such anaesthetic procedures. During general anaesthesia with isoflurane, repeated stimuli were found to be largely unaffected compared with single stimuli.[3]

In this study, ketamine affected repeated stimuli and thermal stimuli of long duration similar to or more than stimuli of short duration. This was interpreted as modulation of the facilitatory mechanisms underlying central temporal summation.

SPATIAL SUMMATION

It has been reported that spinally and extradurally administered analgesics have much less effect on stimuli covering large areas than on localized stimuli.[1 2 4] The threshold to large area stimulation was lower than that to small area stimulation, indicating the role of spatial summation as described previously.[21] The measurements from the large areas were affected to the same degree or even more by ketamine than the small areas, indicating possible reduction by ketamine of the facilitatory mechanism underlying spatial summation. The obvious, complementary efficacy profiles between traditional anaesthetic procedures and ketamine suggest a clinical advantage of combining the two synergetic effects: generalized analgesia together with inhibition of summation.

EFFECT OF KETAMINE ON HEAT AND PRESSURE THRESHOLDS

The increase in heat pain threshold in this study contrasts with the results of Anis and co-workers[22] who found that ketamine had no consistent effect on the responses of dorsal horn neurones to natural stimuli, and to human findings.[23] In the study of Kristensen, Svensson and Gordth,[23] no effect of CPP (a NMDA receptor antagonist) on the thermal pain detection threshold was detected. We have recent evidence that high intensity laser heat pulses and brief electrical (20 ms train) pulses were not affected by ketamine (racemic).[14]

In this study the detection pressure threshold was increased by ketamine more than the tolerance threshold. Animal studies have indicated that the effect of ketamine is dependent on stimulus intensity.[24]

From an "inhibition of temporal summation" point of view, the pressure pain thresholds to small area stimulation should be inhibited more than the thresholds to the large area as the pressure pain thresholds are largest for the small area and hence it takes more time to reach the small area thresholds. From an "inhibition of spatial summation" point of view, the pressure pain thresholds to small area stimulation should be inhibited less than the thresholds to large areas. Therefore, this suggested that ketamine should provoke the largest changes in the pressure pain detection threshold to small area, and pressure pain tolerance threshold to large areas should be affected less. This was the result as seen in table 3 (mean changes of 344 kPa *vs* 116 kPa; $P < 0.001$).

In summary, we found that both ketamine (racemic) and ketamine (S+) had a general analgesic effect, an effect on repeated stimuli, an effect on long duration stimuli and an effect on stimuli covering large areas. The (S+)-isomer was approximately twice as potent in inhibiting central summation as the racemic mixture of ketamine at the chosen target concentrations. The chosen doses had the same number of side effects, although these were minimal.

Normal saline i.v. fluid load decreases uterine activity in active labour

T. G. CHEEK, P. SAMUELS, F. MILLER, M. TOBIN AND B. B. GUTSCHE

Summary

This study was designed to observe the effects of i.v. fluid infusion on uterine activity during normal labour in women receiving an extradural block. Thirty-four women in spontaneous labour at term gestation were allocated randomly and prospectively to one of three i.v. pre-extradural fluid load groups: group A, no fluid load; group B, normal saline 500 ml; and group C, normal saline 1000 ml. Continuous internal measurement of uterine activity was observed before, during and after fluid infusion and extradural block. In groups A and B, uterine activity did not change. In group C, uterine activity decreased after infusion of saline ($P < 0.01$) and returned to baseline over the next 20 min. Extradural block was not associated with a change in uterine activity. Hypotension was not increased in the group that received no fluid preload. (*Br. J. Anaesth.* 1996; **77**: 632–635)

Key words
Fluids, i.v. Anaesthetic techniques, extradural. Uterus, activity.

There is disagreement on the effect of lumbar extradural block on uterine activity and its influence on the progress of labour.[1–5] It is presently common obstetric practice in the USA to infuse 500–1000 ml of i.v. normal saline as initial treatment in the tocolytic therapy of preterm labour.[6] The purpose of this study originated from the question: if an i.v. fluid load of normal saline 500–1000 ml effectively inhibits uterine activity in more than 50% of subjects in preterm labour, what is the effect of similar fluid load during normal active labour? If uterine activity is inhibited by such a fluid load, could this explain observations of decreased uterine activity after extradural block, a procedure normally preceded by an i.v. fluid load? This study was designed to observe the individual effects of i.v. fluid load and extradural block on uterine activity during normal active labour.

Patients and methods

After obtaining approval from the Institutional Committee for Human Studies and informed consent, we studied 34 healthy, ASA I–II term parturients in spontaneous labour. Patients were allocated randomly and prospectively to one of three pre-extradural i.v. fluid load groups: group A, no fluid load; group B, normal saline 500 ml infused over 10 min; group C, normal saline 1000 ml infused over 10 min. All subjects received maintenance i.v. fluids: 5% glucose 125 ml h^{-1} in 1/2 normal saline from admission to the labour ward to just before the time of study (mean = 550 ml). None of the subjects received any medication before the study. Both primiparae and multiparae were studied. Extradural analgesia was performed with the subject in the lateral position with a total of 12 ml of 0.25% bupivacaine without adrenaline (a 3-ml test dose followed by 9 ml). After insertion of the extradural, continuous uterine displacement with a right hip wedge was maintained throughout the study. Fetal heart rate and maternal arterial pressure were noted at 5-min intervals and treatment for maternal hypotension was recorded. Maternal arterial pressure was determined at 1-min intervals for 5 min and at 5-min intervals thereafter for the first 30 min after local anaesthetic injection. If maternal arterial pressure decreased to less than 100 mm Hg for more than 1–2 min, i.v. ephedrine was given in 5-mg increments to obtain an arterial pressure of >100 mm Hg.

Continuous internal measurement of uterine activity was divided into 7–10-min intervals: 10 min of baseline uterine activity, 10 min of fluid infusion, 20 min (2 × 10 min) for recovery from possible fluid load effects, and for 30 min after extradural injection. Measurements were continuous after both fluid load and extradural injection, with 10 min allowed between measurements for insertion of the extradural catheter. Intrauterine pressure was measured with catheters positioned by an obstetrician in the uterine cavity. These were placed electively for the purpose of the study and not for obstetric indications. Quantitative measurement of

uterine activity units, frequency, duration and intensity of contractions were calculated from the area under the graphic curve produced on tracing paper from the fetal heart monitor (Corometrics). Calculation of uterine activity for each interval was made by the same obstetrician (P. S.) who was unaware of the amount of fluid load or the time of extradural injection. One uterine activity unit is equivalent to 50 mm Hg s^{-1}.[7]

Two subjects were excluded in group A because precipitous delivery occurred before extradural block was performed. One subject each from groups B and C received fluid load measurements but rapidly progressed to delivery before extradural block could be accomplished. Constraints during the measurement period included avoidance of change in subject position, voluntary pushing or intrauterine pressure system flushing. Measurements were not made if the subject vomited, in the presence of asymmetric tracing or if there was a suspicion of system malfunction. Cervical dilatation at the time of measurements was 4–6 cm.

Statistical analysis included paired Student's t test for patient variables. Analysis of variance over time within and between groups was determined for uterine activity with Tukey's test because of the number of subjects involved.

Results

There were no differences between groups in maternal age, height, weight, gestational age or cervical dilatation at the start of the study (table 1).

In group A (maintenance fluid only), uterine activity did not change during any period. In group B (fluid infusion of 500 ml i.v.), there was a decrease in uterine activity after the infusion, but this was not significant. In group C (infusion of 1000 ml i.v.), uterine activity decreased after the infusion ($P < 0.01$) but returned to baseline over the next 20 min. Mean uterine activity did not decrease in any group after induction of extradural block. Uterine activity in the three groups in response to fluid load and extradural block is summarized in figure 1. There were no differences between groups in changes in maternal arterial pressure and there were no abnormal changes in fetal heart rate during the study. Duration of labour was not different between groups after initiation of the study.

There were no differences in incidence and severity of hypotension between the groups.

Discussion

Several factors associated with extradural block are reported to decrease uterine activity, including inadvertent aorto-caval compression, maternal hypotension, β agonist activity from low-dose adrenaline in the local anaesthetic solution, and possible direct local anaesthetic effects on the myometrium. After controlling for these variables, our data indicated that an i.v. fluid load before regional block caused a transient decrease in uterine activity.

Rout and co-workers have reported attenuated protection against hypotension with pre-spinal i.v.

Vaginal delivery	9/11	7/8	9/11
Caesarean delivery	2/11	1/8	2/1

fluid loading during Caesarean section.[8] On a smaller scale we found that subjects who received no fluid load had no greater incidence or severity of hypotension after 0.25% bupivacaine 12 ml than subjects who received 1000 ml i.v. fluid preload. It may be that as all subjects received maintenance i.v. fluids, intravascular volume was adequate to compensate for the increased vascular capacitance associated with a T9 (mean) sympathectomy. Our data suggest that a fluid load of 1 litre i.v. did not decrease the incidence of maternal hypotension in labouring patients.

The incidence of slowing or arrest of labour, as defined by failure of cervical dilatation in the absence of extradural block, was reported by Bottoms, Sokol and Rosen as approximately 20%, with 5.5% defined as secondary arrest requiring obstetric intervention.[9] Arrest or slowing of labour was associated most commonly with decreased uterine activity. This indicates that under normal conditions one of five parturients experiences decreased uterine activity during labour, independent of external medication.

The effect of extradural block on labour and uterine activity has been debated almost from the beginning of its use in obstetrics. Unfortunately, the clinical evidence offered in these arguments is largely anecdotal, uncontrolled, non-randomized and usually retrospective. Friedman and Sachtleben, in 1959, reported that caudal block to T10 did not alter uterine activity but that higher levels of block were associated with longer labours.[10] This report was not based on a prospective, randomized series and maternal position or arterial pressure after caudal block was not reported. Lowensohn and colleagues prospectively studied the effect of extradural lignocaine and propitocaine (a drug no longer in use) and reported a decrease in uterine activity after each injection of lignocaine that lasted approximately 20 min.[1] This study was flawed by the addition of adrenaline to the local anaesthetic injectate, and neither the amount of preblock fluid loading nor the assurance of uterine displacement were reported.

Quantitation of uterine activity during labour cannot be done with external tocodynamometry. Accurate measurement requires intra-cavitary placement of either a transducer or a fluid-filled catheter with a pressure transducer connected to a fetal monitor where the signal is expressed as a continuous tracing calibrated in mm Hg. Earlier investigators estimated uterine activity in Montevideo units where peak height of the contraction was multiplied by the number of contractions.[11] Hon and Paul described a more precise method for quantitation of uterine activity measurement in which the integral under the uterine contraction curve was calculated and expressed in "torr seconds".[7] In this study, uterine activity was estimated by directly measuring the area under the uterine contraction curve and above baseline tone.

Despite strict adherence to uterine displacement, avoidance of maternal hypotension and pre-block i.v. fluid load, transient decreases in uterine activity are still observed occasionally after extradural block for analgesia in labour. Normal uterine activity requires a complex interplay between ongoing uterine smooth muscle biochemical changes and a set of external maternal and fetal signals.[12] These external signals may be neural, or hormonal; the uterine smooth muscle and vascular system are innervated by sympathetic and peptidergic fibres and their transmitter and receptor content changes during pregnancy. Our data suggest that prehydration before extradural block attenuated uterine activity. There are several possible explanations for decreased uterine activity observed after a fluid load. Valenzuela, Cline and Hayashi speculated that oxytocin and vasopressin secretion are inhibited directly at the neurohypophysis.[6] Transient dilution of plasma oxytocin concentrations by a fluid load may temporarily attenuate uterine activity. Both of these suggestions are in dispute because the effect of oxytocin on uterine activity is no longer thought to be dependent on circulating oxytocin concentrations but related rather to the number of myometrial oxytocin receptors and their degree of activity.[12] Another suggestion is that the temperature (~22 °C) of the infused i.v. solution may affect uterine activity. This is unlikely because cooling of the blood by 1 litre of room temperature saline would be both small and rapidly dissipated.

Rapid volume expansion increases transmural atrial distending pressure. This stimulates vagal neural afferents which may decrease posterior pituitary hormone secretion and sympathetic (particularly renal) nerve activity, and perhaps efferent peptidergic nerve activity. We speculate that the mechanism may lie either in a sudden humoral release, such as atrial natriuretic peptide (ANP) after rapid atrial distension, or a direct mechanical effect on the uterine vasculature producing local release of endothelial vasoactive peptides. Bek, Ottesen and Fahrenkrug have shown ANP to be a potent inhibitor of rat uterine smooth muscle contraction.[13]

Recently Eledjam and co-workers reported a 172% increase in ANP plasma concentrations of labouring women 15 min after i.v. fluid challenge with dextran 40 250 ml.[14] ANP is a 28 amino acid peptide which is secreted directly by the atrium into the coronary veins, and causes vasodilatation, natriuresis and diuresis, and inhibition of secretion or end-organ effects of several vasoactive hormones, including angiotensin II and noradrenaline.[15] Concentrations of ANP increase slightly during pregnancy, and increase further with volume loading.[14] In contrast, Grunewald and colleagues infused 0.9% Ringer's lactate 15 ml kg^{-1} in normal parturients over 30 min. This caused a decrease in ANP from 6.5 to 4.6 pmol $litre^{-1}$.[16] This may indicate that different i.v. infusates have different effects on ANP concentrations. ANP receptors are present in the non-pregnant rat uterus and inhibit uterine contraction and blood flow.[14 17] The time course of ANP release and action is consistent with the role of ANP in decreasing uterine activity during volume loading. However, the overall role of ANP in parturition is unknown.

Fuzzy logic control of mechanical ventilation during anaesthesia

J. SCHÄUBLIN, M. DERIGHETTI, P. FEIGENWINTER, S. PETERSEN-FELIX AND A .M. ZBINDEN

Summary

We have examined a new approach, using fuzzy logic, to the closed-loop feedback control of mechanical ventilation during general anaesthesia. This control system automatically adjusts ventilatory frequency (f) and tidal volume (VT) in order to achieve and maintain the end-tidal carbon dioxide fraction (FE$'_{CO_2}$) at a desired level (set-point). The controller attempts to minimize the deviation of both f and VT per kg body weight from 10 bpm and 10 ml kg^{-1}, respectively, and to maintain the plateau airway pressure within suitable limits. In 30 patients, undergoing various surgical procedures, the fuzzy control mode was compared with human ventilation control. For a set-point of FE$'_{CO_2}$ = 4.5 vol% and during measurement periods of 20 min, accuracy, stability and breathing pattern did not differ significantly between fuzzy logic and manual ventilation control. After step-changes in the set-point of FE$'_{CO_2}$ from 4.5 to 5.5 vol% and *vice versa,* overshoot and rise time did not differ significantly between the two control modes. We conclude that to achieve and maintain a desired FE$'_{CO_2}$ during routine anaesthesia, fuzzy logic feedback control of mechanical ventilation is a reliable and safe mode of control. (*Br. J. Anaesth.* 1996; **77**: 636–641)

Key words

Ventilation, mechanical. Carbon dioxide, partial pressure. Computers. Model, ventilatory mechanics. Model, computer simulation.

During anaesthetic procedures, mechanical ventilation must be controlled continuously and adjusted in order to maintain a suitable arterial carbon dioxide tension (Pa_{CO_2}). In anaesthesia for intracranial surgery, for example, hypocapnia is used deliberately to reduce brain volume and intracranial pressure. For this purpose, recommendations have been provided for the initial ventilator settings, particularly for ventilatory frequency (f) and tidal volume (VT).[1–3] These settings are corrected according to periodic measurements of arterial blood-gas tensions or by using capnometry, or both.[4] Monitoring the end-tidal carbon dioxide fraction (FE$'_{CO_2}$) allows indirect, non-invasive, breath-by-breath estimate of Pa_{CO_2} and is therefore essential for the control of the patient undergoing mechanical ventilation. As carbon dioxide production per minute ($\dot{V}_{CO_2}$) and the relation of alveolar ventilation to pulmonary perfusion ($\dot{V}$A/$\dot{Q}$) may change during anaesthesia and surgery, adjustment of the ventilator settings by the anaesthetist is required. Alternatively, automatic, closed-loop control of mechanical ventilation has been designed and applied to lung models, animals and patients, using feedback control of FE$'_{CO_2}$,[5–12] of either FE$'_{CO_2}$, inspired (FI$_{CO_2}$) or mixed expired ($F\bar{E}_{CO_2}$) carbon dioxide fraction,[13] of the end- tidal carbon dioxide partial pressure (PE$'_{CO_2}$),[14 15] Pa_{CO_2},[16–21] arterial blood pH (pH$_a$),[22] alveolar pressure over time (PA(t))[23] and gross alveolar ventilation ($\dot{V}_g$A).[24 25] The most frequently used output variables of these controllers were the ventilator settings for f, VT and respiratory minute volume (VE), but other variables such as the ratio of inspiratory to expiratory time (I/E ratio) and the inspiratory pressure support were adjusted, and carbon dioxide, delivered from a rebreathing bag and added to the inspiratory fresh gas mixture, was applied, using proportional–integral–derivative (PID) principles.[26]

Recently, there has been increasing interest in the use of so-called intelligent control techniques in biomedicine[27] and promising modern feedback control systems, based on fuzzy logic,[28] have been developed for various applications in industry, for anaesthesia and for other branches of medicine.[29–32] The software and methodology of a fuzzy controller of artificial ventilation have been developed,[23] but automatic control of FE$'_{CO_2}$ for the respiratory care of patients using fuzzy logic has not yet been performed. It was the aim of this study to compare the performance of this automatic, closed-loop control system to human control.

Patients and methods

We studied 30 patients, 10 females and 20 males, ASA I–III, mean age 47.0 (range 12–84) yr, mean weight 67.2 (41–93) kg, mean height 168.5 (153–192) cm. Written informed consent had been obtained for the study which was approved by the Ethics Committee of the medical faculty of the University of Bern. These patients were undergoing

Correspondence to A. M. Z.

elective general, orthopaedic and ENT surgery. Exclusion criteria were patients of ASA classes >3, those <10 yr old (or body weight <35 kg), those whose lungs were not ventilated mechanically and where surgery was expected to last less than 2 h, and patients undergoing emergency or intracranial surgery.

Anaesthetic management, except for mechanical ventilation, was selected and performed by the attending anaesthetists according to usual practice. An additional anaesthetist, responsible for the study, was present as a supervisor. We used a modified Cicero ventilator (Drägerwerk AG, Lübeck, Germany), where f and V_T could be adjusted electronically by the control computer.

$F_{E'CO_2}$ was measured at the mouthpiece, using an airway adapter fitted with a gas sampling port and a flow and airway pressure sensor, and a side-stream infrared gas analyser (D-LITE adapter and Capnomac Ultima-SV, respectively, Datex Instrumentarium Corp., Helsinki, Finland). (Medical electrical equipment shall cause no safety hazard in normal and in single fault condition (International Standard 601-1 Clause 3.1 of the International Electrotechnical Commission.)) In the feedback control of mechanical ventilation, any failure of the Datex Capnomac Ultima-SV would be a single fault condition. Therefore, for safety reasons, an auxiliary side-stream anaesthetic gas analyser (M1025B, Hewlett Packard Co, Andover, USA), which was not implemented in the feedback control system, was used. Before the experiment, the gas monitors were calibrated according to the operator's manual. In addition to inspired/expired gas concentrations, peak airway pressure (*P*peak), plateau airway pressure (*P*plat), positive end-expiratory airway pressure (PEEP), inspired and expired volumes and pulse oximetry data were measured and displayed by the Datex Capnomac Ultima-SV. According to the manufacturer, accuracy and resolution of this monitor for $F_{E'CO_2}$ measurements were < 0.2 and 0.1 vol%, respectively, and for airway pressure measurements 0.15 and 0.1 kPa (1.5 and 1.0 cm H_2O), respectively. Values of $F_{E'CO_2}$ were displayed breath-by-breath with a response time of less than 360 ms and were transformed, together with the values of the additionally measured variables, to a serial data string and transferred every 10 s to the control computer. Values of the data string output were for $F_{E'CO_2}$, the mean value of the latest 10 s breath-by-breath values, and for *P*peak, *P*plat and PEEP, the momentary values of the previous breath.

AUTOMATIC FEEDBACK CONTROL

With the input of measured ($F_{E'CO_2}$, *P*plat) and set variables (f, V_T), the rule-based fuzzy controller determined new ventilator settings for f and V_T with a sample rate of 0.1 Hz, which compensated for the current deviation of $F_{E'CO_2}$ from the set-point ($eF_{E'CO_2}$) (fig. 1). Details on the fuzzy control algorithm are given in the appendix.

An IBM compatible personal computer was used for feedback control and for acquisition, display and storage of data. Computer programmes for these tasks were written in Modula-2 (Logitech SA, Romanel/Morges, Switzerland).

For human and automatic closed loop control of mechanical ventilation, alarm messages were displayed by the monitoring devices and the control computer if any of the preset limits of various variables were exceeded. The fuzzy control mode could be switched to human control at any time.

CLINICAL INVESTIGATIONS

In 30 patients automatic fuzzy logic feedback control of artificial ventilation was compared with human control, which was performed by five staff members, 15 residents and 10 anaesthesia nurses.

Measurements were started during maintenance of anaesthesia, independent of whether or not surgery had begun. Patients were allocated randomly

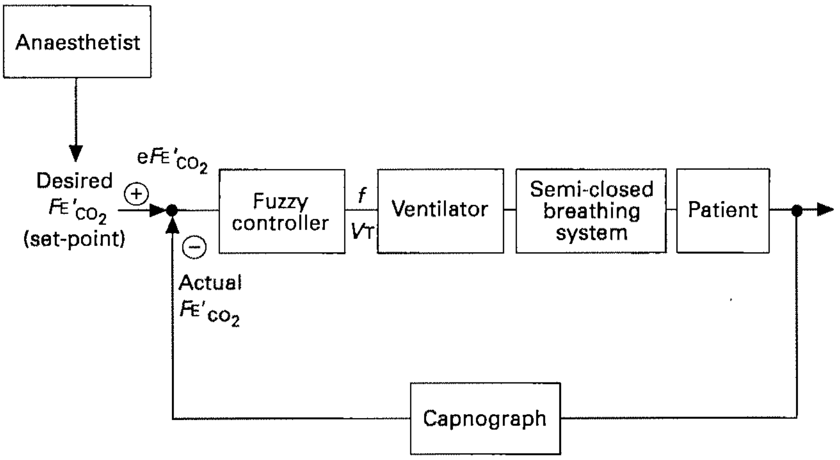

Figure 1 Block diagram of the control loop for mechanical ventilation. From the actual end-tidal carbon dioxide fraction ($F_{E'CO_2}$), measured by the capnograph (Datex Capnomac Ultima-SV), the deviation from the desired end-tidal carbon dioxide fraction ($eF_{E'CO_2}$) = desired $F_{E'CO_2}$ (set-point) − actual $F_{E'CO_2}$ was determined and compensated by changes in ventilatory frequency (f) or tidal volume (V_T), or both, computed by the fuzzy controller. Every 10 s, f and V_T were set on the ventilator (Dräger modified Cicero) by the control computer.

Table 1 Sequence of control periods for mechanical ventilation. Set-point of $F\text{E}'_{\text{CO}_2}$ = desired end-tidal carbon dioxide fraction; f = fuzzy logic control; m = manual control. Thirty investigated patients were allocated randomly to group A or B

	Period No.							
	1	2	3	4	5	6	7	8
Duration (min)	5	20	20	20	5	20	20	20
Set-point of $F\text{E}'_{\text{CO}_2}$ (vol%)	4.5	4.5	5.5	4.5	4.5	4.5	5.5	4.5
Group A	m	f	f	f	m	m	m	m
Group B	m	m	m	m	m	f	f	f

to the sequence of control periods (table 1). For each control mode and control period f and $V\text{T}$ were set by the anaesthetist (manual control) or the computer (fuzzy logic control) in order to maintain the desired $F\text{E}'_{\text{CO}_2}$. Step-changes in the desired $F\text{E}'_{\text{CO}_2}$ during periods 3, 4, 7 and 8 (table 1) had to be achieved rapidly and smoothly without considerable overshooting and consecutive oscillation of $F\text{E}'_{\text{CO}_2}$. I/E ratio, the ratio of end-inspiratory pause time to total inspiratory time (Ipause/Iratio), PEEP and the pressure limitation of the ventilator (*P*max) were set manually to 1:2, 10%, 5 and 40 mbar, respectively.

Arterial blood was sampled for blood-gas analysis at the end of periods 2 and 6 (set-point of $F\text{E}'_{\text{CO}_2}$ = 4.5 vol%) for all patients and, as a test, at the end of periods 3 or 7 (set-point of $F\text{E}'_{\text{CO}_2}$ = 5.5 vol%) for only five randomly selected patients during fuzzy ventilation control.

DATA ANALYSIS

Mean e$F\text{E}'_{\text{CO}_2}$, as a measure of accuracy, and the SD of e$F\text{E}'_{\text{CO}_2}$, as a measure of the stability of the control, were determined separately for each patient and each period of the trial programme (table 1) and each control mode. For computation of these two variables, data collected during the whole time interval of periods 2 and 6 were used, whereas for periods 3, 4, 7 and 8, only data of the last 10 min of these periods were considered. Step-changes in the set-point of $F\text{E}'_{\text{CO}_2}$ were judged by the 10–90 rise time ($T_{10\text{-}90}$) and the overshoot. For an increase in the set-point (periods 3 and 7), $T_{10\text{-}90}$ was defined as the time required for $F\text{E}'_{\text{CO}_2}$ to increase from 10% ($F\text{E}'_{\text{CO}_2}$ = 4.6 vol%) to 90% ($F\text{E}'_{\text{CO}_2}$ = 5.4 vol%) of the desired change. Because of small fluctuations in measured $F\text{E}'_{\text{CO}_2}$, $T_{10\text{-}90}$ was determined as the interval between the two events, for which $F\text{E}'_{\text{CO}_2}$ were $\geqslant$ 4.6 and $\geqslant$ 5.4 vol% for more than 1 min, respectively. For a decrease in the set-point of $F\text{E}'_{\text{CO}_2}$ (periods 4 and 8), $T_{10\text{-}90}$ was analogously defined. The overshoot was the peak absolute value of e$F\text{E}'_{\text{CO}_2}$ during the first 5 min after achievement of 90% of the step-change in the set-point.

In addition to the mean e$F\text{E}'_{\text{CO}_2}$, the SD of e$F\text{E}'_{\text{CO}_2}$, $T_{10\text{-}90}$ and the overshoot, mean f, tidal volume per kg body weight ($V\text{T}$/BW), minute volume per kg body weight ($V\text{E}$/BW), *P*peak and *P*plat were determined for any patient, control period and control mode. Using this reduced sample, means, SD and differences (fuzzy logic minus manual control) of the above mentioned variables were computed. In testing differences between the control modes the Wilcoxon signed rank test was performed. Statistical software used was SigmaStat (Jandel Scientific GmbH, Erkrath, Germany).

Results

Redundant measurements of $F\text{E}'_{\text{CO}_2}$ with both side-stream anaesthetic gas analysers revealed differences < 0.4 vol%.

Figure 2 shows the measured $F\text{E}'_{\text{CO}_2}$ during fuzzy and manual control of mechanical ventilation of the lungs of the patients.

With respect to the accuracy of the control, the mean of the averaged e$F\text{E}'_{\text{CO}_2}$ for any individual period (table 1) ranged from -0.01 to 0.00 vol% (SD 0.05 vol%) during fuzzy logic control (table 2). The minor increase in both, the corresponding range

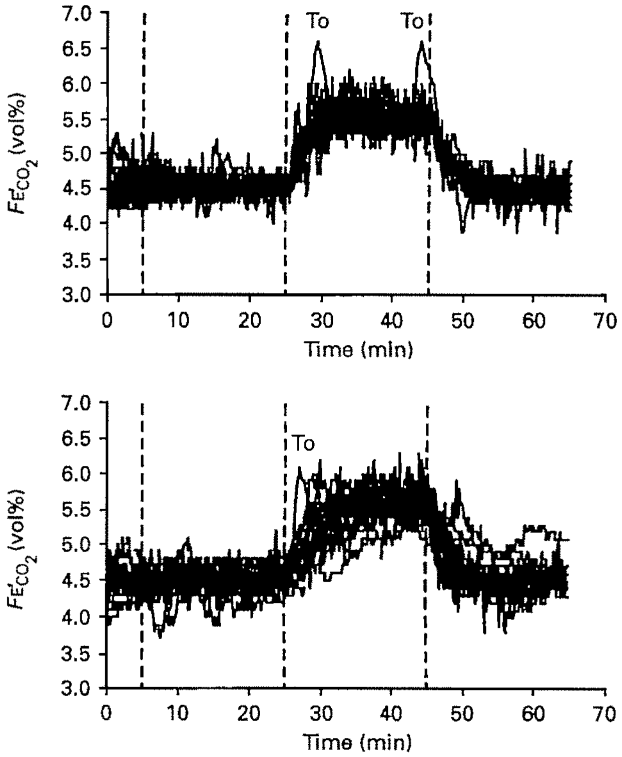

Figure 2 Measured end-tidal carbon dioxide fraction ($F\text{E}'_{\text{CO}_2}$) during fuzzy logic control (top) and manual control (bottom) of mechanical ventilation of the lungs of 30 patients according to the sequence of control periods of the trial programme (table 1). To = Transient increase in $F\text{E}'_{\text{CO}_2}$ as a result of limb tourniquet release in two patients; other peaks = inadequate feedback control. The time of initiation of data analysis and of the change in desired end-tidal carbon dioxide fraction (set-point) from 4.5 to 5.5 vol% and from 5.5 to 4.5 vol%, respectively, are indicated by the vertical broken lines.

(from -0.06 to 0.00 vol%) and SD (from 0.07 to 0.14 vol%) during manual control, yielded a statistically significant but irrelevant difference in averaged eFE'_{CO_2} values between the control modes ($P < 0.01$) when the set-point of FE'_{CO_2} was 5.5 vol%. Values for the SD of eFE'_{CO_2}, as a measure of the stability of the control, $T_{10\text{-}90}$ and the overshoot of any control period, averaged over all patients were approximately, 0.1 (SD 0.05) vol%, 350 (150) s and 0.2 (0.2) vol%, respectively (ns between control modes) (table 2). Comparison of fuzzy *vs* manual control as regards the set (*f*, *V*T/BW) and measured respiratory variables (*P*peak, *P*plat) yielded only statistically significant differences for mechanical ventilation during period 3 or 7 (set-point of FE'_{CO_2} = 5.5 vol%) for these variables (table 2). To achieve and maintain this set-point the fuzzy controller performed, on average, with slightly larger *f* and smaller *V*T/BW, and consequently smaller *P*peak and *P*plat compared with human controllers.

Blood-gas analyses revealed that the lungs of the patients were ventilated adequately with a set-point of FE'_{CO_2} = 4.5 vol% for both control modes (table 3). When the set-point of FE'_{CO_2} was 5.5 vol% the five randomly selected patients exhibited, as expected, a moderate respiratory acidosis during fuzzy control of mechanical ventilation.

Discussion

We have demonstrated that during general anaesthesia, fuzzy logic control of mechanical ventilation of the lungs of 30 patients of different ages, with various disease states and surgical procedures, was safe and reliable. Compared with human controllers, the fuzzy controller maintained desired FE'_{CO_2} with similar precision and stability and performed with a resembling dynamic response on set-point changes in FE'_{CO_2}. The breathing pattern, selected by the fuzzy controller, was within clinically acceptable ranges (fig. 2, table 2).

The ventilator settings of the fuzzy controller were based on the recommendations of Kacmarek and Venegas.[3] Except for maintaining *P*plat within suitable limits, the controller did not adapt these settings to the actual state of lung function or lung mechanics of an individual patient, which was the special feature of the lung ventilator controller described by Laubscher and co-workers[24] and Weiler, Heinrichs and Kessler.[25] It was not within the scope of this study to investigate and qualify various physiological effects as a result of automated ventilation control on respiratory and haemodynamic function. Although the results of blood-gas analyses (table 3) were clinically satisfying for both fuzzy and manual control of ventilation with a set-point of FE'_{CO_2} = 4.5 vol%, this does not prove that breathing patterns were optimal. Tweed and colleagues,[33] examining the old controversy of the influence of *V*T on the well-known impaired pulmonary gas exchange during general anaesthesia, concluded that results from previous investigations had not been consistent. Their own study revealed that patient and surgical factors were more important determinants of pulmonary gas exchange during anaesthesia than *V*T or inspired gas composition.

Table 2 Comparison of the quality, and of set and measured ventilatory variables of fuzzy logic *vs* manual control of mechanical ventilation. Values are mean (SD) or mean [SEM] for the 30 investigated patients. For period numbers see table 1. Set-point of FE'_{CO_2} = desired end-tidal carbon dioxide fraction; eFE'_{CO_2} = desired FE'_{CO_2} − actual FE'_{CO_2}; $T_{10\text{-}90}$ = 10 to 90 rise time for step changes in the set-point of FE'_{CO_2}; *f* = ventilatory frequency; *V*T/BW = tidal volume per kg body weight; *V*E/BW = minute volume per kg body weight; *P*peak = peak airway pressure; *P*plat = plateau airway pressure. One of the aims of artificial ventilation control is to maintain Pa_{CO_2} within a small range of a desired value. In this study, however, the automatically and manually controlled variable was $F\text{E}'_{CO_2}$ as an expression of $P\text{E}'_{CO_2}$. The arterial to end-tidal $P\text{CO}_2$ difference ($Pa_{CO_2} - P\text{E}'_{CO_2}$) is small in healthy individuals, but in anaesthetized patients with altered alveolar ventilation ($\dot{V}\text{A}$) and pulmonary perfusion ($\dot{Q}$) ($\dot{V}\text{A}/\dot{Q}$ mismatch) the difference may be considerable.[34] An increased and variable end-tidal to arterial gradient may result from pre-existing cardiovascular and respiratory disease states and from the patient's physiological reactions to anaesthesia and surgery, such as variations in arterial pressure, temperature and positioning, prolonged anaesthesia, pulmonary embolism, etc. These situations, but also failing anaesthesia equipment, monitoring devices and control computer, may lead to "erroneous" control. This may be circumvented by changing the set-point of $F\text{E}'_{CO_2}$, for example after control of blood-gas tensions. Safeguards were independent alarm systems implemented on the ventilator, monitoring devices and control computer, in addition to continuous supervision of the feedback control system by the anaesthetist responsible for the study, who had some understanding of the "intelligent" systems built into the research anaesthesia workplace.

Because artificial ventilation of the lungs of a patient represents an ill-defined biological process, fuzzy logic control by its imitation of the anaesthetist's management is promising. In contrast with many studies on computer-controlled ventilation, fuzzy logic ventilation control is feasible in the "uncontrolled" clinical environment and is convenient as it relieves the anaesthetist from routine control work. It is planned to implement the control of mechanical ventilation into the developing control systems for the delivery of inhaled anaesthetics, as reported in this journal by Zbinden and co-workers[31] and Curatolo and colleagues.[32]

Appendix

FUZZY CONTROL ALGORITHM USED FOR AUTOMATIC CONTROL OF MECHANICAL VENTILATION

Basic knowledge on fuzzy logic control, which is necessary for understanding the following, has been given previously.[29–32]

Input variables of the fuzzy controller were: $\text{e}F\text{E}'_{CO_2}$ ($\text{e}F\text{E}'_{CO_2}$ = desired $F\text{E}'_{CO_2}$ − actual $F\text{E}'_{CO_2}$) (vol%) and $\text{de}F\text{E}'_{CO_2}$, which was defined as the difference between actual $\text{e}F\text{E}'_{CO_2}$ and $\text{e}F\text{E}'_{CO_2}$, 60 s before ($\text{de}F\text{E}'_{CO_2}(t_0) = \text{e}F\text{E}'_{CO_2}(t_0) - \text{e}F\text{E}'_{CO_2}(t_0 - 60\ \text{s})$) (vol%), f (bpm), tidal volume per kg body weight ($V\text{T}$/BW) (ml kg^{-1}) and Pplat (kPa). The change in minute volume per kg body weight ($\text{d}\dot{V}\text{E}$/BW) (ml min^{-1} kg^{-1}) and the change in f ($\text{d}f$) (bpm) were the output variables.

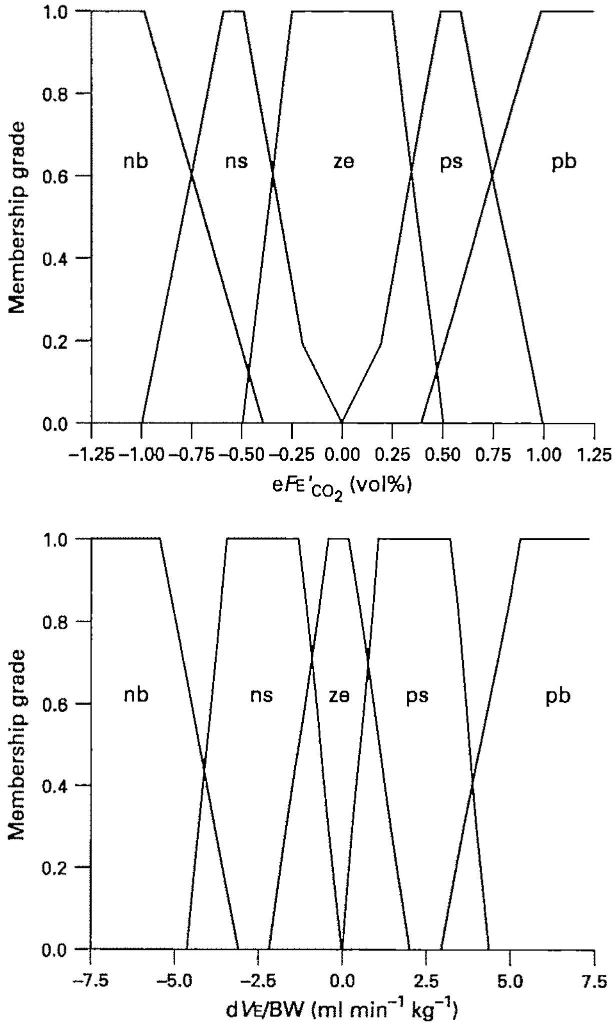

Figure 3 Subdivision of the deviation of actual from desired end-tidal carbon dioxide fraction $\text{e}F\text{E}'_{CO_2}$ = desired $F\text{E}'_{CO_2}$ − actual $F\text{E}'_{CO_2}$ and of the change in minute volume per kg body weight ($\text{d}\dot{V}\text{E}$/BW) into fuzzy sets nb (negative big), ns (negative small), ze (zero), ps (positive small) and pb (positive big), with graphs of their membership functions. For example, $\text{e}F\text{E}'_{CO_2}$ = −0.75 vol% belongs simultaneously to both the fuzzy set nb and ns, with an equal membership grade of 0.6.

Twenty-nine linguistic rules were designed, which expressed the intention to achieve and maintain the desired $F\mathrm{E}'_{\mathrm{CO_2}}$ by selection of appropriate ventilator settings and at the same time to minimize the deviation in both *f* and *V*T/BW, from 10 bpm and 10 ml kg^{-1}, respectively, and to maintain *P*plat within suitable limits (<3–4 kPa). By mean of the following examples of rules, the concept of fuzzy logic control of artificial ventilation is explained. In figure 3, typical membership functions of fuzzy sets of the input variable $\mathrm{e}F\mathrm{E}'_{\mathrm{CO_2}}$ and of the output variable d*V*E/BW are presented.

IF $\mathrm{e}F\mathrm{E}'_{\mathrm{CO_2}}$ = ns AND $\mathrm{de}F\mathrm{E}'_{\mathrm{CO_2}}$ = pb THEN d*V*E/BW = ns

If actual $F\mathrm{E}'_{\mathrm{CO_2}}$ is slightly larger than desired $F\mathrm{E}'_{\mathrm{CO_2}}$ (set-point), which implies $\mathrm{e}F\mathrm{E}'_{\mathrm{CO_2}}$ is negative small (ns), and $F\mathrm{E}'_{\mathrm{CO_2}}$ was much larger than the set-point of $F\mathrm{E}'_{\mathrm{CO_2}}$ 60 s before, which implies $\mathrm{de}F\mathrm{E}'_{\mathrm{CO_2}}$ is positive big (pb), then reduce *V*E/BW slightly, which implies d*V*E/BW is negative small (ns). Performance of this rule acts as a deceleration manoeuvre, which minimizes overshooting or oscillation of $F\mathrm{E}'_{\mathrm{CO_2}}$, or both, about the set-point.

IF *f* = ps AND *V*T/BW = pb THEN d*f* = pm

If actual *f* is small, which implies *f* is positive small (ps), and *V*T/BW is large, which implies *V*T/BW is positive big (pb), then increase *f* moderately, which implies d*f* is positive medium (pm). By maintaining *V*E/BW, *V*T/BW then decreases.

IF *P*plat = pb THEN d*f* = pb

If actual *P*plat is large (*P*plat = pb), then increase *f* considerably (d*f* = pb). By maintaining *V*E/BW, *V*T/BW and *P*plat then decrease.

Rules, sets and membership functions were designed according to clinical experience and modified in pilot studies with 14 anaesthetized patients undergoing mechanical ventilation from whom written informed consent had been obtained.

Maximum–minimum inference was used for determination of fuzzy values of output variables. Applying the centre of gravity method defuzzificated, crisp values for the ventilator settings resulted at a rate of 0.1 Hz.

In the computer programme for automatic feedback control of mechanical ventilation various safety restrictions were incorporated to keep the values of input and output variables within reasonable limits. One of these restrictions was that ventilator settings for *f* were limited to values between 6 and 20 bpm and for *V*T/BW to values between 4 and 20 ml kg^{-1}.

An oral sodium citrate–citric acid non-particulate buffer in humans

J. J. HAUPTFLEISCH AND K. A. PAYNE

Summary

We have investigated the effect on the pH of the gastric fluid of a single dose of sodium citrate 0.3 mol litre^{-1} (antacid) and a solution containing sodium citrate dehydrate (100 mg ml^{-1}) with citric acid monohydrate (66 mg ml^{-1}) (buffer). The dose for both solutions was 0.4 ml kg^{-1} via a nasogastric tube. Each group comprised 10 patients undergoing neurosurgical operations of 5–7 h duration. A control group of 10 patients received no gastric solution. The pH of the gastric aspirate was measured hourly using a Metrohm 632 digital pH meter (Synectics Medical, Sweden). Mean baseline gastric pH was 2.64 (SD 1.71). In the control group, pH increased to 4.4 (1.51) at 5 h, returning to baseline at 7 h. In the antacid group, pH increased to 6.11 (0.47) at 15 min and decreased to 3.70 (1.94) at 7 h ($P < 0.01$). In the buffer group, pH was stable at 3.80–3.95 (0.22) over 7 h ($P > 0.01$). Total mean gastric aspirate was 0.5 ml kg^{-1}. (*Br. J. Anaesth.* 1996; **77**: 642–644)

Key words
Gastrointestinal tract, pH. Acid–base equilibrium, pH. Acid–base equilibrium, buffers. Gastrointestinal tract, antacids. Fluids, oral.

Aspiration pneumonitis from inhaling acid gastric content is an anaesthetic hazard. This is associated with a gastric pH of less than 2.5, and factors that contribute to this include prolonged fasting time, ileus, unconsciousness and the stress response to surgery.[1–3] These factors apply to patients undergoing prolonged surgical procedures, so that the extubation and recovery phases of anaesthesia have the potential for regurgitation and aspiration of gastric content.[2 4]

Antacid therapy with an alkaline solution such as sodium citrate 0.3 mol litre^{-1} is used commonly to antagonize gastric acidity in the preanaesthetic phase. However, reported problems include short duration of action (2–4 h),[5 6] increase in gastric volume[4] and rebound gastric acid secretion.[7]

A buffer solution of sodium citrate dihydrate 100 mg ml^{-1} and citric acid monohydrate 66 mg ml^{-1} is designed to buffer the gastric content, rather than neutralize it[8] (Pneucid, Narkopharm). This is postulated to have a longer duration of action than sodium citrate and to prevent rebound gastric secretion, thus improving the safety profile at extubation.

It had been shown that this buffer solution did not cause chemical pneumonitis in canine lungs,[8] hence human trials could proceed. We studied the efficacy of this agent in controlling gastric pH in humans undergoing anaesthesia of 5 h or more duration.

Patients and methods

We undertook a prospective, randomized study in 30 neurosurgical patients, aged 18 yr or more. Surgery was for excision of cerebral tumours or clamping of cerebral aneurysms and duration was 5 h or longer. Patients were free of other pathology and were conscious and orientated before operation. Preoperative medication included dexamethasone for patients with tumours, and labetalol and diazepam for aneurysm patients. The hospital Ethics Committee gave consent for the study and written informed consent was obtained from the patients.

We studied three groups of 10 patients each: the control group received no gastric medication, the antacid group received sodium citrate 0.3 mol litre^{-1} (0.4 ml kg^{-1}),[9] and the buffer group received a solution containing sodium citrate dehydrate 100 mg ml^{-1} with citric acid monohydrate 66 mg ml^{-1} at 0.4 ml kg^{-1}.[8]

Premedication comprised oral diazepam 0.15 mg kg^{-1} and induction of anaesthesia was with thiopentone 3–5 mg kg^{-1} i.v. Neuromuscular block was produced with an infusion of atracurium 0.5 mg kg^{-1} h^{-1} and morphine 10–30 mg i.v. was given for analgesia. The patient's lungs were ventilated with 1–2% isoflurane and 50% nitrous oxide in oxygen as needed. Ventilation was set to provide an end-expired carbon dioxide concentration of 3–3.5% and a 20° head-up tilt was used. Labetalol was used to maintain heart rate at less than 80 beat min^{-1} and a 0.01% sodium nitroprusside infusion provided hypotension when needed. Mean arterial pressures were maintained at 80 mm Hg except in some aneurysm cases when mean pressures of 70 mm Hg were used during clamping. Normal temperatures were maintained using convective air blankets.

Standard monitors included oximetry, capnography, oesophageal temperature, electrocardiography, direct arterial pressure, central venous pressure, neuromuscular block and urinary catheter. Arterial blood was obtained hourly for measurement of blood-gas tensions, electrolyte concentrations and acid–base balance.

When patients' lungs had been intubated and stabilized, a 10-gauge orogastric tube was passed and its position verified by aspirating 2 ml of gastric content. The test solutions, 0.4 ml kg^{-1}, were then injected down the gastric tube and flushed with 5 ml of sterile water. The control group received no fluid down their gastric tube. Fifteen minutes thereafter, 2 ml of gastric content were aspirated. This was repeated every 60 min for the duration of the anaesthetic. The gastric tube was removed before tracheal extubation, after aspirating as much volume as possible. Patients were supine at this time.

The pH of the samples was measured in a Metrohm 632 Digital pH meter (Synectics Medical, Sweden). This was calibrated before each patient at a temperature of 36 °C using the manufacturer's buffer solution.

Data were compared by analysis of variance and multiple linear regression analysis. This compared the pH values and their changes over time in the three groups. $P = 0.01$ was taken as significant.

Results

The three groups were comparable in age, weight, sex and duration of surgery (table 1). pH values are shown in figure 1. There were no differences at baseline. Overall mean pH was 2.64 (SD 1.71), with 19 patients having values of less than 2.5. However, at 15 min, both groups had pH values significantly higher than that of the control group (2.18 (1.00); $P < 0.01$). The antacid group had a significantly higher pH (6.11 (0.47)) than the buffer group (3.92 (0.24)) ($P < 0.01$).

Over the next 7 h the pH of patients in the antacid group decreased steadily from the peak at 15 min to 3.70 (1.94) at 7 h. Patients in the buffer group remained stable, with mean pH values of 3.80–3.95 (0.22) throughout this time. Mean pH values in the control group increased to a plateau of 4.10–4.41 (1.51) at 2–5 h, thereafter returning to baseline values at 7 h. Mean pH values in the antacid group were significantly different from those of the control and buffer groups for 4 h ($P < 0.01$) but there was no difference between mean values in the control and buffer groups , except at 15 min.

While mean pH values were greater than 2.5, individual patient values revealed potentially dangerous decreases. In the control group, two patients had pH values of less than 2.5 throughout the study and four others had pH values less than 2.5 for the first hour, one of whom returned to less than 2.5 by 7 h. In the antacid group, one patient had a pH of 2.08 at 5 h which decreased to 1.46 at 7 h. No patient in the buffer group had a pH value less than 3.71 during the study and the highest value was 4.43.

In the two groups who received oral solutions, total gastric volume aspirated during the study was approximately 0.5 ml kg^{-1}. Mean volumes were 42 (12.1) ml in the antacid group and 39.2 (23.3) ml in the buffer group. The control group had a significantly lower mean volume (20.3 (6.4) ml; $P < 0.01$). Final residual volumes aspirated were 27.6 (12.4) ml, 26.7 (23.0) ml and 8.8 (5.6) ml, respectively ($P < 0.01$).

Discussion

Our study has confirmed that preoperative fasting adults are likely to have gastric pH values that put them at risk of the aspiration pneumonitis syndrome[1,4]; 63% had baseline pH values of less than 2.5. The response to both of the test solutions was rapid, safe levels being obtained by 15 min. As the buffer solution has a pH of 4.8,[8] the initial increase in gastric pH was less than that with sodium citrate 0.3 mol $litre^{-1}$, but the pH values remained within a stable mean range of 3.80–3.94 for 7 h. These values would avoid the danger of rebound acid secretion which might result from gastric values of greater than 6.[7]

In contrast, sodium citrate 0.3 mol $litre^{-1}$ has a pH of 8.4[8] and it caused mean pH to increase to greater than 6 for 1 h. In one patient this was followed by a sustained decrease to less than 2.5, possibly because of rebound acid secretion.[7] This rebound phenomenon is one of the reasons why sodium citrate 0.3 mol $litre^{-1}$ is recommended as a regular 2–4 hourly regimen for women in labour.[5,6] The more prolonged effect seen here would be a

Table 1 Patient data and operations performed (mean (SD or range) or number)

Duration of surgery (h)	5 (1.44)	5 (1.63)	5 (0.95)

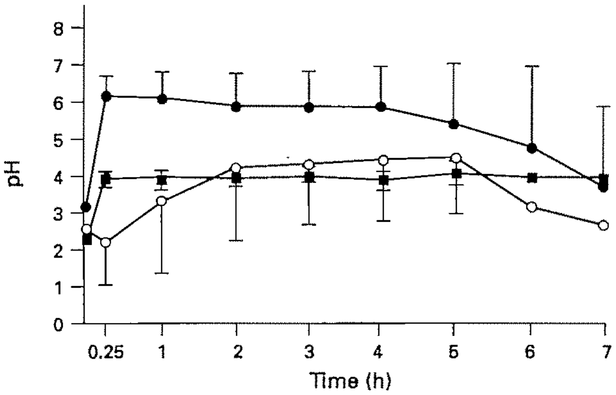

Figure 1 Mean (SD) pH values. At 15 min, pH values in the buffer (■) and antacid (●) groups were significantly higher than those in the control group (○) ($P < 0.01$). The pH values in the antacid group were significantly higher than those in the two other groups for 4 h. The buffer and control groups had two and one patient, respectively, after 6 h, hence no SD are given after 5 h.

result of the influence of the anaesthetic on the gastric mucosa during non-stressful surgery,[4] compared with a woman in active labour. Halothane anaesthesia is known to decrease gastric acid production via a directly depressant effect on acid producing cells.[10] It is likely that isoflurane would have a similar effect. This would explain the increase in mean gastric pH in the control group to 3–4 for the duration of the anaesthetic. However, this was very variable and six of 10 patients had pH values of less than 2.5 at some stage during the anaesthetic.

The danger of developing the pulmonary acid aspiration syndrome is also related to the volume inhaled. Primate data indicate that a volume in excess of 0.8 ml kg^{-1}, together with a low pH, is needed.[11] Therefore, any oral solution should not result in volumes greater than this. Both of the test solutions gave total aspirated gastric volumes of 0.5 ml kg^{-1}. While these are increased compared with resting gastric volumes of 0.3–0.4 ml kg^{-1} reported from fasting adults,[12 13] they are below the suggested danger level of 0.8 ml kg^{-1}.

From the duration of action of the buffer solution, systemic absorption was not rapid. Nevertheless, the potential effects on the systemic system need to be considered. No effects were seen and hourly arterial acid–base and electrolyte values were unaffected. This is to be expected, as the agents in the buffer solution were used for many years as anticoagulants (acid citrate glucose anticoagulant) in transfused blood.[14 15] The mean volume administered (32 ml) contained a similar amount of sodium citrate dihydrate and citric acid monohydrate as was present in 2 u. of blood.

Patients undergoing neurosurgery and other prolonged procedures are likely to be in the high dependency unit for some time. Because of the increased incidence of stress ulcers developing at gastric pH values of less than 3[16 17] and the decrease in gastric bacterial barrier at pH values greater than 4.5,[17 18] a desired pH range of 3–4.5 has been proposed.[19] Therapy to achieve this should commence as early as possible. In this regard, sodium citrate 0.3 mol $litre^{-1}$ was inadequate, with mean pH values of 5–6 for 5 h with one less than 2.5. The buffer solution produced closely grouped values within the proposed range for the 7 h studied. If used in a high dependency unit, duration of effective gastric pH control would need to be monitored from nasogastric tube aspirate.

We conclude that the buffer solution of sodium dihydrate (citric acid monohydrate) was an effective gastric acid inhibitor, with a duration of action of 7 h in neurosurgical operations.

LABORATORY INVESTIGATIONS

Effects of local anaesthetics on carrageenan-evoked inflammatory nociceptive processing in the rat

J. BURITOVA, D. FLETCHER, P. HONORÉ AND J.-M. BESSON

Summary

We have assessed the effects of intraplantar local anaesthetics (bupivacaine and lignocaine) on carrageenan-induced oedema, mechanical allodynia and spinal *c-fos* protein expression. Mechanical allodynia was evaluated using the vocalization threshold to paw pressure (VTPP) every 30 min until 60, 180 or 240 min after administration of carrageenan. Peripheral oedema, mechanical allodynia and spinal *c-fos* protein expression were maximal 180 min after carrageenan. Lignocaine did not influence either oedema or VTPP, but reduced spinal *c-fos* expression at 60 min after carrageenan without later effects. Bupivacaine induced an increase in VTPP at 30 and 60 min, limitation of oedema at 60 min and a reduction in spinal *c-fos* expression at 60 and 180 min, but these effects were not present 240 min after carrageenan. Intraplantar infiltration with lignocaine and bupivacaine before carrageenan transiently limited signs of inflammatory pain but did not prevent them. (*Br. J. Anaesth.* 1996; **77**: 645–652)

Analgesia, pre-emptive. Pain, experimental. Genetic factors, proto-oncogenes. Anaesthetics local. Spinal cord. Rat.

Bupivacaine and lignocaine, long- and short-acting local anaesthetics respectively, are used in both acute and chronic pain therapy (see references in Bonica and Butler[1]). There is evidence that pain processing may be reduced by pre-administration of various agents (e.g. opioids, local anaesthetics, non-steroidal anti-inflammatory drugs (NSAID)) leading to the concept of pre-emptive analgesia.[2] However, this concept is still debated[3] and few clinical studies have confirmed the clinical significance of pre-emptive analgesia.[4–6] Administration of local anaesthetics before tissue injury may prevent peripheral and central sensitization of the nervous system induced by nociceptive input (see references in Coderre and colleagues[4]). The pre-emptive analgesic effect of local anaesthetics has been observed in different animal models of pain (see references in Coderre and colleagues[4]).

In this study, we have investigated the possible pre-emptive effects of local anaesthetics (lignocaine and bupivacaine) in the carrageenan model of inflammatory pain in rats.[7] As shown previously, intraplantar injection of carrageenan induces ipsilateral inflammation (see references in Kocher and colleagues[8]) associated with mechanical allodynia[9] and *c-fos*-protein-like immunoreactivity (*c-fos* LI) in the ipsilateral dorsal horn of the spinal cord.[10–12] The method based on the immunoreactivity of *c-fos*-protein is used widely as a form of neuronal-activity mapping (see references in Morgan and Curran[13]). For a recent review of the mechanisms of expression of *c-fos* protein within the nervous system see Hughes and Dragunow.[14] Many studies following the original report[15] have provided evidence that various noxious stimulations evoked expression of *c-fos* protein in spinal neurones (see references in Zimmermann and Herdegen[16]), thus providing an indirect marker of neurones involved in spinal nociceptive transmission. In our previous studies, we used immunohistochemical revelation of spinal *c-fos* expression in the carrageenan model of inflammatory pain to assess the effects of analgesic/anti-inflammatory drugs, including systemic[17] and intraplantar[18] morphine and various systemic NSAID (see Buritova and colleagues[19] and references therein). In this study, we have combined behavioural and immunohistochemical approaches to investigate the effects of pre-administered intraplantar local anaesthetics in carrageenan-induced inflammatory pain in rats.

Materials and methods

EXPERIMENTAL ANIMALS

Experiments were performed on 52 adult male albino Sprague–Dawley rats (Charles River, France; 48 carrageenan-stimulated and four non-stimulated rats), weighing 225–250 g. Rats were acclimatized to the laboratory for 8 days before the experiment. Rats were tested using the vocalization threshold to paw pressure (VTPP) and were trained in the experimental conditions during the last 2 days before the experiment. The

ethics guidelines of the IASP were followed for investigations of experimental pain in conscious animals.[20]

DRUG ADMINISTRATION

Peripheral inflammation was induced by intraplantar injection of carrageenan (λ-carrageenan, Sigma; 6 mg per 150 μl of saline (0.9% NaCl)) in the right hind paw of the non-anaesthetized rat. In this study, control rats receiving intraplantar injection of saline were not included as we have shown previously negligible spinal *c-fos* expression after intraplantar saline (<5 *c-fos* LI neurones per section L4–L5) which was not significantly different from that observed in non-stimulated rats.[12] The preliminary unpublished study demonstrated that intraplantar administration of local anaesthetics (0.5% Marcaine, 2% xylocaine) without carrageenan injection did not induce spinal *c-fos* expression significantly different from that observed in intraplantar saline injected rat (<5 *c-fos* LI neurones per section L4–L5).

Intraplantar bupivacaine (0.5% Marcaine, Astra, France) and lignocaine (2% Xylocaine, Astra, France) were injected into the right hind paw of non-anaesthetized rats (200 μl for both drugs) 5 min before intraplantar injection of carrageenan. The timing, concentration and volume of local anaesthetic were chosen according to a previous study to obtain complete anaesthesia of the paw before injection of carrageenan.[21] Control carrageenan rats received 200 μl of saline under the same experimental conditions. Intraplantar injections of carrageenan or local anaesthetic were made subcutaneously with a 25-gauge needle.

MEASUREMENT OF CARRAGEENAN-INDUCED PERIPHERAL OEDEMA

Two indicators of peripheral oedema, ankle and paw diameters, were measured with a calliper square, immediately before perfusion at 60, 180 or 240 min after injection of carrageenan. Ankle and paw diameters of carrageenan-stimulated and non-stimulated rats were measured. Oedema was determined as percentage increases in ankle and paw diameters of carrageenan-treated rats compared with non-stimulated rats.

TEST OF VOCALIZATION THRESHOLD TO PAW PRESSURE

The vocalization threshold to paw pressure (VTPP) was measured using a Basile Analgesimeter (Apelex, tip diameter of the probe = 1 mm) according to a method adapted from the Randall-Selitto description.[22] All VTPP measurements were performed blind by the same investigator. For each rat, the thresholds for vocalization (mean of two values), expressed in grams (g), were determined by applying increasing pressure to the right hind paw until an audible squeak was elicited. A control value was determined before injection of carrageenan. We then determined, at each time after carrageenan, two stable consecutive thresholds, which were averaged. This criterion of the VTPP was chosen according to a previous study,[22] as it represents a more integrated nociceptive behaviour than paw withdrawal. The choice of a cut-off value was necessary to limit injury to the paw and excessive stimulation of the nociceptors. The cut-off value was 600 g and was considered sufficient to represent an anaesthetic state.

IMMUNOHISTOCHEMISTRY FOR EVALUATION OF SPINAL C-*FOS* PROTEIN EXPRESSION

As demonstrated previously, carrageenan-evoked spinal *c-fos* expression was detected at 60 min[17] and was maximal at 180 min[12] after intraplantar injection of carrageenan. Therefore, in this study of the time course of the local anaesthetic effects, rats were perfused at various times after injection of carrageenan: 60, 180 and 240 min, immediately after the last test of VTPP. As described previously (see references in Buritova and colleagues[19]), rats were deeply anaesthetized (pentobarbitone (Sanofi) 55 mg kg^{-1} i.p.) and perfused intracardially with phosphate-buffered saline (PBS) 0.1 mol $litre^{-1}$ followed by 4% paraformaldehyde in phosphate buffer (PB) 0.1 mol $litre^{-1}$. The spinal cord was removed, post-fixed for 4 h and cryoprotected in 30% sucrose overnight. Frozen serial frontal sections (40 μm) of the lumbar L4–L5 segments were cut. Immunohistochemistry of the free floating sections was performed with polyclonal antiserum, generated in rabbits, directed against the *c-fos* protein (Oncogene Science Inc., Ab-2 solution 0.1 mg ml^{-1} diluted 1:4000), using the conventional avidin–biotin–peroxidase complex method with visualization by 1-naphthol ammonium carbonate solution (for more details see methods in Buritova and colleagues[19]).

COUNTING OF SPINAL C-*FOS* LI NEURONES

As described previously (see Buritova and colleagues[19] and references therein), distribution of *c-fos* LI neurones was studied in four defined regions: superficial laminae (laminae I–II), nucleus proprius (laminae III–IV) and neck (laminae V–VI) of the dorsal horn and, in addition, ventral horn (laminae VII–X; ventral) of the spinal cord. For each rat, two counts were made: (1) the total number of *c-fos* LI neurones in the grey matter for 10 sections through L4–L5 segments, and (2) in these 10 sections, the number of *c-fos* LI neurones in the four defined regions. Plotting and counting the *c-fos* LI neurones were performed blind to the experimental condition. Statistical analysis was performed using analysis of variance (ANOVA) and the Fisher's protected least squares difference test (Fisher's PLSD test) for multiple comparisons. The effects of local anaesthetics on peripheral oedema, VTPP and number of spinal *c-fos* LI neurones were determined compared with controls (control group).

EXPERIMENTAL DESIGN

To evaluate the time course of the effects of local anaesthetics on carrageenan-induced inflammatory nociceptive processing, the experiment was performed in three different series. In each series, rats were perfused immediately after the last test of VTPP.

In the first series (n = 18), rats in the control, lignocaine and bupivacaine groups were tested for VTPP every 30 min for 60 min after administration of carrageenan at which time rats were perfused. In the second series (n = 18), rats in the control, lignocaine and bupivacaine groups were tested for VTPP every 30 min for 180 min after administration of carrageenan at which time rats were perfused. In the third series (n = 12), control and bupivacaine groups were tested for VTPP every 30 min for 240 min after administration of carrageenan at which time rats were perfused. In this series, the lignocaine group was not included as intraplantar pre-administration of lignocaine was not efficacious as early as 180 min after carrageenan administration.

In these experimental series, three distinct groups of rats were defined: in the control group (n = 6 for each time), rats received saline 200 μl, 5 min before administration of carrageenan and were tested for VTPP after carrageenan; in the bupivacaine group (n = 6 for each time) rats received bupivacaine 200 μl, 5 min before carrageenan and were tested for VTPP after carrageenan; in the lignocaine group (n = 6 for each time) rats received lignocaine 200 μl, 5 min before carrageenan and were tested for VTPP after carrageenan.

Results

DEVELOPMENT OF CARRAGEENAN-EVOKED OEDEMA

In the control group, 60, 180 and 240 min after intraplantar administration of carrageenan, both paw (0.8 (SEM 0.1), 1.1 (0.1) and 1.1 (0.1) cm, respectively) and ankle (0.8 (0.1), 1.2 (0.1) and 1.1 (0.1) cm, respectively) diameters were increased significantly compared with carrageenan non-stimulated rats (mean values for paw and ankle diameters: 0.5 (0.1) and 0.7 (0.1) cm, respectively). Inflammatory oedema was not present in the contralateral hind paw at each time.

At 60 min after carrageenan, in the bupivacaine group, carrageenan-evoked ankle oedema (0.75 (0.02) cm) was reduced slightly compared with the control group ($P < 0.01$) but paw oedema was not influenced. Bupivacaine had no effect on paw or ankle oedema at 180 and 240 min after carrageenan.

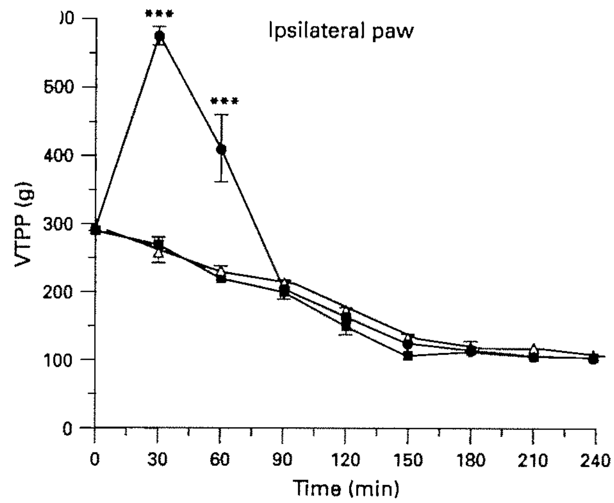

Figure 1 Effects of intraplantar 0.5% bupivacaine (●) and 2% lignocaine (■) on VTPP over 4 h after administration of carrageenan. From 0 to 60 min: n = 18; from 60 to 180 min: n = 12; from 180 to 240 min: n = 6. Results are expressed as absolute mean (SEM) of the threshold value, each 30 min after intraplantar carrageenan. Significance compared with control group (Δ) was performed using ANOVA and Fisher's PLSD test (***$P < 0.001$). The study of the effect of lignocaine at 4 h was not performed.

In the lignocaine group, paw and ankle oedema were not influenced at each time after carrageenan.

CARRAGEENAN-EVOKED DECREASE OF VTPP

The results were similar for the three series and were therefore pooled (see fig. 1).

Intraplantar carrageenan decreased VTPP at each time, with a final decrease to 35% of control values at 240 min after carrageenan (fig. 1). Overall, VTPP decreased from 288 (7) g at time 0 min, to 100 (3) g at 240 min after carrageenan (fig. 1).

In the lignocaine group, VTPP never reached the cut-off value at each time after carrageenan. At 60 and 180 min after carrageenan, VTPP decreased to 76% and 37% of control values, respectively, reflecting the development of mechanical allodynia. Overall, VTPP decreased from 287 (6) g at time 0 min to 108 (9) g at 180 min after carrageenan (fig. 1).

In the bupivacaine group, VTPP reached the cut-off value in 95% of rats at 60 min after carrageenan. At later times, 180 and 240 min, VTPP decreased to 37% and 35% of control values, respectively. Overall, VTPP decreased from 287 (6) g at time

Table 1 Effects of intraplantar 0.5% bupivacaine and 2% lignocaine on the number of c-*fos* LI neurones in the superficial (I–II) and deep (V–VI) laminae of the dorsal horn and in the ventral horn (Ventral) of the L4–L5 segments of the rat spinal cord at 1, 3 and 4 h after intraplantar carrageenan. Results are expressed as the absolute mean (SEM) of the number of c-*fos* LI neurones per section for each region. Significance of the effects of both anaesthetics, compared with the control group, was performed using ANOVA and Fisher's PLSD test (**$P<0.01$, ***$P<0.001$). The effect of lignocaine at 4 h was not performed

0 min to 100 (3) g at 240 min after carrageenan (fig. 1). The mean duration of analgesic effect of bupivacaine was 55 (16) min.

TIME COURSE OF CARRAGEENAN-EVOKED SPINAL C-*FOS* EXPRESSION

In the control group, the total number of c-*fos* LI neurones was greatly increased in the ipsilateral spinal cord at 60, 180 and 240 min after carrageenan (fig. 2, fig. 4A; table 1). At all times after carrageenan, spinal c-*fos* LI neurones of the control group were located predominantly in laminae I–II and V–VI of the dorsal horn of the lumbar spinal cord (fig. 2, fig. 4B,C, table 1). At 60, 180 and 240 min after carrageenan, the number of c-*fos* LI neurones in the nucleus proprius (laminae III–IV: 6 (1), 10 (2) and 8 (1) c-*fos* LI neurones per L4–L5 section, respectively) was moderate compared with the total number of c-*fos* LI neurones per L4–L5 section (101 (8), 200 (15) and 141 (6), respectively) (table 1). At each time, c-*fos* LI neurones were almost absent in the contralateral spinal cord (<5 c-*fos* LI neurones per L4–L5 section).

At 60 min after intraplantar carrageenan, carrageenan-evoked spinal c-*fos* expression in the bupivacaine and lignocaine groups was significantly different from that observed in the control group, for both the total number of c-*fos* LI neurones in segments L4–L5 (F (3, 20) = 16.17; $P < 0.001$) and their laminar distribution (F (3, 80) = 34.20; $P < 0.001$). Intraplantar pre-administration of both bupivacaine and lignocaine reduced the total number of c-*fos* LI neurones induced at 60 min after carrageenan (60 (3) % and 37 (6) % reduction of control group values, respectively; $P < 0.001$ for both drugs) (fig. 4A, table 1). Furthermore, in both the bupivacaine and lignocaine groups, the significant reduction in the number of superficial (laminae I–II: 63 (6) % and 44 (6) % reduction of control group values, respectively; $P < 0.001$ for both drugs) (fig. 3) and deep (laminae V–VI: 59 (3) % and 39 (5) % reduction of control group values, respectively; $P < 0.001$ for both drugs) c-*fos* LI neurones was observed

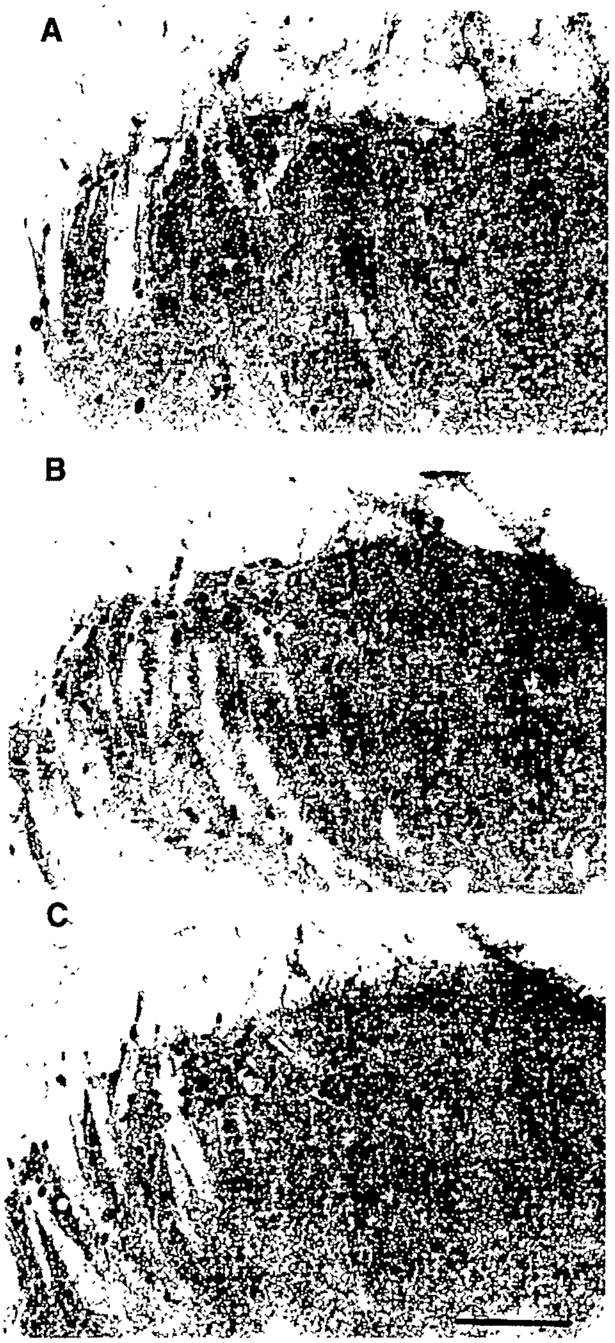

Figure 3 Microphotographs of superficial laminae of spinal dorsal horn showing reducing effects of intraplantar 0.5% bupivacaine and 2% lignocaine on the number of c-*fos* LI neurones, 1 h after intraplantar carrageenan in rats. Each microphotograph is an individual example, including labelled nuclei of c-*fos* LI neurones in superficial laminae (laminae I–II) per section (40 μm) of L4–L5 segments of the spinal cord; scale bar=100 μm. A = Control; B = 0.5% bupivacaine; C = 2% lignocaine.

at 60 min after carrageenan (fig. 4B,C, table 1). Therefore, intraplantar pre-administration of both bupivacaine and lignocaine had a similar effect on the number of superficial and deep c-*fos* LI neurones induced at 60 min after carrageenan (table 1).

In the bupivacaine group, a significant reduction in the total number of c-*fos* LI neurones induced at 180 min after intraplantar carrageenan was observed (29 (4)% reduction of control group values; $P < 0.01$) (fig. 4A, table 1). This effect resulted from a significant reduction in the number of deep c-*fos* LI neurones (31 (5) % reduction of control group values; $P < 0.001$) without effect on the superficial laminae (fig. 4B,C, table 1). In contrast, in the lignocaine group, the number of spinal c-*fos* LI neurones induced at 180 min after carrageenan was not affected (table 1).

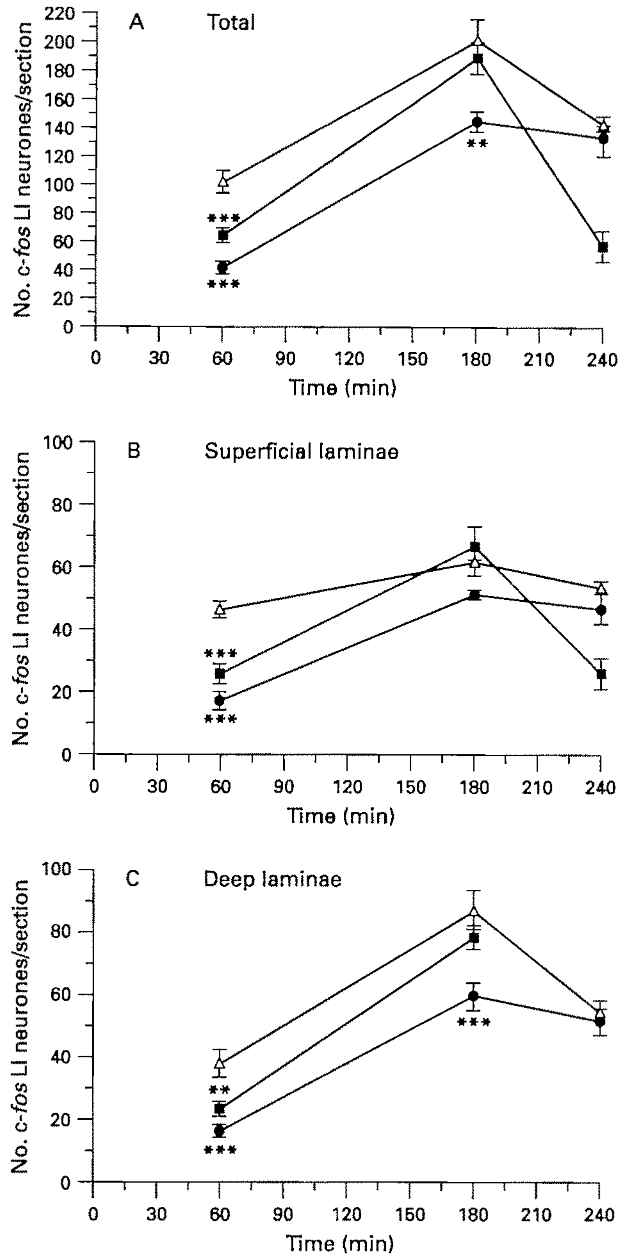

Figure 4 Effects of intraplantar 0.5% bupivacaine (●) and 2% lignocaine (■) on the number of c-*fos* LI neurones in the L4–L5 segments of the rat spinal cord at 1, 3 and 4 h after intraplantar carrageenan. Results are expressed as absolute mean (SEM) of (A) total number of carrageenan evoked c-*fos* LI neurones per section of segments L4–L5 and number of superficial (B) and deep (C) c-*fos* LI neurones per section for each region in the L4–L5 segments, 3 h after intraplantar carrageenan. Significance compared with control group (Δ) was performed using ANOVA and Fisher's PLSD test ($^{**}P < 0.01$, $^{***}P < 0.001$). The study of the effect of lignocaine at 4 h was not performed.

Intraplantar pre-administration of bupivacaine did not influence spinal c-*fos* expression induced at 240 min after carrageenan (table 1). As intraplantar lignocaine did not influence spinal c-*fos* expression at 180 min after carrageenan, the study of its effect at 240 min after carrageenan was not performed.

Discussion

Intraplantar administration of a long-acting local anaesthetic, bupivacaine, postponed mechanical allodynia and spinal c-*fos* protein expression associated with the inflammatory state induced by intraplantar injection of carrageenan in rats, while a short-acting local anaesthetic, lignocaine, reduced only transiently carrageenan-induced spinal c-*fos* protein expression. Overall, the effects of intraplantar bupivacaine and lignocaine in the carrageenan model of inflammatory pain were related to the duration of action of the anaesthetics.

TIME COURSE OF VOCALIZATION THRESHOLD AND OEDEMA

In accordance with previous studies (Kayser and Guilbaud[9], see references in Buritova and colleagues[19]) intraplantar injection of carrageenan induced ipsilateral oedema, without influencing the contralateral hind paw, at all times. The lack of effect of pre-administered intraplantar 2% lignocaine 200 μl on either oedema or VTPP after carrageenan was in concordance with previous studies showing the short duration of the antinociceptive effect of similar doses of lignocaine in behavioural experiments using the carrageenan model of inflammatory pain (18 min after 2% lignocaine 50 μl[9]) or formalin response in an orofacial pain model (6 min after 2% lignocaine 50 μl[23]).

In a carrageenan model of inflammatory pain, analgesia was defined previously as VTPP within the range of usual variability of the control value in normal situations (i.e. 85–115% of control value[9]). In this study, the duration of analgesic action of 0.5% bupivacaine 200 μl was estimated to be 55 (16) min after carrageenan. Similarly, pre-administered intraplantar bupivacaine reduced ankle oedema evoked at 60 min after carrageenan but this effect did not persist. The combined effect of bupivacaine on extension of oedema and reduction of VTPP may be related, at least in part, to the transient abolition of the axon reflex involved in the development and extension of inflammation[24]. The mechanism of action of bupivacaine involves binding of bupivacaine to voltage-dependent Na^+ channels which reduces neuronal transmission, axon reflex and consequently development of inflammation (see Butterworth and Strichartz[25] and references therein). In addition, local anaesthetics have been shown to block peripheral release of inflammatory substances such as substance P.[26] Thus the mechanisms mentioned above may be involved in the transient peripheral anti-inflammatory effect of intraplantar bupivacaine. The limited extent of peripheral oedema in the bupivacaine group, at 60 min after carrageenan, corresponded to the peripheral analgesic effect of bupivacaine during the period of its action. Overall, the peripheral effects of local anaesthetics probably reduced the nociceptive inputs and consequently influenced carrageenan-induced spinal c-*fos* expression.

TIME COURSE OF SPINAL C-*FOS* EXPRESSION

In the control group, spinal c-*fos* expression at 60, 180 and 240 min after intraplantar carrageenan was in agreement with our previous study showing the time course of spinal c-*fos* expression in the same model of inflammatory pain (see references in Buritova and colleagues[19]). This carrageenan evoked spinal c-*fos* expression was localized predominantly in the superficial (I–II) and deep (V–VI) laminae of the dorsal horn of the spinal cord in accordance with the spinal areas containing neurones activated by noxious stimuli driven by C- and Aδ-fibres[27] which evoked the spinal c-*fos* expression.[28]

Pre-administration of lignocaine attenuated spinal c-*fos* expression in both superficial and deep laminae at 60 min after carrageenan. This effect did not persist and the maximal number of c-*fos* neurones similar to the control group was reached at 180 min after carrageenan. This effect is in keeping with an electrophysiological study showing that administration of 2% lignocaine 50 μl s.c. into the site of peripheral injection of formalin completely blocked the first phase of the response to formalin of the deep dorsal horn neurones (about the first 10 min) without affecting second phase activity.[29] Thus 2% lignocaine 50–200 μl seems to be sufficient to prevent transmission of nociceptive inputs during the initial phase of nociceptive primary afferent activation with consequent attenuation of the time pattern of spinal c-*fos* expression. In this study, the reduced number of c-*fos* LI neurones at 60 min may reflect both a short duration of block of noxious input produced by lignocaine at the initial phase of inflammation and c-*fos* protein synthesis delay related to delay of c-*fos* messenger RNA (mRNA) expression about 30 min after carrageenan.[30]

In the bupivacaine group, the reduction in spinal c-*fos* expression in both superficial and deep laminae was observed 60 min after carrageenan. At 180 min after carrageenan when the reduction in VTPP, reflecting mechanical allodynia, was equivalent to control group values, c-*fos* expression in the superficial laminae was similar to the control group. However, at this time the total number of c-*fos* LI neurones and c-*fos* expression in deep laminae were lower than in the control group. This laminar pattern is not surprising as c-*fos* protein is initially expressed in superficial neurones, and subsequently in the neurones in the deep laminae of the spinal dorsal horn at a later phase of noxious stimulus transmission, as has been shown after intraplantar injection of formalin[31] and carrageenan.[12 17] Thus, in this study, the laminar pattern of carrageenan-induced spinal c-*fos* expression, influenced by intraplantar administration of both bupivacaine and lignocaine, may result from peripheral block of nociceptive input by local anaesthetics and consequently delayed c-*fos* expression at the spinal cord level.

Interestingly, the effect of pre-administered intraplantar bupivacaine on the laminar pattern of carrageenan-induced spinal c-*fos* expression at 60 min after carrageenan was similar to that observed with pre-administered intraplantar morphine[18] and various systemic NSAID (see references in Buritova and colleagues[19]) observed previously in the same experimental paradigm at 180 min after carrageenan. In these previous studies, the period of 180 min after intraplantar carrageenan had been covered by activity of the analgesic/anti-inflammatory drugs which resulted in reduction of c-*fos* expression in both superficial and deep laminae of the spinal dorsal horn. Overall, during the period of drug activity, both bupivacaine (60 min after carrageenan) and analgesic/anti-inflammatory drugs (180 min after carrageenan (see references in Buritova and colleagues[19]) had a similar effect on reducing spinal c-*fos* expression in both superficial and deep laminae. In contrast, after the period of drug activity (e.g. at 180 min after carrageenan), administration of bupivacaine induced a dissociative laminar pattern of spinal c-*fos* expression without effect on c-*fos* expression in superficial laminae. This dissociative effect of bupivacaine was similar to that described previously with the NMDA receptor antagonist, ($^+$)-HA966, in the same experimental paradigm.[32] Interestingly, bupivacaine and ($^+$)-HA 966[33] have a similar duration of antinociceptive effect (about 60 min).

In this study, the absence of persistent effects of intraplantar local anaesthetic on both behavioural nociceptive test and spinal c-*fos* expression in the superficial laminae does not support the hypothesis of efficacy of pre-emptive analgesia. However, the reduction in both total and deep laminae c-*fos* expression by bupivacaine may have an influence on the development of chronic pain states but additional studies are required to test this hypothesis.

LOCAL ANAESTHETICS AND PREVENTION OF PAIN

In this study we used parallel behavioural and immunohistochemical approaches to assess the possible pre-emptive effect of local anaesthetics. The reduction in spinal c-*fos* expression in both the superficial and deep laminae at 60 min suggests that local anaesthetic pre-infiltration interrupted nociceptive inputs during the initial phase of carrageenan inflammation. However, a longer block may be necessary to reveal a pre-emptive analgesic effect of local anaesthetics. Thus an increase in the dose of local anaesthetic used for infiltration or a nerve block technique may be proposed. Unfortunately, re-injection in this study would have been toxic (1 mg of bupivacaine was already injected; i.e. more than 4 mg kg^{-1}). Furthermore, we have previously used 0.5% bupivacaine with adrenaline or higher doses (5 mg of bupivacaine instead of 1 mg in 200 μl) of bupivacaine included in microspheres[34] which produced, respectively, a 100%[21] and 175% (unpublished data) increase in analgesia related to infiltration but without a pre-emptive effect detected by behavioural tests in the same carrageenan model. In contrast, the intervention required for nerve block may induce additional nociceptive stimulation which influences carrageenan-induced spinal c-*fos* expression and consequently impairs the homogeneity of control values. In addition, the behavioural test used in this study (vocalization threshold to paw pressure) may be difficult to evaluate when there is total paralysis of the limb.

The development of inflammatory nociception induced by intraplantar carrageenan in the rat is comparable to the time course of postoperative pain (24–96 h) and it might explain the similar results of this study and clinical studies on pre-emptive analgesia with local anaesthetic infiltration of the site of superficial surgery (see references in Dahl and Kehlet[5]). Our results extend clinical studies showing that pre-emptive anaesthesia with infiltration by local anaesthetics has no long-term benefits for postoperative analgesia (see references in Dahl and Kehlet[5]).

In summary, the effects of intraplantar pre-administration of bupivacaine and lignocaine on carrageenan-induced mechanical allodynia did not persist beyond the direct local anaesthetic effect. Similarly, carrageenan-induced nociceptive inputs were reduced only briefly by local anaesthetics, as shown by the transient reduction in spinal c-*fos* expression, an indicator of nociceptive transmission at the spinal cord.

Myocardial effects of eltanolone in hamsters with hypertrophic cardiomyopathy

P. RUEL, J.-L. HANOUZ , B. RIOU, Y. LECARPENTIER AND P. CORIAT

Summary

Eltanolone is a new short-acting i.v. induction agent that induces less cardiovascular depression than propofol or thiopentone and has no significant effect on intrinsic contractility in normal myocardium. However, its effects on diseased myocardium are unknown. We have studied *in vitro* the effects of eltanolone 0.1, 1, and 10 $\mu g\ ml^{-1}$ on the intrinsic contractility of left ventricular papillary muscles from normal hamsters and those with hypertrophic cardiomyopathy (strain BIO 14.6, 6-month-old) (Krebs–Henseleit solution, 29 °C, pH 7.40, Ca^{2+} 2.5 mmol $litre^{-1}$, stimulation frequency 3 min^{-1}). Cardiac hypertrophy (mean 134 (SD 9) %, $P < 0.001$) was observed in cardiomyopathic hamsters. Contractility of papillary muscles from hamsters with cardiomyopathy was less than that of controls, as shown by the lower active isometric force (8 (3) *vs* 35 (14) mN mm^{-2}, $P < 0.001$). Eltanolone did not induce any significant inotropic or lusitropic effects in normal hamsters, and the effects of eltanolone were not significantly different between normal hamsters and those with cardiomyopathy.(*Br. J. Anaesth.* 1996; **77**: 653–657)

Key words
Anaesthetics i.v., eltanolone. Heart, cardiomyopathy. Heart, myocardial function. Heart, inotropism. Hamster.

Eltanolone is a new short-acting i.v. anaesthetic agent which has undergone preliminary clinical investigation.[1–3] Eltanolone (3α-hydroxy-5β-pregnan-20-one) is a naturally occurring metabolite of progesterone which has been shown to be 3.2 times more potent than propofol and six times more potent than thiopentone.[3] The decrease in arterial pressure produced by eltanolone has been shown to be smaller than that after an equipotent dose of propofol.[3]

Because of concomitant changes in preload, systemic resistance, sympathetic activity and central nervous system activity, the exact effects of anaesthetic agents on intrinsic myocardial contractility are difficult to assess *in vivo*.[4] *In vitro*, eltanolone has been shown to induce no significant inotropic effect on rat myocardium.[5] Nevertheless, eltanolone induced a decrease in the calcium release function of the sarcoplasmic reticulum.[5]

The effects of eltanolone on diseased myocardium are unknown. It has been demonstrated that the myocardial effects of anaesthetic agents may differ between normal and diseased myocardium.[6 7] The various strains of Syrian hamsters with hereditary cardiomyopathy offer an opportunity to investigate the effects of anaesthetic agents on intrinsic myocardial contractility. Contractility, cellular biochemistry, molecular biology and pathophysiology have been studied extensively in the model, and impairment in contractility is caused primarily by cardiac muscle cell disease, and thus may be more relevant to clinical cardiomyopathies.[8 9] We therefore conducted an *in vitro* study of the effects of eltanolone on intrinsic contractility of left ventricular papillary muscle from normal hamsters and those with cardiomyopathy.

Materials and methods

Care of the animals conformed to the recommendations of the Helsinski Declaration, and the study was performed in accordance with the regulations of the official edict of the French Ministry of Agriculture. We studied eight normal Syrian hamsters (strain F1B) and 13 cardiomyopathic Syrian hamsters (strain BIO 14.6) (Bio Breeders Inc., Fitchburg, MA, USA). In this strain, all animals of both sexes develop hypertrophic cardiomyopathy from the age of 6 weeks. All animals were aged 6 months. Body weight (BW) and heart weight (HW) were determined at the moment of killing and the HW/BW ratio was calculated. Cardiac hypertrophy index was calculated by dividing the HW/BW value of each cardiomyopathic hamster by the mean HW/BW value in normal hamsters.

We studied 21 left ventricular papillary muscles. After brief anaesthesia with ether, the hearts were removed rapidly and left ventricular papillary

muscles were excised carefully and suspended vertically in a 200-ml jacketed reservoir with Krebs–Henseleit bicarbonate buffer solution containing (mmol litre^{-1}): NaCl 118, KCl 4.7, $MgSO_4$ 1.2, KH_2PO_4 1.1, $NaHCO_3$ 25, $CaCl_2$ 2.5 and glucose 4.5 . The Krebs–Henseleit solution was prepared daily with highly purified water (Ecopure, Barnstead/Thermolyne Corporation, Dubuque, IA). The jacketed reservoir was maintained at 29 °C with a thermostatic water circulator (Polystat 5HP, Bioblock, Illkirch, France) and continuous monitoring of the solution temperature with a temperature probe (Pt100, Bioblock). Preparations were field-stimulated at 3 pulses min^{-1} by two platinum electrodes with rectangular wave pulses of 5-ms duration just above threshold. The bathing solution was bubbled with 95% oxygen–5% carbon dioxide, resulting in a pH of 7.40. After a 90-min stabilization period at the initial muscle length at the apex of the length-active isometric tension curve (*l*max), papillary muscles recovered their optimal mechanical performance, which remained stable for many hours.

The pharmaceutical form of eltanolone in which a soya bean emulsion is the solvent (Pharmacia, Stockholm, Sweden) was tested. The solvent has been shown to be devoid of significant effects on intrinsic myocardial contractility.[5,10,11] Concentrations of eltanolone during anaesthesia range from 0.3 to 3 μg ml^{-1}.[12] Eltanolone is highly bound (99%) to plasma proteins,[13] but this does not seem to influence its rapid disappearance from blood and extensive tissue distribution. Thus three concentrations of eltanolone were tested in a cumulative manner: 0.1 μg ml^{-1} (0.31 μmol litre^{-1}), 1 μg ml^{-1} (3.14 μmol litre^{-1}) and 10 μg ml^{-1} (31.4 μmol litre^{-1}), with a lapse of 15 min between each dose, as reported previously in rat myocardium.[5]

ELECTROMAGNETIC LEVER SYSTEM AND RECORDING

The electromagnetic lever system has been described previously.[14] Briefly, the load applied to the muscle was determined by means of a Servo mechanism-controlled current through the coil of an electromagnet. Muscular shortening induced displacement of the lever, which modulated the light intensity of a photoelectric transducer. All analyses were made from digital records of force and length obtained with a computer, as described previously.[15]

MECHANICAL VARIABLES

Conventional mechanical variables at *l*max were calculated from three twitches. The first twitch was isotonic and was loaded with the preload corresponding to *l*max. The second twitch was clamped abruptly to zero load just after the electrical stimulus; the muscle was released from preload to zero load with a critical damping in order to slow the first and rapid shortening overshoot resulting from recoil of series passive elastic components, as reported previously[16]; maximum unloaded shortening velocity (*v*max) was determined from this twitch. The third twitch was fully isometric at *l*max. The mechanical variables characterizing the contraction and relaxation phases, and the coupling between contraction and relaxation were defined as follows.

Contraction phase

We determined *v*max using the zero load clamp technique: maximum shortening velocity ($v_c$max) of the twitch with preload only; maximum isometric active force normalized per cross-sectional area (AF); and peak of the positive force derivative normalized per cross-sectional area (+d*F*. d*t*$^{-1}$). *v*max and AF tested the inotropic state under low and high loads, respectively.

Relaxation phase

We determined maximum lengthening velocity of the twitch with preload only ($v_r$max) and the peak of the negative force derivative at *l*max normalized per cross-sectional area (−d*F*. d*t*$^{-1}$). These two variables examined relaxation under low- and high-loading conditions, respectively. Nevertheless, as changes in the contraction phase induce coordinated changes in the relaxation phase, $v_r$max and −d*F*. d*t*$^{-1}$ cannot assess lusitropy, and thus variations in contraction and relaxation must be considered simultaneously to quantify drug-induced changes in lusitropy. Indices of contraction–relaxation coupling have therefore been developed to study lusitropy.[17]

Contraction–relaxation coupling

Coefficient R1 = $v_c$max/$v_r$max examined the coupling between contraction and relaxation under low load, and thus lusitropy. Under isotonic conditions the amplitude of sarcomere shortening is twice that observed under isometric conditions.[18] Because of the lower sensitivity of myofilament for calcium when cardiac muscle is markedly shortened under low load, relaxation proceeds more rapidly than contraction, apparently as a result of rapid uptake of calcium by the sarcoplasmic reticulum (SR). Thus R1 tests SR function. In contrast with $v_c$max and $v_r$max, R1 is not modified significantly by major inotropic changes induced by decreasing calcium.

Coefficient R2 = (+d*F*. d*t*$^{-1}$/−d*F*. d*t*$^{-1}$) studied the coupling between contraction and relaxation under high load, and thus lusitropy under high load. When the muscle contracts isometrically, sarcomeres shorten very little.[18] Because of the higher sensitivity of myofilament for calcium,[19] the relaxation time course is determined by calcium unbinding from troponin C rather than by calcium sequestration by the SR. Thus R2 reflects myofilament calcium sensitivity. The variables R1 and R2 which examine lusitropy have been used empirically for many years, but have been validated recently.[20,21]

At the end of the study, muscle cross-sectional area was calculated from the length and weight of papillary muscle, assuming a density of 1. Shortening and lengthening velocities were expressed in *l*max s^{-1}, force in mN mm^{-2} and force derivative in mN mm^{-2} s^{-1}.

STATISTICAL ANALYSIS

Data are expressed as mean (SD). Control values in normal hamsters and those with cardiomyopathy were compared using the Student's *t* test. The effects of eltanolone in normal hamsters and in those with cardiomyopathy were compared by repeated-measures analysis of variance and the Newman–Keuls test. All P values were two-tailed, and $P < 0.05$ was required to reject the null hypothesis.

Results

Heart weight (HW) was not significantly different between normal hamsters and those with cardiomyopathy. However, the HW/BW ratio was significantly greater in cardiomyopathic hamsters, indicating marked cardiac hypertrophy (table 1). The intrinsic mechanical performance of papillary muscles from hamsters with cardiomyopathy was significantly lower during isometric (AF) and isotonic (*v*max) twitches (table 2, fig. 1). R1 and R2, which test lusitropy under low and high load, were not significantly different between the two groups.

Eltanolone induced no significant inotropic effect on normal muscles, as shown by the absence of changes in *v*max and AF (table 3). There were no differences in these inotropic variables between normal hamsters and those with cardiomyopathy (table 3). Under isotonic conditions, eltanolone had no significant lusitropic effect (R1), and there were no significant differences between normal hamsters and those with cardiomyopathy (table 3). Under isometric conditions, eltanolone had no significant lusitropic effect (R2) in normal hamsters, and no significant differences were noted between normal hamsters and those with cardiomyopathy (table 3).

AF (mN mm^{-2})	35 (14)	8 (3)*
R1	0.94 (0.12)	1.02 (0.14)
R2	1.57 (0.13)	1.47 (0.19)

Discussion

We have observed that eltanolone induced no significant effects on the intrinsic mechanical properties of left ventricular papillary muscles from normal hamsters, and that there were no significant differences in the effects of eltanolone in normal hamsters and those with cardiomyopathy.

Eltanolone did not modify contraction–relaxation coupling under low load (Rl). Under isotonic conditions, the amplitude of sarcomere shortening is twice that observed under isometric conditions,[18] and the time course of isotonic relaxation occurs earlier and more rapidly than that of isometric relaxation, partly via two mechanisms[19]: (1) easier removal of calcium from troponin C caused by a decrease in myofilament calcium sensitivity; and (2) rapid uptake of calcium by the SR. Under low load, the SR appears to

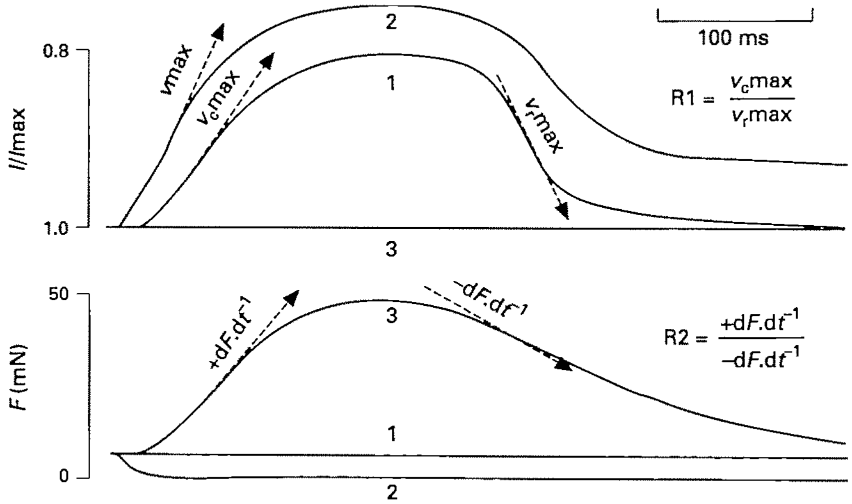

Figure 1 Mechanical variables of contraction and relaxation. Top: Muscle shortening length (*l*/*l*max) *vs* time. Bottom: Force (*F*) *vs* time. Twitch 1 was loaded with preload only at *l*max. Twitch 2 was loaded with the same preload as twitch 1 and was abruptly clamped to zero load just after the electrical stimulus. Twitch 3 was fully isometric.

Table 3 Comparison of the effects of eltanolone on left ventricular papillary muscles from normal ($n = 8$) and cardiomyopathic hamsters ($n = 13$). *v*max = Maximum unloaded shortening velocity; AF = isometric active force normalized per CSA; R1 = contraction–relaxation coupling under low load; R2 = contraction–relaxation coupling under high load. Values are mean (SD) percentage of control values. No significant differences between groups

play a major role in the regulation of isotonic relaxation. Therefore, our results suggest that eltanolone did not modify uptake of calcium by the SR. This result agrees with that obtained previously in rat myocardium.[5]

Contraction–relaxation coupling under high load (R2) was not modified by eltanolone. Under isometric conditions and because of slight sarcomere shortening, myofilament calcium sensitivity is decreased less than under isotonic conditions and becomes the limiting step that appears to play a major role in the regulation of the time course of isometric relaxation. The absence of any lusitropic effect of eltanolone under high load suggests that it did not modify myofilament calcium sensitivity, as reported previously in rat myocardium.[5]

Genetically induced cardiomyopathy in Syrian hamsters is characterized by progressive occurrence of focal myocardial degeneration, fibrosis and calcifications during the life of the animal.[8 9] At age 30–40 days, histological lesions become apparent and myocardial performance decreases. Additional cardiac changes include hypertrophy, or dilatation, or both, depending on the strain, then congestive heart failure and death. In our study, myocardial contractility was impaired markedly in cardiomyopathic muscles, as reflected by the decrease in *v*max and AF (table 2). Decreased myocardial contractility in cardiomyopathic hamsters may be explained by decreased activity of G proteins,[22] decreased sarcolemmal Ca^{2+} and Na^+–K^+ ATPase activities,[23] alterations in Na–Ca exchange,[24] decreased conductance and density of voltage-sensitive calcium channels,[25] alterations in the creatine kinase system,[26] and alteration in myofilament regulatory proteins.[27] Nevertheless, a decrease in SR function is not observed in all strains, and the strain used in our study (BIO 14.6) which develops hypertrophic cardiomyopathy has been shown to exhibit normal SR function.[28] In this study, the lack of significant increase in R1 is consistent with these results and concords with results obtained previously in other strains with hypertrophic cardiomyopathy.[29]

Because of the complex action of anaesthetic agents on cardiac muscle and because of the various pathological changes observed in the myocardium of cardiomyopathic hamsters, it is not easy to predict the mechanical effects of anaesthetic agents on this diseased myocardium. Indeed, it has been demonstrated that the mechanical effects of ketamine[6] and etomidate[7] differ in normal and cardiomyopathic hamsters. In contrast, in this study, we observed that the mechanical effects of eltanolone did not differ in left ventricular papillary muscles from normal and cardiomyopathic hamsters.

The following points must be considered in the assessment of the clinical relevance of our results. First, because this study was conducted *in vitro*, it dealt only with intrinsic myocardial contractility. Observed changes in cardiac function after *in vivo* administration of eltanolone also depend on modifications in venous return, afterload and compensatory mechanisms. This point should be of special importance in patients with cardiomyopathy whose cardiac function depends not only on intrinsic contractility but also on preload, postload and sympathetic activity. Second, this study was conducted at 29 °C and at a low stimulation frequency; however, papillary muscles must be studied at this temperature because stability of mechanical variables is not sufficient at 37 °C and at a low frequency because high stimulation frequency induces core hypoxia.[30] Moreover, higher stimulation rates frequently induce extrasystoles in cardiomyopathic muscles, resulting in an unreliable recording of mechanical variables. Third, this study was performed on hamster myocardium, which differs from human myocardium. Furthermore, because eltanolone is highly bound to plasma proteins[13] and because the bathing solution was protein-free, the concentrations tested might be considered high.

In summary, in studies conducted on isolated left ventricular papillary muscle, eltanolone did not modify intrinsic myocardial contractility in normal hamsters, and no significant differences were observed between normal and cardiomyopathic hamsters. These results could be important as most anaesthetic agents decrease myocardial contractility.[31]

Comparison of the effects of controlled ventilation with 100% oxygen, 50% oxygen in nitrogen, and 50% oxygen in nitrous oxide on responses to venous air embolism in pigs

J. KYTTÄ, P. TANSKANEN AND T. RANDELL

Summary

In this randomized, experimental study in 18 pigs, we have investigated the effects of inspiratory air in oxygen, 100% oxygen and 50% nitrous oxide in oxygen on the detection and consequences of venous air embolism. Each animal was tested with injections of 1.0 ml kg^{-1} and 2.0 ml kg^{-1} of air. All animals, except one in the nitrous oxide group, survived the air emboli. Systolic and diastolic arterial pressures decreased significantly in all groups after both injections of air. Pulmonary diastolic pressures increased most in the nitrous oxide group. End-tidal concentration of carbon dioxide decreased significantly in all groups after air injections. The difference in concentration of oxygen in the inspiratory and expiratory gas (O_2 (I − E)) was lowest in the air group after both injections of air. On the basis of our studies we suggest that nitrous oxide should not be used during surgery associated with an increased risk of venous air embolism. (*Br. J. Anaesth.* 1996; **77:** 658–661)

Key words

Oxygen, inspired concentration. Ventilation, mechanical. Anaesthetics gases, nitrous oxide. Embolism, air. Pig.

The incidence of venous air embolism (VAE) has varied from 6% to more than 30% in patients undergoing surgery in the sitting position[1–3] and episodes of VAE have also been reported during orthopaedic operations.[4] Suggested alternatives for maintenance of anaesthesia during posterior fossa surgery include volatile anaesthetics in 100% oxygen, in nitrous oxide in oxygen or in air in oxygen.[5–7] Using nitrous oxide may facilitate detection of VAE,[8] but on the other hand, nitrous oxide may increase the size of the air bubbles and may therefore be detrimental. However, Losasso and co-workers[7] did not find any differences in the incidence of VAE in neurosurgical patients receiving 50% nitrous oxide in oxygen or 100% oxygen as part of isoflurane and fentanyl-based anaesthesia.

In a previous experimental study we demonstrated a decrease in airway compliance and an increase in pulmonary diastolic pressure after VAE during ventilation with 100% oxygen.[6] Simultaneous administration of nitrous oxide may further increase pulmonary vascular resistance in the case of VAE. Therefore, in this randomized, experimental study in pigs, we investigated the effects of three different mixtures of inspiratory gases, one of which included 50% nitrous oxide, on the detection and consequences of air embolism.

Materials and methods

The study was approved by the Animal Use and Care Committee of the hospital. We used 18 domestic pigs, weighing 17–22 kg, and the animals were unpremedicated. A vein on one ear was cannulated and Ringer's acetate was given i.v. Glycopyrronium 10 μg kg^{-1} was administered and anaesthesia was induced with a sleep dose of thiopentone. Pancuronium 0.2 mg kg^{-1} was used to facilitate tracheal intubation. Before instrumentation, fentanyl 5 μg kg^{-1} was given. Anaesthesia was maintained with isoflurane and nitrous oxide in 50% oxygen (six animals, nitrous oxide group), 100% oxygen (six animals, oxygen group) or 50% oxygen in nitrogen (six animals, air group). The concentration of isoflurane was adjusted to produce 0.7 MAC in a pig. The gas mixture used was selected randomly. Pancuronium, in 1-mg increments, was given as needed to maintain the animal paralysed throughout the experiment. The anaesthetic technique was similar to that used in patients undergoing surgery in the sitting position.

The ventilator used was a Servo 900C (Siemens Elema, Sweden). The inspiration–expiration flow ratio was set to 25% and the pause time to 10%. Ventilatory frequency was set to 20 bpm and tidal volume was adjusted to maintain $P\text{E}'_{CO_2}$ at 4.0–4.5%.

A side-stream spirometer (Datex Ultima, Instrumentarium, Finland) was connected to the ventilator tubing, providing continuous information on lung compliance, tidal volume and minute volume. The difference in concentration of oxygen in the inspiratory and expiratory gas (O_2 (I − E)), inspiratory and end-tidal isoflurane concentrations and $P\text{E}'_{CO_2}$ were analysed continuously and displayed on the same monitor screen.

One of the femoral arteries was cannulated for continuous monitoring of arterial pressure. A pulmonary artery catheter (size 5-French gauge) was

Accepted for publication: July 10, 1996.

introduced through the right jugular vein. Pulmonary artery pressures were monitored continuously. Haemoglobin saturation of oxygen (Sp_{O_2}) and ECG were monitored continuously.

Baseline values of arterial and pulmonary artery pressures, cardiac rhythm and rate, Sp_{O_2} and ventilatory variables were recorded. Air was then injected via the peripheral vein at a rate of 1 ml s^{-1}. Haemodynamic and ventilatory variables were recorded at the end of and 30 s after injection, and then at 1-min intervals for 10 min and every 2 min for another 10 min. The ratios of systolic arterial and pulmonary pressures were calculated after both injections of air to evaluate the magnitude of changes in pulmonary pressures at the time of ensuing circulatory collapse.

Each animal was tested with two injections of air. The volumes and order of injections were 1.0 ml kg^{-1} and 2.0 ml kg^{-1} and they were given 50 min apart. The doses used were based on our previous study.[6] After the experiment, the animals were killed with a toxic dose of barbiturate and i.v. injection of air 10 ml kg^{-1}.

Data were analysed using ANOVA. If significant differences were observed, the Fisher PLSD test was used for *post hoc* analysis. The results are presented as mean (SEM). $P < 0.05$ was considered statistically significant.

Results

All animals, except one, survived the air emboli; in one pig in the nitrous oxide group, 8 min after injection of 2.0 ml kg^{-1} of air, electromechanical dissociation was noted. No attempt was made at cardiopulmonary resuscitation and the results obtained after injection of 2.0 ml kg^{-1} of air in this animal were omitted from the analysis.

After injection of 1.0 ml kg^{-1} of air, systolic and diastolic arterial pressures decreased significantly in all groups and returned to baseline values within 5 min (table 1). After injection of 2.0 ml kg^{-1} of air, a significant decrease in systolic and diastolic pressures was observed in all groups at 30 s after the end of injection (table 2). At 16 min, systolic arterial pressure increased to a significantly higher level in the nitrous oxide group compared with the other groups (122 (6) mm Hg in the air group, 126 (7) mm Hg in the oxygen group and 156 (15) mm Hg in the nitrous oxide group; $P < 0.05$). The differences between the groups persisted to the end of the study period.

Pulmonary diastolic pressures increased after injection of air and the highest pressures were observed in the nitrous oxide group (fig. 1). The ratios of systolic pressures were highest in the nitrous oxide group after injection (fig. 2).

In the oxygen group, heart rate decreased from 140 (12) to 125 (13) beat min^{-1} at 30 s ($P < 0.05$) after injection of 1.0 ml kg^{-1} of air, and remained at this level until the end of the first study period. No significant changes were noted in the other groups. After injection of 2.0 ml kg^{-1} of air, changes in heart rate were not significant until 10 min, when heart rate had increased from 155 (7) to 194 beat min^{-1} in the nitrous oxide group ($P < 0.05$). At 8 min, heart rate was significantly higher in the nitrous oxide group than in the other groups (147 (15) beat min^{-1} in the air group, 136 (13) beat min^{-1} in the oxygen group and 194 (17) beat min^{-1} in the nitrous oxide group; $P < 0.05$). Heart rate remained significantly higher to the end of the study in the nitrous oxide group.

End-tidal concentration of carbon dioxide decreased significantly in all groups at 30 s after injection of 1.0 ml kg^{-1} of air and immediately after injection of 2.0 ml kg^{-1} of air (fig. 3).

There were no significant decreases in arterial saturation of oxygen after injection of 1.0 ml kg^{-1} of air. After injection of 2.0 ml kg^{-1} of air, Sp_{O_2} decreased from 100% to 77 (5) % in the nitrous oxide group ($P < 0.01$ between nitrous oxide and other groups). In the air group, the lowest observed Sp_{O_2} value was 88 (7) % at 5 min ($P < 0.05$ compared with

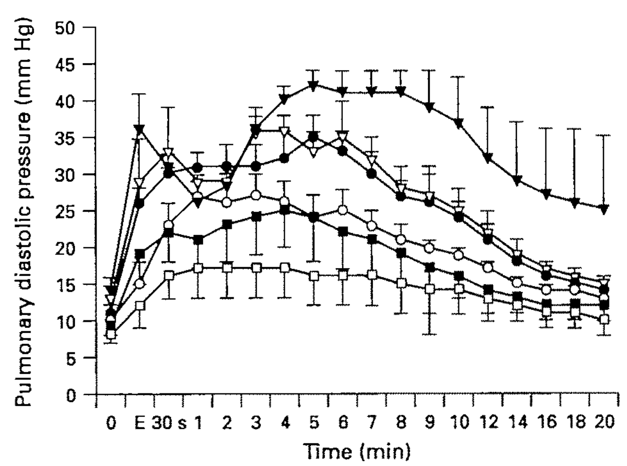

Figure 1 Changes in pulmonary diastolic pressure after injection of air: air group 1.0 ml kg^{-1} (●) and 2.0 ml kg^{-1} (○) of air, respectively; oxygen group, 1.0 ml kg^{-1} (■) and 2.0 ml kg^{-1} (□) of air, respectively; nitrous oxide group, 1.0 ml kg^{-1} (▼) and 2.0 ml kg^{-1} (▽) of air, respectively. 0 = Baseline, E = immediately after the end of injection of air. There were significant increases after injection of 1.0 ml kg^{-1} of air ($P < 0.001$) in the air group and nitrous oxide group immediately after the end of injection (E), and in the oxygen group at 30 s. Values returned to baseline at 18 min in the air group and at 14 min in the oxygen and nitrous oxide groups. There were significant differences ($P < 0.05$) between the oxygen and nitrous oxide groups from baseline to 18 min and significant increases after injection of 2.0 ml kg^{-1} of air in the air group ($P < 0.001$) from immediately after the end of the injection (E) to 12 min , in the oxygen group ($P < 0.001$) from E to 8 min, and in the nitrous oxide group ($P < 0.01$) at E, and again from 3 min to 12 min. There were significantly lower values in the oxygen group ($P < 0.05$ or $P < 0.01$) from baseline to 1 min, and from 4 min to 16 min.

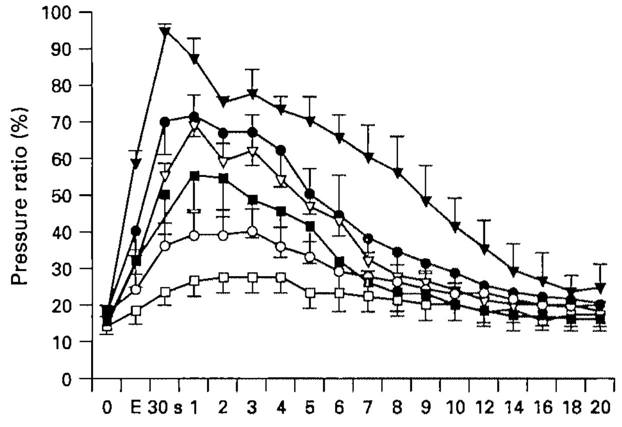

Figure 2 Changes in systolic pressure ratios after injection of air: air group 1.0 ml kg^{-1} (●) and 2.0 ml kg^{-1} (○) of air, respectively; oxygen group, 1.0 ml kg^{-1} (■) and 2.0 ml kg^{-1} (□) of air, respectively; nitrous oxide group, 1.0 ml kg^{-1} (▼) and 2.0 ml kg^{-1} (▽) of air, respectively. 0 = Baseline, E = immediately after the end of injection of air. There were significant increases after injection of 1.0 ml of air ($P < 0.05$) in the nitrous oxide group immediately after injection of air (E) and in all groups at 30 s ($P < 0.001$). Values returned to baseline at 9 min in the air group, 16 min in the oxygen group and 7 min in the nitrous oxide group. There were significant differences between the groups: $P < 0.05$ at E, 3 and 5 min, oxygen *vs* nitrous oxide group; $P < 0.001$ at 30 s, 1 and 2 min, and $P < 0.05$ at 4 min, nitrous oxide *vs* other groups. After injection of 2.0 ml kg^{-1} of air, there were significant increases at the end of injection: $P < 0.001$ in the air and nitrous oxide groups immediately after the end of injection (E), $P < 0.01$ in the oxygen group at E and $P < 0.001$ at 30 s. Values returned to baseline at 12 min in the air group, at 8 min in the oxygen group and at 16 min in the nitrous oxide group. There were significantly higher values in the nitrous oxide group: $P < 0.05$ from E to 3 min, at 5 min, and from 9 min to 12 min, $P < 0.01$ from 6 min to 8 min.

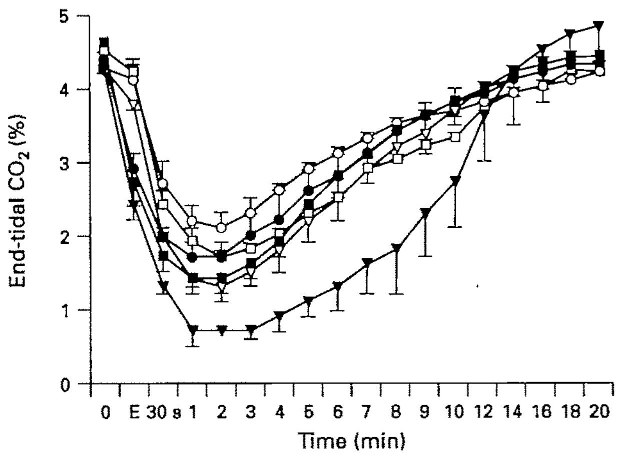

Figure 3 Changes in end-tidal concentration of carbon dioxide (CO_2) after injection of air: air group 1.0 ml kg^{-1} (●) and 2.0 ml kg^{-1} (○) of air, respectively; oxygen group, 1.0 ml kg^{-1} (■) and 2.0 ml kg^{-1} (□) of air, respectively; nitrous oxide group, 1.0 ml kg^{-1} (▼) and 2.0 ml kg^{-1} (▽) of air, respectively. 0 = Baseline, E = immediately after the end of injection of air. There were significant decreases after injection of 1.0 ml kg^{-1} of air ($P < 0.001$) from 30 s to 7 min in the air group, to 14 min in the oxygen group and to 9 min in the nitrous oxide group. Values returned to baseline at 12 min in the air and nitrous oxide groups. In the oxygen group, there were significant differences ($P < 0.05$) at 20 min compared with baseline. Differences between the groups: $P < 0.05$ between the air group and nitrous oxide group at 1, 2, 3, 6 and 8 min, and between the air group and other groups at 4 and 5 min. There were significant decreases after injection of 2.0 ml kg^{-1} of air: in the air group, $P < 0.05$ at 8 min, $P < 0.001$ from E to 7 min; in the oxygen group, $P < 0.05$ at 14 and 16 min, $P < 0.01$ at 12 min, $P < 0.001$ from E to 10 min; in the nitrous oxide group, $P < 0.05$ at 10 min, $P < 0.01$ from E and 9 min, $P < 0.001$ from 30 s to 8 min. Values were lowest in the nitrous oxide group: $P < 0.05$ at 30 s and at 9 min, $P < 0.01$ from 1 min to 8 min.

baseline) and in the oxygen group 80 (15) % at 1 min ($P < 0.05$ compared with baseline). In the nitrous oxide group the lowest recorded value was noted at 8 min, but on several occasions poor perfusion to the tail rendered monitoring of Sp_{O_2} impossible.

The difference in concentration of oxygen in the inspiratory and expiratory gas (O_2 (I − E)) was lowest in the air group after both injections of air (fig. 4).

Changes in airway compliance were similar in all groups. After injection of 1.0 ml kg^{-1} of air, compliance decreased from 21 (2) to 19 (2) ml cm H_2O^{-1} in the air group at 5 min ($P < 0.05$), from 20 (2) to 19 (2) ml cm H_2O^{-1} in the oxygen group at 30 s ($P < 0.01$) and from 20 (1) to 17 (1) ml cm H_2O^{-1} in the nitrous oxide group at 1 min ($P < 0.05$). After injection of 2.0 ml kg^{-1} of air significant changes occurred at 30 s, and were from 18 (2) to 16 (3) ml cm H_2O^{-1} ($P < 0.01$), from 17 (2) to 16 (2) ml cm H_2O^{-1} ($P < 0.05$) and from 16 (2) to 14 (1) ml cm H_2O^{-1} ($P < 0.05$) in the air, oxygen and nitrous oxide groups, respectively.

Discussion

The haemodynamic changes after VAE were slightly smaller than those noted in our previous study, in which three doses of air were injected into the right atrium at 50-min intervals.[6] In this study, air was injected via a peripheral vein in an attempt to better mimic an air embolism during craniotomy. Furthermore, we evaluated only the effects of two doses of

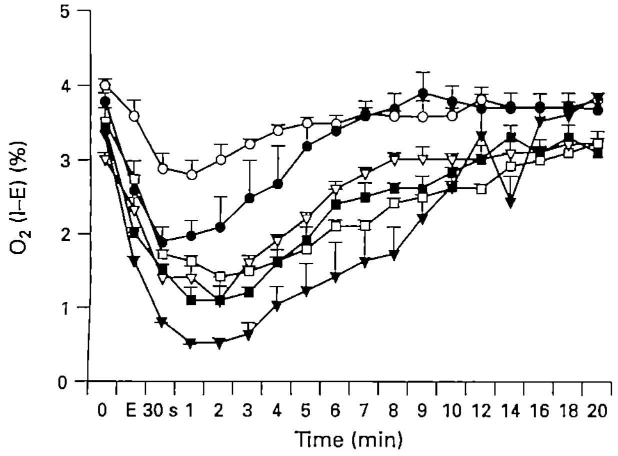

Figure 4 Changes in the difference in concentration of oxygen in the inspiratory and expiratory gas (O_2 (I – E)) after injection air: air group 1.0 ml kg^{-1} (●) and 2.0 ml kg^{-1} (○) of air, respectively; oxygen group, 1.0 ml kg^{-1} (■) and 2.0 ml kg^{-1} (□) of air, respectively; nitrous oxide group, 1.0 ml kg^{-1} (▼) and 2.0 ml kg^{-1} (▽) of air, respectively. 0 = Baseline, E = immediately after the end of injection of air. There were significant decreases after injection of 1.0 ml kg^{-1} of air: in the air group, $P < 0.05$ from 6 min to 10 min, $P < 0.01$ at 5 min, $P < 0.001$ from 30 s to 4 min; in the oxygen group, $P < 0.01$ at 14 and 16 min, $P < 0.001$ from E to 12 min; in the nitrous oxide group, $P < 0.05$ at 6 min, $P < 0.01$ at E, $P < 0.001$ from 30 s to 5 min. Differences between groups: air group *vs* other groups, $P < 0.01$ at 0 to 4 min, and from 14 min to 20 min, all other times significant differences ($P < 0.001$) between all groups. There were significant decreases after injection of 2.0 ml kg^{-1} of air in the air group: $P < 0.01$ at E, 3 and 4 min, $P < 0.001$ from 30 s to 2 min; in the oxygen group $P < 0.05$ at 16 min, $P < 0.01$ at 10 and 12 min, $P < 0.001$ from E to 9 min; in the nitrous oxide group, $P < 0.05$ at 9 min, $P < 0.001$ from E to 8 min. Differences between groups: $P < 0.05$ at 0 min between air group and nitrous oxide group. Significant differences between all groups from E to 10 min.

air, thus the cumulative effect of VAE was expected to be less evident. Our previous results suggested that some air can remain in the pulmonary circulation thus creating cumulative effects of two air emboli.[6]

It has been suggested that 50% nitrous oxide in the inspiratory gas mixture can be used safely provided it is discontinued after VAE has occurred.[7] We did not include discontinuation of nitrous oxide in our study design because in a clinical situation diagnosis of VAE can be delayed or missed. Furthermore, even if VAE is diagnosed promptly, nitrous oxide cannot be washed out immediately.

We observed marked increases in pulmonary pressures after VAE, consistent with previous results.[6] The changes were most prominent in animals receiving nitrous oxide. Similar changes have been observed after venous carbon dioxide embolism in experimental animals.[9] The increases in pulmonary pressures in this study not only reflected changes in pulmonary vascular resistance, but also mechanical block caused by air embolism. Cardiac output was not measured in this study because injection of air (which conducts heat poorly) would have affected the thermodilution technique.

The small haemodynamic changes after VAE in the oxygen group suggested that the use of 100% inspiratory oxygen is preferable to oxygen in air when there is increased risk of VAE during surgery.

A study be Vik and co-workers demonstrated that when VAE exceeds a certain threshold volume, breakthrough of air from pulmonary arteries to the systemic circulation occurs.[10] The volumes used in their study were comparable with those we injected. Even small bubbles of air may be detrimental in end arteries and nitrous oxide aggravates these effects by enlarging the size of the bubbles.

Changes in the inspiratory to expiratory end-tidal oxygen difference in healthy subjects are not dependent on cardiac output but on ventilation and metabolism.[11] In our earlier report, oxygen extraction diminished progressively with VAE.[6] In the present study, the changes were greater in the nitrous oxide and oxygen groups than in the air group. We used a constant minute ventilation and metabolism can be assumed to be similar in the animals. Thus we speculate that our observations are in part related to greater oxygen reserves in the oxygen group resulting in decreased uptake of oxygen when acute VAE caused diminished gas exchange. The difference between the nitrous oxide and air groups may be a manifestation of a greater decline in the gas exchange capacity in the former group, probably as a result of enlarged air bubbles.

In summary, on the basis of our studies we suggest that nitrous oxide should not be used during surgery associated with an increased risk of venous air embolism.

SHORT COMMUNICATION

Use of the fibrescope–video camera system for difficult tracheal intubation

K. AOYAMA, I. TAKENAKA, T. SATA AND A. SHIGEMATSU

Summary

We describe an alternative technique for difficult intubation using a fibrescope and a video camera system. The fibrescope attached to the video camera was passed nasally, which provided a view of the larynx on the monitor screen. Then the operator inserted a tracheal tube into the trachea orally using a second fibrescope or a stylet under video visual control. This technique permits a view of the tube passing through the vocal cords in patients who present difficulty in intubation. (*Br. J. Anaesth.* 1996; **77**: 662–664)

Key words

Intubation tracheal. Intubation tracheal, technique. Intubation tracheal, difficult. Equipment, fibrescope. Equipment, video camera.

Fibreoptic intubation is a reliable method for tracheal intubation in patients with difficult airways.[1 2] However, advancement of the tracheal tube over the fibrescope cannot be seen by conventional techniques. Despite intratracheal placement of the fibrescope, difficulty can be encountered while passing the tracheal tube through the vocal cords because the tube bevel is caught on the laryngeal structure.[1–3] Although rotating the tube while re-advancing may solve the problem, several attempts are sometimes required and damage to the larynx may occur.[2] In addition, the blindly advanced tracheal tube may enter the oesophagus, and its recognition is occasionally difficult.[2 4] We report an alternative intubation technique using a fibrescope attached to a video camera monitor system, which permits a view of passage of the tube into the glottis in patients who present with difficulty in intubation.

Methods and results

A 51-yr-old, 55-kg man was undergoing partial gastrectomy. His previous anaesthetic record revealed that the lungs had been ventilated easily by mask, while intubation with direct laryngoscopy was impossible. Fibrescope-guided oral intubation had been performed, but difficulty had been encountered while advancing the tube over the fibrescope. Even with the jaw thrust manoeuvre or with an aid of a rigid laryngoscope, multiple attempts at fibreoptic intubation had been required. During attempts, oesophageal intubation had occurred which was recognized by capnography. This history was explained to the patient, but he refused awake intubation. Thus we planned to insert a fibrescope attached to a video camera into the nasopharynx to observe advancement of the tracheal tube during oral fibreoptic intubation.

The patient was monitored by electrocardiography, indirect arterial pressure, pulse oximetry and capnography. After induction of general anaesthesia with thiopentone 250 mg, the patient's lungs were ventilated easily with 1–2% isoflurane in oxygen via a face mask. Neuromuscular block was produced with vecuronium 6 mg. After administration of a vasoconstrictor, a 6.5-mm i.d. Linder nasopharyngeal airway was inserted into the nostril and an Ovassapian intubating airway into the mouth. During mask ventilation, a 4.9-mm o.d. fibreoptic bronchoscope (FOB, Olympus, BF P-30) attached to a video camera monitor system (Olympus, OTV-F3) was passed through a face mask diaphragm into the nasopharyngeal airway by an assistant and a complete view of the glottis was displayed on the television screen (fig. 1).

After the mask was removed with the FOB left in place through the mask diaphragm, the operator inserted another fibreoptic laryngoscope (FOL, Olympus, LF-1), which was passed into the tracheal tube previously, through the airway intubator into the pharynx. The FOL was passed easily into the trachea, but the tracheal tube could not be advanced over the FOL. The tracheal tube caught on the right arytenoid cartilage was seen on the video monitor. The tracheal tube was then advanced with rotation and passed through the cords under video visual control. After passage of the tube through the glottis into the trachea was confirmed visually on the monitor screen, the FOB and FOL were removed. Successful intubation was confirmed further by capnography and clinical signs. Anaesthesia was

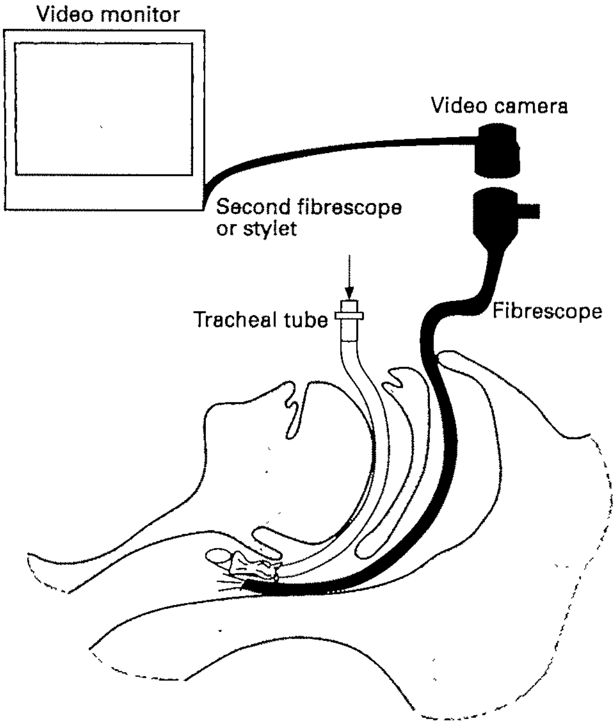

Figure 1 Intubation technique using a fibrescope and a video camera system. The fibrescope attached to the video camera is passed into the nasopharynx, which provides a view of the larynx on the video monitor. An operator can insert a tracheal tube into the trachea orally using a second fibrescope or a stylet under video visual control. This technique permits a view of passage of the tube into the glottis in patients who present with difficulty in intubation.

maintained with isoflurane and nitrous oxide in oxygen. Surgery and recovery were uneventful.

A 62-yr-old, 65-kg man was undergoing acromioplasty. Preanaesthetic examination revealed Mallampati class 2 and one-third reduction of atlanto–occipital joint extension. Anaesthesia was induced with fentanyl 100 μg and thiopentone 300 mg, and neuromuscular block was produced with vecuronium 7 mg. With conventional laryngoscopy, only the epiglottis could be seen despite application of external laryngeal pressure and manipulation of the head position. Several attempts using a straight blade, a longer Macintosh blade (No. 4) or a curved stylet were made by two experienced anaesthetists, but intubation failed. Then, the view of the larynx was obtained on a video monitor using an FOB and a video camera, as described in the first patient. The operator inserted a tracheal tube, equipped with a lubricated curved stylet, into the mouth with the jaw pulled forward and advanced the tracheal tube into the glottis under video visual control. Passage of the tube between the cords was confirmed visually. Successful placement of the tube was confirmed further by capnography.

Comment

This is the first report of tracheal intubation performed under video visual control in patients presenting with difficulty in intubation. The fibrescope, attached to the video camera and passed nasally, provided an excellent view of the larynx on the monitor screen, even in patients who presented with difficulty in intubation, during and after intubation. When fibreoptic-guided oral intubation was performed using a second fibrescope, this technique allowed a view of advancement of the tracheal tube over the second fibrescope. When difficulty was encountered while passing the tracheal tube through the cords, we rotated the tube and re-advanced it under video visual control. We did not re-advance the tube blindly, as a blind manoeuvre, even with the aid of a rigid laryngoscope, had been difficult previously. In our experience, direct vision of the tube rotation and tube advancement could help to introduce the tracheal tube into the glottis smoothly and so avoid tissue damage. In addition, our technique permits a view of the tube passing through the vocal cords, which could be useful in confirming correct placement of the tracheal tube. Intratracheal placement of the tube should be confirmed further by capnography, oximetry and traditional clinical signs after this technique. Another advantage of our technique is that both the operator and assistants can view the airway, and therefore help each other.

We could easily perform oral tracheal intubation using a stylet instead of the second fibrescope, as described in the second patient. This technique requires only one fibrescope. The tracheal tube with the curved stylet as a hockey stick could be placed around the tongue without the use of a laryngoscope and introduced into the trachea under video visual control. This technique can be used in combination with a bougie.

The concept of our technique seems to be similar to that of some rigid fibreoptic laryngoscopes, including the Bullard laryngoscope, the Upsherscope and the Wu scope system, which permit a view of passage of the tube through the glottis on a video monitor. Although these devices may be available in patients with difficult intubation, there are some cases in which the rigid blade or fixed intubating mechanism, or both, was unsuitable.[5] Our technique may be an acceptable alternative in these patients because a flexible fibrescope can be manipulated freely to view the glottis and the tracheal tube can be controlled independently with a second fibrescope or a stylet.

A disadvantage of our technique is the necessity to use the nasal route, some equipment and an assistant. Our technique may be unsuitable in patients with coagulopathy, intranasal pathology and basilar skull fracture. Although there is the potential for nasal bleeding, we used the vasoconstrictor and the Linder nasopharyngeal airway to avoid this. This airway can be inserted with a soft inflatable introducer, which can minimize tissue damage.[6]

We suggest that the use of the fibrescope–video camera system may be available for management of difficult intubation. This technique may be useful where conventional fibreoptic techniques are difficult or fail. Then, if only one fibrescope is available, the technique used in the second case can be used. However, further studies are needed to determine the usefulness of this technique.

CASE REPORTS

General anaesthesia for Caesarean section in a parturient with Noonan's syndrome

H. A. McLure and S. M. Yentis

Summary

We describe the anaesthetic management of a parturient with Noonan's syndrome. Her problems included severe cardiac disease, facial abnormalities and extreme phobia to needles. After intrauterine death at 30 weeks' gestation, induction of labour was attempted and extradural analgesia initiated using low-dose bupivacaine. She failed to progress and underwent Caesarean section under general anaesthesia using awake oral fibreoptic intubation. (*Br. J. Anaesth.* 1996; **77**: 665–668)

Key words
Complications, Noonan's syndrome. Complications, cardiomyopathy. Anaesthesia, obstetric.

Noonan's syndrome is a clinical entity resembling Turner's syndrome but with a normal karyotype.[1] Features include facial, skeletal and cardiovascular abnormalities. There has been only one case report of anaesthesia for Caesarean section in a parturient with Noonan's syndrome, using regional anaesthesia.[2] We describe the management of a parturient with Noonan's syndrome who required analgesia for labour, then general anaesthesia for Caesarean section.

Case report

A 25-yr-old primigravida with Noonan's syndrome was referred to the obstetric anaesthetic high-risk clinic at 14 weeks' gestation. She was known to have cardiomyopathy, and was under regular cardiological review having undergone pulmonary, aortic and mitral valvotomy with excision of left and right ventricular outflow obstruction at the age of 12 yr. Her maintenance therapy included iron supplementation, digoxin 250 μg, amiloride 5 mg and frusemide 40 mg once daily, and sotalol 40 mg twice daily. Haematological investigation revealed no coagulation or platelet defects. She had atrial fibrillation (AF) with a dilated left atrium and so was at risk of embolic events. She therefore received the low molecular weight heparin (LMWH) enoxaparin 40 mg s.c. once daily, which was changed to warfarin at 12 weeks' gestation after small vaginal bleeds. She was dyspnoeic on climbing one flight of stairs and had occasional palpitations associated with dyspnoea and chest tightness. On examination she had AF with a ventricular frequency of 110–130 bpm, arterial pressure (AP) of 110/50 mm Hg, with no evidence of cardiac failure. Chest x-ray showed evidence of previous surgery. An electrocardiogram (ECG) revealed AF, left axis deviation with left bundle branch block and septal hypertrophy. Echocardiographic findings included a dilated left atrium (5.5 cm) with mitral stenosis (estimated area 2.5 cm^2, peak gradient 23 mm Hg, mean 10 mm Hg), a hypoplastic pulmonary valve and mild regurgitation in all valves. Overall left ventricular function was impaired with a fractional shortening of 30%. The interventricular septum was thickened (1.2 cm) with no evidence of outflow tract obstruction.

Her face was typical of Noonan's syndrome with hypertelorism, downward slanting palpebral fissures and thickened hooded eyelids. She had a depressed nasal root with a wide base, small jaw, normal gape (Mallampati grade II) and a "nasal" voice. She had the characteristic "shield" chest deformity of pectus carinatum superiorly and pectus excavatum inferiorly, but minimal neck webbing. Her intelligence appeared normal, although she had a morbid fear of needles.

At 23 weeks' gestation the cardiologists stopped administration of sotalol because of concerns about its negative inotropic effects. One week later she was admitted to another hospital with pulmonary oedema and tachycardia of 150–160 beat min^{-1}. An echocardiograph showed worsened left ventricular function. She was started on propranolol 10 mg three times daily with clinical and echocardiographic improvement. After antepartum haemorrhage at 27 weeks' gestation she was admitted to our hospital. Her international normalized ratio (INR) was 3.8. Warfarin therapy was stopped and replaced with the LMWH dalteparin 5000 u. s.c. once daily. Repeat echocardiography studies were unchanged. Serial cardiotocographs (CTG) were unremarkable, and a scan at 28 weeks' showed normal fetal growth. Plans were made with the anaesthetic department for elective Caesarean section at 38 weeks. At 30 weeks the baby was noted to be less active with reduced fetal heart rate variability on CTG. On the following

Accepted for publication: May 26, 1996.

morning no fetal movements were felt. CTG failed to find a heart beat and ultrasound examination confirmed *in utero* death.

The obstetric team chose to induce labour that afternoon. After discussing the analgesic options with the patient, an extradural technique was chosen. Physical examination showed a 65-kg pregnant woman, height 157 cm, with AF: ventricular frequency 105–115 bpm, AP 100/65 mm Hg, without evidence of cardiac failure. Investigations revealed a haemoglobin concentration of 11.6 g dl^{-1}, platelets 187 × 10^9 $litre^{-1}$, prothrombin time 15 s, activated partial thromboplastin time 32 s, thrombin time 10 s, sodium 137 mmol $litre^{-1}$, potassium 3.8 mmol $litre^{-1}$, urea 2.4 mmol $litre^{-1}$ and creatinine 49 μmol $litre^{-1}$. Her last dose of LMWH had been given 20 h previously. Non-invasive AP, ECG and pulse oximetry were applied, and oxygen administered via nasal cannulae. She was extremely anxious about needles and so required EMLA for siting an i.v. cannula, then slow increments of midazolam i.v. to a total of 5 mg for insertion of the extradural catheter. Systolic AP decreased to 80 mm Hg but returned to 100 mm Hg with 250 ml of crystalloid. An extradural was sited at L2–3 in the left lateral position. Over the next 30 min she received four 5-ml extradural boluses of 0.1% bupivacaine, achieving a decrease in cold sensation to T9, but no motor block or haemodynamic instability. Dinoprostone 1 mg was then administered vaginally to induce labour, and she was started on regular oral ranitidine.

The following morning the cervix remained unfavourable. As induction of labour had proved unsuccessful the decision was made to proceed to Caesarean section. She had received no further extradural bupivacaine and no sensory block was detectable. Again anaesthetic options were discussed with the patient. She adamantly refused any invasive tests or monitoring while awake, and wished to be asleep during the operation. In view of her cardiac status, possible difficult airway and risk of acid aspiration, general anaesthesia with an awake oral fibreoptic intubation was suggested as the safest option. She agreed only after lengthy discussions with her husband.

Antisialogue premedication of glycopyrronium 200 μg was given slowly i.v. with ECG monitoring. Heart rate remained at 100–112 beat min^{-1}. She was positioned semi-recumbent with a wedge under the right hip, received 30 ml of sodium citrate 0.3 mol $litre^{-1}$ orally, ampicillin 1 g and gentamicin 80 mg i.v., and was then sedated with increments of diazepam i.v. to a total dose of 10 mg. After two 10-mg sprays of lignocaine to the oropharynx, a flexible fibreoptic bronchoscope preloaded with a size 7 armoured tracheal tube was introduced via an Ovassapian oral airway. Topical anaesthesia was achieved using a "spray-as-you-go" technique with 4 ml of 4% lignocaine. This enabled the bronchoscope to be passed easily through the cords. The tracheal tube was "railroaded" into the trachea and its position confirmed by visual inspection of the carina. General anaesthesia was induced with fentanyl 700 μg and etomidate 4 mg i.v. followed by vecuronium 6 mg i.v. and the lungs ventilated with 50% nitrous oxide in oxygen to an end-tidal carbon dioxide concentration of 4.5-5%. When anaesthetized a left radial arterial catheter, right internal jugular central venous catheter and urinary catheter were sited. She remained haemodynamically stable allowing the slow introduction of 0.5% isoflurane. Direct laryngoscopy with the tube *in situ* gave a good view of the vocal cords. After delivery of a dead male fetus, Syntocinon 10 u. was administered over 10 min. A retroplacental blood clot suggesting placental abruption as the cause of death was noted. Heart rate was 105–130 beat min^{-1}, AP 105–115/60 mm Hg, central venous pressure 22–26 mm Hg and oxygen saturation at least 99% throughout intubation and surgery. Blood loss was minimal and peroperative transfusion amounted to 1.25 litre of crystalloid. At the completion of surgery the patient was transferred to the intensive care unit for postoperative care. Tracheal extubation occurred the following morning after an uneventful night. She left hospital after an uncomplicated recovery of 7 days, and is planning a further pregnancy.

Discussion

In 1963 Dr Jacqueline Noonan, a paediatric cardiologist, described a series of nine cases with congenital heart disease associated with a phenotype similar to Turner's syndrome, but with apparently normal chromosomes.[3] The main features included pulmonary stenosis, short stature, a webbed neck and typical facial abnormalities.[4] The characteristics distinguishing it from Turner's syndrome include karyotype analysis, sex distribution, fertility, the site of the cardiac lesion, facial appearance and the presence of mental retardation.[2]

Turner's syndrome occurs exclusively in females; Noonan's, although more common in males, is found in both sexes. Males often have cryptorchidism and are rarely fertile, whereas females have normal fertility but a delayed menarche.[2] The estimated incidence is 1 in 1000 to 1 in 2000 live births. The exact incidence is unknown.[1] It follows an autosomal dominant pattern with variable penetrance and expression.[5] Maternal transmission of the gene is said to be three times more common than paternal transmission.[6] With an affected parent there is a 50% risk of subsequent children inheriting the still unknown gene.[6]

Cardiac lesions are characteristically right-sided in Noonan's syndrome, compared with left-sided in Turner's syndrome.[7–9] The most frequently reported abnormality in Noonan's syndrome is pulmonary stenosis, usually with a dysplastic pulmonary valve. The annulus is normal in size but the cusps are thickened and immobile.[1] In one series, pulmonary stenosis occurred in 62%;[1] there was an atrial septal defect in 13% and septal hypertrophy in 6%. Hypertrophic cardiomyopathy was present in 20%. Only 12.5% of patients had a normal echocardiograph.[1] Other documented cardiac lesions include patent ductus arteriosus, aortic stenosis or coarctation, polyvalvular dysplasia, ventricular septal defects, systemic venous abnormalities and Fallot's tetralogy.[8]

The facial abnormalities of Noonan's syndrome include hypertelorism with downward slanting palpebral fissures, high arched eyebrows and thickened hooded eyelids, sometimes with a ptosis.[1] There may be low set ears with a thickened helix, and coarse curly hair with a low hair line at the back. The typical flattened mid face with depressed nasal root, wide nasal base, full upper lip, high arched palate, micrognathia and dental malocclusion combined with a webbed sometimes fused neck may present a challenge to the anaesthetist, making conventional oral or nasal intubation difficult, if not impossible.[2 9 10] These facial abnormalities usually become less marked with age, and are not a feature of Turner's syndrome.[1]

Musculoskeletal abnormalities include short stature, webbed neck and cubitus valgus.[8] The chest deformity is typical and gives the appearance of widely spaced nipples.[10] It may be associated with kyphoscoliosis and respiratory compromise.[10] Other features include joint contractures, cervical spine fusion and lumbar lordosis.[1] Association of Noonan's syndrome with malignant hyperpyrexia has not been substantiated.[1]

Abnormal bleeding and bruising are often seen in Noonan's syndrome (56–74%), associated with a mixed collection of defects in the platelet and coagulation systems.[6 11 12] Isolated factor XI deficiency has been recognized as the commonest single factor deficiency, and may be treated with single factor replacement.[6] Most of the bleeding problems are mild, and may only be revealed by surgery such as dental extraction. Interestingly, cases of severe postoperative bleeding have been reported despite normal *in vitro* clotting assays and platelet counts.[6]

Other associated features with anaesthetic implications include renal dysfunction, dermatological, hearing and visual abnormalities, and hepatosplenomegaly.[1 2 5]

Our patient was known to have impaired left ventricular function with multiple valvular involvement. Her cardiac status represented a significant risk not only for any anaesthetic intervention, but also for labour. Sympathetic stimulation of a painful labour exacerbated by episodic prolonged Valsalva manoeuvres, increases in blood volume with uterine contractions or reductions with bleeding could cause significant haemodynamic instability.[13–15] To avoid precipitating ventricular failure an analgesic technique was required which would reduce sympathetic stimulation and minimize variations in heart rate, contractility and filling pressures. A cautious extradural technique using low concentrations of local anaesthetic was therefore chosen. Higher concentrations of local anaesthetic are associated with greater disturbance in cardiovascular indices.[16] Extradural opioids were not administered although we intended to use these drugs if she went into labour.

Skeletal abnormalities in Noonan's syndrome may lead to difficulties with regional anaesthetic techniques.[2] Kyphoscoliosis and lumbar lordosis may make it difficult to position the patient for axial block. The bony vertebral spinal canal may be narrowed with a normal calibre spinal cord, thereby reducing the size of the extradural space. Location of the space may be more complicated with increased problems threading the catheter and less predictable spread of local anaesthetic.[2] Additional concerns in this patient focused on her potential coagulopathy with the possibility of an extradural haematoma. She had been treated with LMWH for embolic prophylaxis although she had not had a dose for 20 h. As her coagulation screen was normal it was thought that the benefits of extradural analgesia outweighed the risk of producing an extradural haematoma. Continuous subarachnoid analgesia would have been an alternative method. Theoretically, this might carry less risk of bleeding but exposes the patient to an increased risk of post-dural puncture headache.

Many of the typical facial features of Noonan's syndrome suggest a difficult airway, and additionally our patient was pregnant with an increased risk of acid aspiration. Although she had an extradural catheter already *in situ* the block had worn off many hours previously, and it was felt that her cardiac status represented a contraindication to the dense block that would be required for surgery, especially given her refusal of invasive monitoring.[16] For safe general anaesthesia tracheal intubation would be required. A fibreoptic technique was chosen using the oral route because of concerns about her abnormal nasal anatomy. Laryngoscopy after intubation was easy, providing a view of the whole glottis. This may influence subsequent anaesthetic management, although full assessment would be required at that time. A relatively high-dose opioid–nitrous oxide–oxygen technique was used initially as opioids have a relatively benign effect on myocardial contractility avoiding drug-induced myocardial depression.

In summary, patients with Noonan's syndrome present a multiplicity of challenges to the anaesthetist, particularly with regard to cardiovascular and airway abnormalities. Their fertility and improving results from cardiac surgery in children imply an increasing number may present to anaesthetic departments requesting analgesia and anaesthesia in the peripartum period. To achieve a successful outcome for mother and baby, Noonan's parturients must be detected early in pregnancy so that time is available to order appropriate investigations and formulate a suitable plan of action between obstetricians, midwives and anaesthetists.

Acknowledgement

Use of rocuronium in a pregnant patient with an open eye injury, receiving magnesium medication, for preterm labour

R. R. GAISER AND E. H. SEEM

Summary

We present a case where rocuronium 80 mg (3 × ED_{95}) was used in a rapid sequence induction in a 80-kg pregnant patient with an open eye injury. The patient was also receiving magnesium 2 g h^{-1} i.v. for preterm labour. The expected duration for neuromuscular block of rocuronium in the absence of magnesium would be approximately 53 min; with infusion of magnesium, the duration of neuromuscular block was prolonged four-fold (215 min). It is important to remember that magnesium potentiates the effects of all non-depolarizing neuromuscular blocking agents, including rocuronium. (*Br. J. Anaesth.* 1996; **77**: 669–671)

Key words

Neuromuscular block, rocuronium. Ions, magnesium. Complications, eye injury.

Magnesium is used frequently in the USA both for pre-eclampsia as an anticonvulsant and for preterm labour. For the treatment of preterm labour, magnesium inhibits myometrial activity, but the mechanism of its tocolytic effect is unknown[1]; presumably myometrial contractility is depressed by modulating calcium uptake, binding or distribution in smooth muscle cells.[2] Serum concentrations of 4–8 mmol $litre^{-1}$ are required. Maternal side effects include nausea, vomiting, ileus, visual blurring, diplopia, headaches and the potential for pulmonary oedema.[3] Magnesium also causes increased sensitivity to neuromuscular blocking agents.[4] We present the first report of magnesium prolonging the neuromuscular blocking effect of rocuronium. Rocuronium was chosen as this patient also had an open eye injury with the concern that suxamethonium increases intraocular pressure.

Case report

The patient was a 31-yr-old parturient with a 28-week gestation and an unremarkable prenatal course who presented for repair of a penetrating eye injury. The patient was involved in a motor vehicle accident in which she was an unrestrained passenger. She suffered temporary loss of consciousness, but presented to the emergency room with a Glasgow coma scale of 15. Her injuries included laceration to the left forehead, corneal scleral laceration and prolapsed vitreal tissue of the left eye, and a left styloid fracture. Initial vital signs on presentation were: arterial pressure 140/88 mm Hg, heart rate 95 beat min^{-1}, temperature 36.5 °C and ventilatory frequency 18 bpm. Her height was 162 cm, weight 80 kg. She was placed in a cervical collar.

A CT scan of the head and neck revealed a ruptured left globe with medial wall fracture. The view of the cervical spine was unable to exclude injury. Other laboratory values included haemoglobin concentration 12.3 g dl^{-1}, packed cell volume 36.1%, blood urea nitrogen concentration 7 mg dl^{-1}, creatinine concentration 0.6 mg dl^{-1}, prothrombin time 12.2 s, activated partial thromboplastin time 28.3 s and fibrinogen concentration 358 mg dl^{-1}. Tocodynometry and continuous Doppler fetal heart tones were commenced to monitor uterine contractile activity and fetal heart rate, respectively. Fetal heart rate was 130–140 beat min^{-1} with good long- and short-term variability. Uterine contractions were occurring every 3 min, for which she received a loading dose of magnesium 4 g, and a continuous infusion of 2 g h^{-1} was started.

She was transferred to our hospital for operative management. Additional laboratory studies before induction of anaesthesia included a magnesium concentration of 5.8 mmol $litre^{-1}$ (therapeutic range 4–8 mmol $litre^{-1}$). In the operating room, a 16-gauge i.v. catheter was inserted into her right forearm. ECG, end-tidal carbon dioxide, pulse oximetry, fetal heart rate and uterine contraction monitoring with a tocodynometer, and neuromuscular block monitoring using a Neurotechnology peripheral nerve stimulator were commenced.

The patient was premedicated with sodium bicitrate 30 ml orally and metoclopramide 10 mg i.v. After placement in left uterine displacement and 5 min of preoxygenation with 100% oxygen, anaesthesia was induced with fentanyl 200 μg, thiopentone 400 mg and rocuronium 80 mg (0.9 mg kg^{-1}, 3 × ED_{95}). At 60 s, her train of four had disappeared and her trachea was intubated under direct laryngoscopy with a 7.0 tracheal tube. The patient did not cough during intubation and arterial pressure did not

increase. Her oxygen saturation decreased to 90% but returned to 100% after intubation. Anaesthesia was maintained with isoflurane in oxygen and fentanyl.

Five minutes after induction, there was a decrease in short-term variability on the fetal heart rate monitor, with a heart rate of 140–150 beat min^{-1}. We could not detect post-tetanic facilitation until 110 min after induction and the first twitch in the train of four was detected 215 min after administration of rocuronium. When surgery was completed 6 h after induction, the patient had received a total of rocuronium 80 mg, fentanyl 450 µg and normal saline 1300 ml. The patient was transferred to the labour suite and was weaned from the magnesium infusion over the next 24-h period. The patient was discharged 6 days later with some return of vision in the left eye and no apparent adverse effects on the fetus.

Discussion

This case highlights an anaesthetic challenge of securing the airway in a pregnant patient with an open eye injury. In a pregnant trauma patient with a 28-week gestation, aspiration is a high risk. Pain from injury delays gastric emptying. The enlarging uterus during pregnancy displaces the stomach, altering the competence of the gastro-oesophageal sphincter.[5] Hormonal changes delay gastric emptying,[6] while gastrin excreted by the placenta increases the acidity of the maternal stomach contents.[7] The usual means of securing the airway in such a patient would be an awake intubation or rapid sequence induction using an induction agent, suxamethonium and cricoid pressure. However, our patient also had an open eye injury. Securing the airway by awake intubation is associated with an increase in intraocular pressure via venous congestion of the orbital veins associated with straining or coughing.[8] Suxamethonium also has been shown to increase intraocular pressure[9] with one case report of extrusion of vitreous from this increase.[10] Although pretreatment with a non-depolarizing neuromuscular blocker such as 3 mg of curare or vecuronium 1 mg has been advocated, this does not reliably prevent the increase.[11] The risk of extrusion of intraocular contents in a patient with an open eye injury given suxamethonium is rare; however, we chose to perform a rapid sequence induction using rocuronium as the neuromuscular blocking agent.

Rocuronium is a new steroidal neuromuscular blocking drug related chemically to vecuronium. However, unlike vecuronium, it is less potent with a shorter time to onset.[12] Given this shorter onset period, its use for rapid sequence induction has been investigated. Huizinga and colleagues demonstrated comparable intubating conditions with suxamethonium 1.5 mg kg^{-1}, at 60 and 90 s after administration of rocuronium 0.6 mg kg^{-1} (2 × ED_{95}).[13] Tryba and colleagues found that similar intubating conditions could be obtained with rocuronium 0.6 mg kg^{-1} or suxamethonium 1.5 mg kg^{-1}, provided the dose was administered immediately before administration of thiopentone; the conditions were less optimal if administered immediately after thiopentone.[14] Finally, Abouleish and colleagues investigated its use during Caesarean delivery. With a dose of 0.6 mg kg^{-1}, intubating conditions were poor with a thiopentone dose of 4 mg kg^{-1}; however, increasing the dose of thiopentone to 6 mg kg^{-1} improved intubating conditions.[15] If rapid securing of the airway in a patient with a contraindication to suxamethonium is necessary, rocuronium seems to be a good choice for neuromuscular block.

Rocuronium has been shown not to increase intraocular pressure.[16] Abouleish demonstrated no adverse effects on the neonate and pregnancy did not enhance its neuromuscular blocking properties. Given the gestational age of the fetus (second trimester), teratogenicity was not a concern. The dose chosen for our patient (0.9 mg kg^{-1}) was higher than the doses used in the above studies. By increasing the dose from 0.6 to 0.9 mg kg^{-1} (2 × ED_{95} to 3 × ED_{95}), the onset time decreased from 271 ± 129 s to 135 ± 79 s with excellent intubating conditions at 60 s. The duration to recovery of 25% of twitch increased from 27.3 ± 8.2 min to 53.0 ± 15.2 min.[17] We felt that rapid securing of the airway was important in this patient, as became evident from the decrease in oxygen saturation pulse oximetry reading, and we were willing to tolerate the prolonged duration. Although administration of a priming dose has been shown to reduce onset time,[18] we were concerned as the patient was receiving magnesium which increases sensitivity to non-depolarizing neuromuscular blocking agents.[19] A priming dose may have been sufficient to result in profound weakness in an awake patient.

Our patient was receiving concurrent magnesium therapy for preterm labour. Although the mechanism is unclear, magnesium has become the traditional agent used for the treatment of preterm labour. Side effects of magnesium include pulmonary oedema, sedation and potentiation of neuromuscular block. Therapeutic plasma concentrations are 4–8 mmol litre^{-1}. Our patient's magnesium concentration at the time of induction was 5.8 mmol litre^{-1}. The mechanism of its blocking effects at the neuromuscular junction is suppression of acetylcholine release at the neuromuscular junction or decrease in the depolarizing action of acetylcholine at the motor end-plate.[20] The time to achieve post-tetanic facilitation in this patient was 110 min and the time to achieve one twitch of a train of four was 215 min. Assuming that at 25% recovery of a twitch is when the first twitch of a train of four is perceptible, the duration was more than six times greater, supporting the contention that magnesium also prolongs the duration of action of rocuronium. Although isoflurane has also been shown to prolong the duration of rocuronium,[21] this effect cannot account for the dramatic increase in this our patient.

We were surprised by the obstetrician's concern for the loss of short-term variability on the fetal tracing after induction. This phenomenon has been described previously[22] and is attributed to the baby becoming anaesthetized. We do not feel that this can be attributed to rocuronium.

Isoflurane for sedation in a case of congenital myasthenia gravis

C. McBeth and T. G. L. Watkins

Summary

We describe the use of isoflurane for the management of a 3-yr-old boy with congenital myasthenia gravis who required ventilation for pneumonia. While in the intensive care unit he was sedated with isoflurane for 5 days (81 MAC-h). This provided a safe, easily controllable method of sedation which avoided the use of neuromuscular blocking agents and appeared to have no significant side effects during use. However, after it was stopped the patient developed a fine, self-limiting tremor which lasted for 2 days. Previous reports of paediatric patients sedated with isoflurane suggest that prolonged exposure may result in temporary dose-dependent neurological dysfunction, including hallucinations, ataxia and non-purposeful movements. (*Br. J. Anaesth.* 1996; **77**: 672–674)

Key words

Anaesthetics volatile, isoflurane. Complications, myasthenia gravis.

Myasthenia gravis is an acquired autoimmune disorder which is caused by a decrease in functioning postsynaptic acetylcholine receptors at the neuromuscular junction caused by their destruction or inactivation by circulating antibodies.[1 2] The disease is characterized by muscle fatigue and weakness which is exacerbated by repeated use and which recovers partially with rest. It particularly affects ocular, pharyngeal and laryngeal muscles (bulbar muscles) but may also involve proximal and distal limb muscles and respiratory muscles.[3 4]

Congenital myasthenia is an extremely rare form of the disease which presents during the first few years of life and is usually of autosomal recessive inheritance.[5] Anti-acetylcholine receptor antibodies are absent, and defective neuromuscular transmission may be a result of a variety of different causes, including acetylcholinesterase deficiency, defective resynthesis or vesicular packaging of acetylcholine, or lack of acetylcholine receptors.[5–7] Myasthenic patients are exquisitely sensitive to non-depolarizing neuromuscular blocking agents[2 3 9 10] and use of these agents should generally be avoided.[2 11]

Isoflurane has been used successfully to sedate paediatric patients in the intensive care unit. The low blood-gas solubility (blood-gas partition coefficient 1.4) allows rapid change in the level of sedation and rapid awakening when sedation has been stopped. It does not appear to have significant adverse effects on cardiovascular, renal or hepatic function[12]; however there have been some reports of temporary neurological dysfunction after prolonged sedation with isoflurane. Three cases of peripheral neuropathy which resolved spontaneously have been described in adults.[13 14] In one this was accompanied by flaccid paralysis of all four limbs which lasted for 3 months. In children, agitation, hallucinations and non-purposeful movements which resolved over 72 h have been seen after sedation with isoflurane.[15 16] We describe the use of isoflurane for sedation in a case of congenital myasthenia gravis.

Case report

A boy aged 2 yr 6 months, weighing 19.3 kg, first presented in January 1995 with a short history of choking on solids, dysarthria and partial ptosis of his right eyelid. His mother noted that he had suffered frequent falls. On examination, he had obvious ptosis which was partially compensated for by a head tilt. There was rapid resolution of the ptosis and dysarthria after administration of edrophonium 100 $\mu g\ kg^{-1}$ i.v. Serology was negative for anti-acetylcholine receptor antibodies. A diagnosis of congenital myasthenia gravis was made and oral pyridostigmine commenced at a dose of 1 mg kg^{-1}, five times per day.

He remained well until November 1995 when he developed a cough, pyrexia and vomiting, and as a result became increasingly weak because of failure to absorb oral pyridostigmine. He had a poor cough and was unable to clear secretions adequately. On examination, ventilatory frequency was 60 bpm, heart rate 140 beat min^{-1} and oxygen saturation 88% breathing air. On auscultation of the chest there were widespread coarse crepitations, particularly on the left side. His chest x-ray showed evidence of left-sided pneumonia with almost complete opacification of the left hemithorax, loss of volume and shift of the mediastinum to the left. He was commenced on antibiotic therapy, oxygen via a high-flow fixed-performance face mask and physiotherapy, but over

Correspondence to C. M.

the course of the next few hours became increasingly tired and unable to maintain satisfactory oxygen saturation breathing 60% oxygen. He was admitted to the intensive care unit for ventilation. His trachea was intubated with a 5-mm nasal tracheal tube after inhalation induction with increasing concentrations of isoflurane in 100% oxygen. His lungs were ventilated with 1.5% isoflurane in a mixture of oxygen and air via a circle system using a Roche 3100S ventilator. Total fresh gas flow was 2 litre min^{-1}. End-tidal isoflurane concentration was not measured. The inspired isoflurane concentration (range 1–2.5%) was adjusted to maintain a sedation score of 4–5 on a six-point scale modified from Ramsay and colleagues,[17] and was increased intermittently to enable physiotherapy, suctioning and other procedures to be tolerated.

Pneumonia was treated with cefotaxime 150 mg kg^{-1} day^{-1} i.v., erythromycin 100 mg kg^{-1} day^{-1} i.v. and regular physiotherapy. Erythromycin was stopped the following day because of concern about potential interference with neuromuscular transmission in myasthenic patients.[18] Nasogastric pyridostigmine 1 mg kg^{-1}, 5 times per day, was continued throughout the illness.

By day 5 in the intensive care unit his pneumonia had resolved and his clinical condition had stabilized. A total of 81 MAC-h of isoflurane[19] had been administered. At this stage, isoflurane was stopped and within 15 min the patient was awake and able to respond to commands. He opened his eyes fully, squeezed fingers to command with a strong grip and was able to lift his head off the pillow for a sustained length of time. After breathing 35% oxygen spontaneously via the tracheal tube for 40 min, his arterial blood-gas tensions were satisfactory (pH 7.55, $P\mathrm{CO}_2$ 4.3 kPa, $P\mathrm{O}_2$ 22 kPa, base excess +6.5 mmol litre^{-1}, saturation 99%) and his trachea was extubated uneventfully.

He remained in the intensive care unit breathing 28% oxygen via a face mask for another 46 h during which time he was noted to have a fine tremor. This affected all limbs, was not worsened by intentional movement and disappeared on sleeping. His axillary temperature was 36.5 °C and his metabolic and electrolyte status were normal. The tremor did not require treatment and had disappeared by the time the patient returned to the paediatric ward 2 days later. He was discharged home after 1 week.

Discussion

Congenital myasthenia consists of several extremely rare genetically determined defects, manifest as variable muscle weakness from birth.[2 5–7] It rarely presents in the neonatal period but more commonly during the first 1–2 yr of life. Antibodies to the acetylcholine receptor cannot be demonstrated and a variety of pre- and postsynaptic defects have been described.[5–7] The course of the disease tends to be non-fluctuating and compatible with long survival. As the disease is not autoimmune in nature, steroids and immunosuppressants are ineffective and treatment consists primarily of anticholinesterases. Congenital myasthenia is not to be confused with neonatal myasthenia which is seen in infants of myasthenic mothers and presents at birth. It is thought to be caused by the passage of anti-acetylcholine receptor antibodies across the placenta.[2]

In our case there was no family history of myasthenia gravis or consanguinity, and the patient's sister, who was 1 yr older, showed no sign of disease. In addition, he was antibody-negative but responded to edrophonium, indicating a diagnosis of congenital myasthenia, although the actual structural or electrophysiological abnormality has not yet been defined.

Management of patients with myasthenia gravis who require an anaesthetic or ventilation is problematic; not only does the disease itself lead to a decrease in functioning acetylcholine receptors so the response to both depolarizing and non-depolarizing neuromuscular blocking agents is abnormal,[8–10 20 21] but drugs used to treat the disease also affect the response, and therefore interpretation is difficult. Anticholinesterases inhibit plasma cholinesterase[22 23] and hence hydrolysis of suxamethonium.[24–26] In contrast, inhibition of acetylcholinesterase by anticholinesterases may in theory increase the need for non-depolarizing neuromuscular blocking agents although in practice this has not been documented.[24] As a result, different anaesthetic techniques are described which either aim to reduce the dose of neuromuscular blocking agents or avoid their use.[11 27] In addition, the disease primarily affects bulbar muscles and those of respiration and therefore the patient's ability to swallow, cough, maintain their own airway and breathe adequately is already compromised and assessment of whether or not a patient's trachea is ready to be extubated may be difficult. Clinical assessment of the patient's ability to sustain a head lift off the pillow, generate a negative inspiratory pressure of more than 25 cm H_2O and spontaneously maintain a tidal volume of more than 5 ml kg^{-1} is useful, combined with arterial blood-gas analysis to ensure that oxygenation is adequate and $P\mathrm{CO}_2$ does not exceed 6.6 kPa.[11]

In an attempt to avoid using opioids, neuromuscular blockers or cumulative doses of sedatives, we sedated this patient with isoflurane. Myasthenic patients experience some depression of neuromuscular function with isoflurane, but this does not appear to be clinically significant at concentrations of 1.5% or lower and recovery is rapid.[27 28] Isoflurane has been used for sedation in both adult and paediatric intensive care units.[13 29 30] The low blood-gas solubility and low lipid solubility allow the level of sedation to be titrated easily without drug accumulation so that patients wake up quickly when isoflurane is stopped.[30] There do not appear to be significant cardiovascular or hepatic side effects,[12 15] but concern has been voiced over the potential for nephrotoxicity. Although there have been reports of serum fluoride concentrations exceeding 50 μmol litre^{-1} in patients requiring prolonged sedation with isoflurane, none has suggested isoflurane-induced renal dysfunction.[31 32] Several reports have mentioned the occurrence of neurological dysfunction after sedation with isoflurane. In adults, three cases of peripheral neuropathy have been described.[13, 14] Two patients sedated with isoflurane for 151 and 254 h developed peripheral neuropathies which lasted 4–12 months.[13] A third patient was sedated with 1.5% isoflurane for 9 days and developed a distal sensory neuropathy on day 15 associated with decreased joint position and vibration sense which had disappeared 2 days later. At the same time, this patient developed flaccid paralysis of all four limbs, with absent reflexes. Management was supportive and recovery almost complete by 3 months.[14]

There have also been reports of neurological dysfunction in children. In one report, five of 10 children sedated with at least 70 MAC-h of isoflurane developed agitation and non-purposeful movements.[15] In another, 12 of 29 children developed ataxia, agitation, hallucinations and confusion after 0.25–1.5% isoflurane for 24–76 h. These symptoms had disappeared spontaneously by 72 h.[16] The observations in both of these reports are complicated by the fact that all children had also received opioids and benzodiazepines while in the intensive care unit, and therefore it is difficult to be certain that isoflurane was responsible for the symptoms. The mechanism by which the neurological abnormalities are caused has not yet been satisfactorily explained.[14, 16, 33] Our patient did not receive any other sedatives or hypnotics, however his underlying disease process may have been wholly or partly responsible for the tremor.

Orthotopic liver transplantation in two patients with hypertrophic obstructive cardiomyopathy

I. D. HARLEY, E. F. JONES, G. LIU, P. R. MCCALL AND P. L. MCNICOL

Summary

Orthotopic liver transplantation (OLT) in patients with end-stage liver disease is a procedure associated with high cardiac output, low systemic vascular resistance (SVR), coagulopathy and the potential for significant blood loss. A feature of hypertrophic obstructive cardiomyopathy (HOCM) is left ventricular outflow tract obstruction which may be exacerbated by reduced SVR, reduced filling pressures, tachycardia and positive inotropy. We report two cases of OLT in patients with HOCM. Our anaesthetic technique involved the use of halothane and vecuronium and avoidance of drugs causing tachycardia and positive inotropy. Management was aided by intraoperative transoesophageal echocardiography which showed that filling pressures poorly reflected end-diastolic volumes. Volume administration, vasoconstrictors and avoidance of inotropes and chronotropes reduced the outflow tract obstruction which was particularly severe in the reperfusion period. (*Br. J. Anaesth.* 1996; **77**: 675–677)

Case reports

CASE NO. 1

The patient was a 46-yr-old male with end-stage alcoholic liver disease. He had portal hypertension with severe ascites, oesophageal varices and impaired renal function. Clotting function tests showed mild coagulopathy (international normalized ratio (INR) 1.5). Preoperative transoesophageal echocardiography (TOE) was performed to evaluate a murmur heard on physical examination. It showed asymmetrical septal hypertrophy, systolic anterior motion (SAM) of the mitral valve with normal mitral morphology, mild mitral regurgitation (MR) and left ventricular outflow tract (LVOT) obstruction, and a resting gradient 36 mm Hg (fig. 1) and thus a diagnosis of hypertrophic obstructive cardiomyopathy (HOCM) was made. After nitrate provocation there was increased SAM, severe MR and an LVOT gradient of 64 mm Hg.

Anaesthesia was induced with fentanyl 6 $\mu g\ kg^{-1}$ and thiopentone 100 mg and maintained with fentanyl 3 $\mu g\ kg^{-1}\ h^{-1}$ and halothane in air and oxygen. Neuromuscular block was produced with vecuronium. Monitoring included an oximetric pulmonary artery catheter and TOE. During liver resection a baseline TOE was performed and fluid challenges were given to assess changes in left ventricular (LV) dimensions. Full cardiopulmonary bypass with heparin-bonded tubing was on standby.

Haemodynamic variables at various times are shown in table 1.

During the anhepatic stage the patient developed a low systemic vascular resistance index (SVRI) and increased cardiac index (CI). Fibrinolysis was demonstrated by a decrease in euglobulin clot lysis time and fibrinogen concentration, and 7 litre of blood were lost over 120 min. An infusion of phenylephrine was commenced and fluid was replaced according to LV dimensions on TOE rather than pulmonary capillary wedge pressure (PCWP). Veno–venous bypass (femoro–portal to axillary vein) was used electively during the anastomosis of the new liver.

On reperfusion the patient developed severe reperfusion syndrome. He also developed a severe coagulopathy and another 15 litre of blood was lost in the first hour after reperfusion. Total intraoperative blood loss was 42 litre. Vasodilatation and blood loss were associated with an increase in the severity of the LVOT obstruction measured on TOE. TOE also showed a relatively empty LV with dynamic systolic function (in spite of a PCWP of 30 mm Hg), increased SAM, severe LVOT obstruction (maximum measured gradient 120 mm Hg) and severe MR. This was treated with aggressive volume replacement and infusion of phenylephrine. Inotropes were avoided.

In the 3 h after reperfusion the degree of outflow obstruction reduced gradually as SVRI increased. His postoperative course was relatively uneventful and he was well 18 months after transplant.

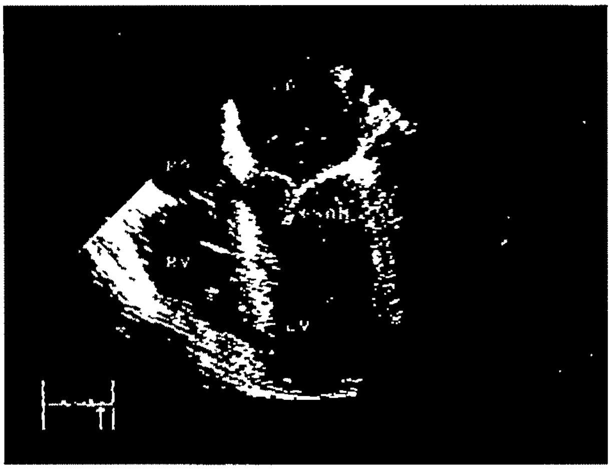

Figure 1 Patient No. 1. Transoesophageal four-chamber view showing septal hypertrophy and systolic anterior motion of the mitral valve. LA = Left atrium, LV = left ventricle, RA = right atrium, RV = right ventricle, SAM = systolic anterior motion of the mitral valve.

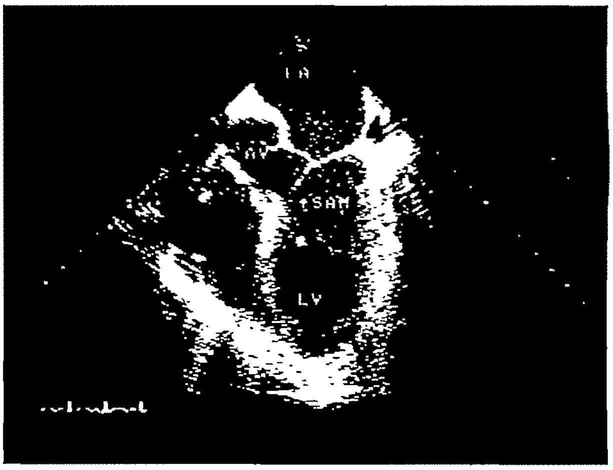

Figure 2 Patient No. 2. Transoesophageal modified four-chamber view showing small left ventricular cavity, severe systolic anterior motion of the mitral valve and almost complete obliteration of the left ventricular outflow tract (peak gradient 120 mm Hg). This was accompanied by severe mitral regurgitation on colour flow Doppler (not shown). AV = Aortic valve. Other abbreviations as in figure 1.

CASE NO. 2

The patient was a 32-yr-old female with a 16-yr history of autoimmune chronic active hepatitis. She was jaundiced, markedly cushingoid and had severe hepato–pulmonary syndrome with cyanosis and clubbing. She was an insulin-dependent diabetic secondary to steroid administration. Her renal function was normal and preoperative clotting tests showed mild coagulopathy (INR 2.0). She had a murmur but no symptoms of HOCM. Preoperative transthoracic echocardiography and TOE demonstrated severe concentric left ventricular hypertrophy, normal mitral morphology and mild SAM associated with moderate MR and an LVOT gradient of 60 mm Hg without provocation.

Anaesthesia was induced with thiopentone 250 mg and fentanyl 8 μg kg^{-1} and maintained with fentanyl 3 μg kg^{-1} h^{-1} and halothane in air and oxygen. Neuromuscular block was produced with vecuronium. Monitoring included TOE and an oximetric pulmonary artery catheter. After induction of anaesthesia, derived cardiac indices showed a hyperdynamic circulation (see table 1). However, TOE showed only mild to moderate SAM and MR and the LVOT gradient was only 12 mm Hg. Cardiac output was maintained during a 5-min trial of inferior vena cava (IVC) occlusion and therefore a decision was made to perform the proximal anastomosis without bypass. The IVC was cross-clamped for 13 min in total. Later in the anhepatic stage, TOE showed mild SAM, mild MR but an increasingly hyperdynamic left ventricle with worsening LVOT obstruction. SVRI decreased from 900 to 530 dyn s m^2 cm^{-5}. An infusion of phenylephrine was therefore started and extra fluids were given in addition to replacement of minimal blood loss.

With reperfusion SVRI decreased to 346 dyn s m^2 cm^{-5}. Transoesophageal echocardiography showed development of marked SAM with severe MR and LV cavity obliteration during systole (fig. 2) The maximal LVOT gradient measured was 64 mm Hg. Multiple boluses and increasing rates of infusion of phenylephrine were administered. Washed donor red cells (600 ml) and Haemaccel 1 litre were infused in the first 30 min after reperfusion, despite minimal blood loss, in an attempt to increase ventricular volumes and reduce LV systolic obliteration as seen on TOE. PCWP increased to 24 mm Hg and CI increased to 10.61 min^{-1} m^{-2} but LV obliteration and outflow tract obstruction changed little.

Slowly over 2 h LVOT obstruction and MR and SAM resolved to levels similar to those in the pre-anhepatic stage. One hour after reperfusion an infusion of prostaglandin E_1 (PGE_1) 10 $\mu g\ h^{-1}$ was started, slowly increasing to 30 $\mu g\ h^{-1}$ as the patient's vasodilatation allowed.

The patient's postoperative course was complicated only by minor sepsis and transient pancytopenia. She was well 1 yr after transplant and her hepato-pulmonary syndrome is resolving.

Discussion

Hypertrophic cardiomyopathy (HCM) is inappropriate myocardial hypertrophy often involving the septum of a non-dilated left ventricle. HOCM is a subset of HCM in which the hypertrophy causes LVOT obstruction. It is an autosomal dominant condition with variable penetrance.[1]

The features of HOCM are a hypercontractile left ventricle, diastolic dysfunction, a high ejection fraction and systolic anterior motion of the mitral valve with or without mitral regurgitation. The obstruction is dynamic in that it changes depending on preload, afterload, sympathetic activity and posture.

The symptoms of HOCM range from none to dyspnoea, syncope, palpitations, chest pain and sudden death. Signs include a jerky pulse, fourth heart sound and an early to mid-systolic murmur increasing with a Valsalva manoeuvre. Diagnosis is usually confirmed by echocardiography.

The problems of providing anaesthesia to a patient with HOCM are exacerbated in liver transplantation. Patients with liver disease tend to have a low systemic vascular resistance and liver transplantation is associated with further vasodilatation, the potential for significant blood loss and occasionally the need for inotropes around the time of reperfusion. All of these factors exacerbate the haemodynamic disturbances of HOCM, which benefits from high afterload and preload, a relatively low heart rate and negative inotropy. Diastolic function is markedly impaired in HOCM and delayed isovolumetric relaxation reduces early diastolic filling.[2 3] There is an increased reliance on atrial contraction, diastolic filling pressures and adequate duration of diastolic filling.[4]

We chose an anaesthetic technique that avoided drugs such as isoflurane and pancuronium which cause vasodilatation and tachycardia and instead used halothane and vecuronium. We used phenylephrine for vasoconstriction as it has no inotropic or chronotropic effect. Our unit routinely administers PGE_1 to all liver transplant patients in the post-reperfusion period to increase hepatic blood flow and for its presumed cytoprotective effect. In case No. 1 we were unable to begin PGE_1 infusion, a potent vasodilator, until the patient had returned to the ICU, because of his extreme peripheral vasodilatation. In case No. 2 the patient tolerated only a very slow increase in the infusion rate to 30 $\mu g\ h^{-1}$ in theatre.

Transoesophageal echocardiography played a very important role in the intraoperative management of both patients. The measured haemodynamics of high PCWP and low mean arterial pressure, especially in the post-reperfusion period, may have prompted the use of inotropic agents with their potentially deleterious effects. However, TOE demonstrated low ventricular volumes despite a high PCWP and management was therefore with additional fluids and a direct acting vasopressor (phenylephrine). It has been shown during OLT that TOE has a better correlation with ventricular volumes than does PCWP.[5–8] In this case we found TOE to be the most useful guide to fluid management, especially in the post-reperfusion period.

COMMENTARY

Permissive hypercapnia and gas exchange in lungs with high $\dot{Q}s/\dot{Q}t$: a mathematical model

C. J. JOYCE AND K. G. HICKLING

Summary

Low volume ventilation with permissive hypercapnia is becoming widely used in the treatment of acute respiratory distress syndrome. A mathematical model was developed to examine the effects of hypoventilation on pulmonary gas exchange in lungs with a range of shunt fractions. Hypoventilation did not worsen gas exchange, provided the inspired oxygen concentration was high enough to maintain PA_{O_2} at an adequate level. In lungs with a high shunt fraction, some improvement in gas exchange may result, but these effects are small. A rightwards shift of the oxygen–haemoglobin dissociation curve induced by hypercapnia, is likely to be beneficial rather than detrimental in patients with acute respiratory distress syndrome. This analysis was limited to the direct effects of hypoventilation in lungs with constant shunt fractions, and did not encompass a number of possible secondary effects such as changes in cardiac output with Pa_{CO_2}, changes in shunt fraction associated with a reduction in mean airway pressure and possible direct effects of hypercapnia on the pulmonary vasculature or airways. (*Br. J. Anaesth.* 1996; **77**: 678–683)

Key words
Carbon dioxide, hypercapnia. Carbon dioxide, ventilatory response. Lung, shunting. Ventilation, hypoventilation. Model, matematical.

Animal models have suggested that orthodox mechanical ventilation during acute respiratory distress syndrome (ARDS), with high peak inspiratory pressures, may result in additional lung injury and possibly remote organ dysfunction. Low volume ventilation with permissive hypercapnia may avoid this ventilator-induced lung injury.[1] However, it has been suggested that the rightward shift of the oxygen–haemoglobin dissociation curve caused by hypercapnia may be detrimental in ARDS, as arterial oxygen content may be reduced more than venous oxygen unloading is facilitated.[2] A theoretical mathematical model was developed to investigate the effects of hypercapnia on pulmonary gas exchange in lungs with high levels of intrapulmonary shunt.

Methods

GENERAL DESCRIPTION

The aim of the model was to describe the effect of hypoventilation on steady state pulmonary gas exchange in lungs with varying degrees of intrapulmonary shunt. The lung was modelled as consisting of two compartments (see fig. 1). One compartment was perfused by mixed venous blood and not ventilated; the other compartment was both perfused and ventilated. It was assumed that the partial pressures of oxygen and carbon dioxide in blood leaving the ventilated lung unit had equilibrated with the lung unit, and that metabolic oxygen consumption and carbon dioxide production by the lung tissue were negligible. The peripheral tissues were modelled as a single compartment, with oxygen consumption and carbon dioxide production determined by the model. Tissue metabolism was modelled in two different ways. In the "constant metabolism" version of the model, $\dot{V}O_2$ was set at 250 ml (STPD)/min and $\dot{V}CO_2$ was set at 200 ml (STPD)/min. These values were maintained constant. In the "constant $P\bar{v}_{O_2}$" version, $P\bar{v}_{O_2}$ was maintained constant as might occur when tissue utilization of oxygen is limited by oxygen delivery, and the respiratory quotient was maintained constant at 0.8.

Pulmonary gas exchange was examined by calculating alveolar, arterial and mixed venous partial pressures and contents of oxygen and carbon dioxide for a range of input variables. The input variables FI_{O_2}, Pa_{CO_2}, P_{50}, $\dot{Q}$ and $\dot{Q}s/\dot{Q}t$ (and $P\bar{v}_{O_2}$ in the constant $P\bar{v}_{O_2}$ model) were specified and held constant during each set of calculations. In the model, P_{50} is defined as the partial pressure of oxygen necessary to 50% saturate haemoglobin at pH 7.4, PCO_2 5.33 kPa and 37 °C.

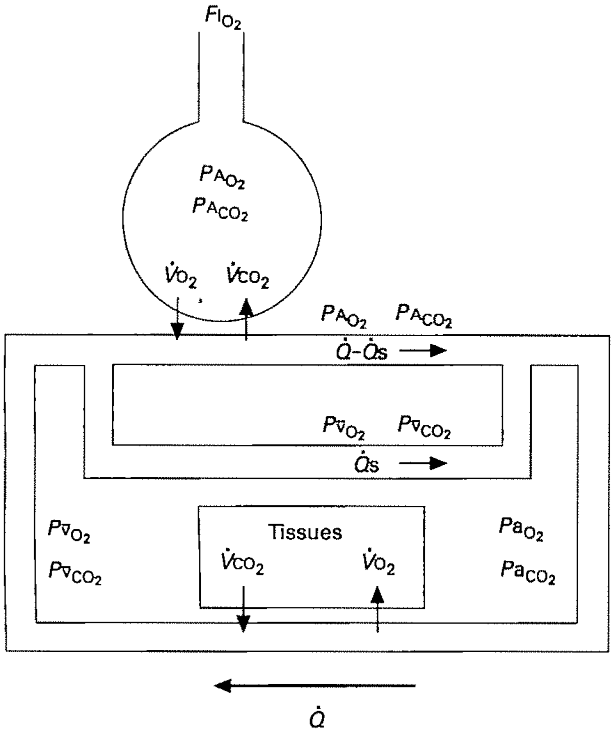

Figure 1 A model of the effect of hypercapnia on gas exchange.

MATHEMATICAL ANALYSIS

When the input variables were specified, there was a unique set of alveolar, arterial and mixed venous partial pressures and contents of oxygen and carbon dioxide that satisfied the constraints of a particular version of the model. Thus $Pa_{O_2} = f$ (FI_{O_2}, Pa_{CO_2}, P_{50}, $\dot{Q}$, $\dot{Q}s/\dot{Q}t$). To simplify calculations in the program, this was re-expressed as $FI_{O_2} = g$ (Pa_{O_2}, Pa_{CO_2}, P_{50}, $\dot{Q}$, $\dot{Q}s/\dot{Q}t$). As the other variables in this function are specified and held constant, this function can be solved for Pa_{O_2} using the false position method.[3] This method uses a trial value of Pa_{O_2} and calculates the corresponding value of FI_{O_2}, then uses this information to generate a better estimate of the Pa_{O_2} corresponding to the desired value of FI_{O_2}, with iteration until the desired precision is obtained (desired value of FI_{O_2} ± 0.00002 in this study). When the solution for Pa_{O_2} is obtained, other values of interest (Ca_{O_2}, Ca_{CO_2}, $C\bar{v}_{O_2}$, $C\bar{v}_{CO_2}$, $P\bar{v}_{O_2}$ and $P\bar{v}_{CO_2}$ are readily calculated. Details of the model equations are in appendix 1.

Both the constant metabolism model and the constant $P\bar{v}_{O_2}$ model were used to study scenarios with P_{50} = 3.57 kPa, over a range of $\dot{Q}$ values from 2.5 to 10 litre min^{-1}, Pa_{CO_2} from 1.33 to 94.64 kPa, FI_{O_2} from 0.21 to 1.0 and $\dot{Q}s/\dot{Q}t$ from 0.05 to 0.8. In the constant $P\bar{v}_{O_2}$ model, a range of $P\bar{v}_{O_2}$ values from 1.33 to 8.00 kPa were studied. In the constant metabolism model, a range of P_{50} from 2.45 to 3.57 kPa, and the effect of varying $\dot{Q}$ as a function of Pa_{CO_2} were studied (see appendix 2). The programs performing these analyses were written using Think Pascal (Symantec) and run on a Macintosh Centris.

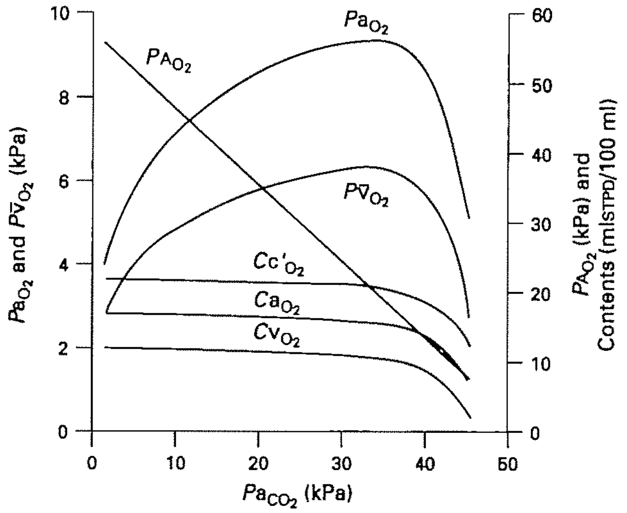

Figure 2 Constant metabolism model: effects of Pa_{CO_2}. Input variables are FI_{O_2} = 0.6, $\dot{Q}s/\dot{Q}t$ = 0.5, P_{50} = 3.57, $\dot{Q}$ = 5 litre min^{-1}. In this figure (and fig. 8) the range of Pa_{CO_2} is 0–50 kPa, while in all other figures only the clinical range of 0–20 kPa is shown.

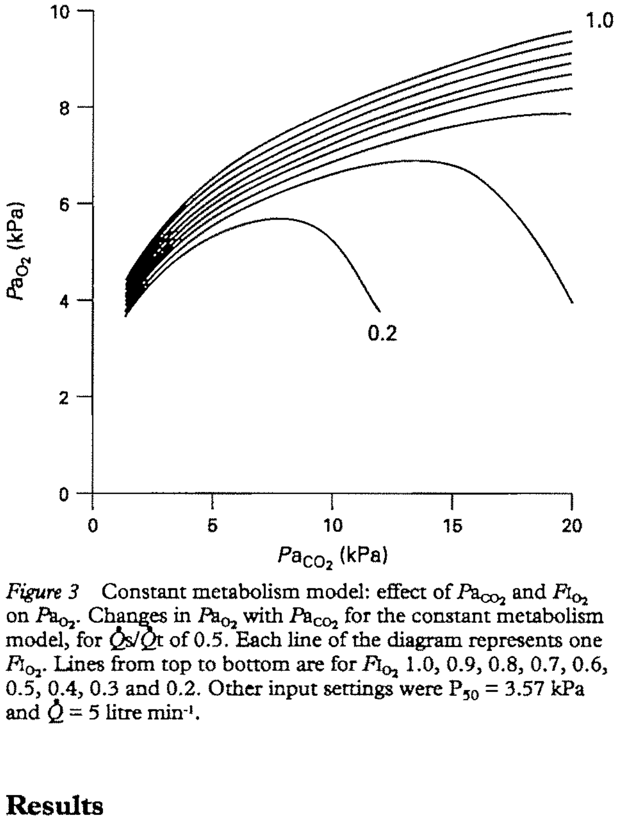

Figure 3 Constant metabolism model: effect of Pa_{CO_2} and FI_{O_2} on Pa_{O_2}. Changes in Pa_{O_2} with Pa_{CO_2} for the constant metabolism model, for $\dot{Q}s/\dot{Q}t$ of 0.5. Each line of the diagram represents one FI_{O_2}. Lines from top to bottom are for FI_{O_2} 1.0, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3 and 0.2. Other input settings were P_{50} = 3.57 kPa and $\dot{Q}$ = 5 litre min^{-1}.

Results

CONSTANT METABOLISM MODEL

The effect on oxygen carriage, of increasing Pa_{CO_2} when other input variables are held constant, is shown in figure 2. As Pa_{CO_2} increases, there is a linear decrease in PA_{O_2} caused by increasing PA_{CO_2}. This has minimal effect on Cc'_{O_2} (and hence Ca_{O_2} and $C\bar{v}_{O_2}$), until PA_{O_2} decreases below a threshold level and desaturation of haemoglobin in blood leaving the ventilated lung compartment begins. Up to this point, the rightward shift of the dissociation curve, in the presence of relatively constant Ca_{O_2} and $C\bar{v}_{O_2}$, produces an increase in Pa_{O_2} and $P\bar{v}_{O_2}$. Beyond this point, Cc'_{O_2}, Ca_{O_2}, $C\bar{v}_{O_2}$, Pa_{O_2} and $P\bar{v}_{O_2}$

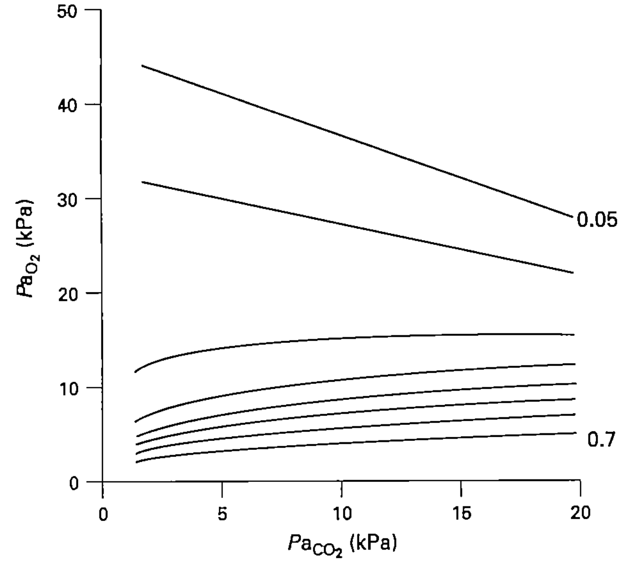

Figure 4 Constant metabolism model: effect of Pa_{CO_2} and $\dot{Q}s/\dot{Q}t$ on Pa_{O_2}. Changes in Pa_{O_2} with Pa_{CO_2} for the constant metabolism model, for FI_{O_2} of 0.6. Each line on the diagram represents one $\dot{Q}s/\dot{Q}t$. Lines from top to bottom are for $\dot{Q}s/\dot{Q}t$ 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 and 0.7. Other input settings were P_{50} = 3.57 kPa and $\dot{Q}$ = 5 litre min^{-1}. In this figure the range of Pa_{O_2} is 0–50 kPa, while in all other figures 0–10 kPa is shown.

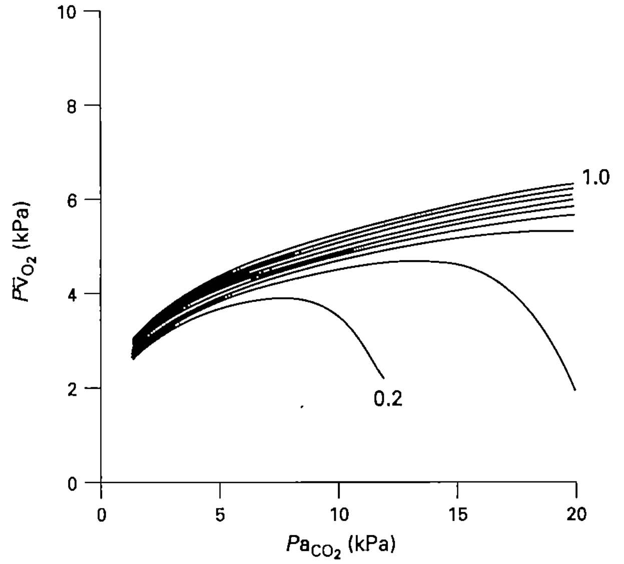

Figure 5 Constant metabolism model: effect of Pa_{CO_2} and FI_{O_2} on $P\bar{v}_{O_2}$. Changes in $P\bar{v}_{O_2}$ with Pa_{CO_2} for the constant metabolism model, for $\dot{Q}s/\dot{Q}t$ of 0.5. Each line of the diagram represents one FI_{O_2}. Lines from top to bottom are for FI_{O_2} 1.0, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3 and 0.2. Other input settings were P_{50} = 3.57 kPa and $\dot{Q}$ = 5 litre min^{-1} (as in fig. 3).

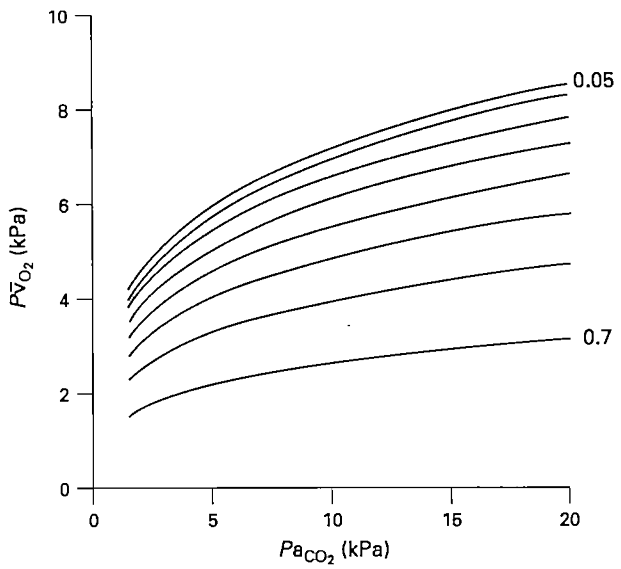

Figure 6 Constant metabolism model: effect of Pa_{CO_2} and $\dot{Q}s/\dot{Q}t$ on $P\bar{v}_{O_2}$. Changes in $P\bar{v}_{O_2}$ with Pa_{CO_2} for the constant metabolism model, for FI_{O_2} of 0.6. Each line on the diagram represents one $\dot{Q}s/\dot{Q}t$. Lines from top to bottom are for $\dot{Q}s/\dot{Q}t$ 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 and 0.7. Other input settings were P_{50} = 3.57 kPa and $\dot{Q}$ = 5 litre min^{-1} (as in fig. 4).

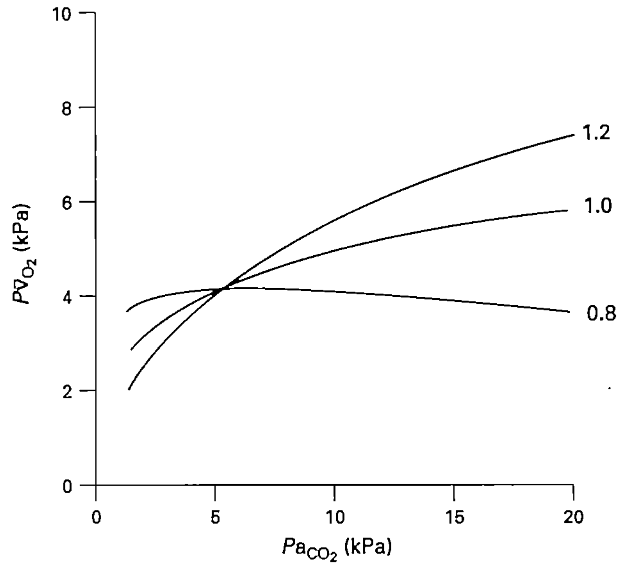

Figure 7 Constant metabolism model: effect on $P\bar{v}_{O_2}$ of varying $\dot{Q}$ with Pa_{CO_2}. Changes in $P\bar{v}_{O_2}$ with Pa_{CO_2} for the constant metabolism model. Other input settings were P_{50} = 3.57 kPa, FI_{O_2} = 0.6 and $\dot{Q}s/\dot{Q}t$ 0.5.

decrease. The PA_{CO_2} at which this threshold is reached varies with FI_{O_2} (figs 3 and 5). The pattern of change in Pa_{O_2} as Pa_{CO_2} increases is different with low $\dot{Q}s/\dot{Q}t$ values (0.05 or 0.1) when Pa_{O_2} decreases in a similar manner to PA_{O_2} (see fig. 4). With low values of $\dot{Q}s/\dot{Q}t$ the reduction in dissolved oxygen in blood leaving the ventilated lung compartment more than offsets the effect on Pa_{O_2} of the right shifted oxygen–haemoglobin dissociation curve, because the ventilated compartment represents most of the lung. With $\dot{Q}s/\dot{Q}t$ = 0, Pa_{O_2} is identical to PA_{O_2}.

Figures 5 and 6 show the changes in $P\bar{v}_{O_2}$ over a range of Pa_{CO_2}. For all $\dot{Q}s/\dot{Q}t$, $P\bar{v}_{O_2}$ increases as Pa_{CO_2} increases, provided that FI_{O_2} is adequate to maintain PA_{O_2} above the threshold level for haemoglobin desaturation (fig. 6). If FI_{O_2} is not adequate, then the threshold level for haemoglobin desaturation is exceeded within the clinical range of Pa_{CO_2}, and $P\bar{v}_{O_2}$ decreases (fig. 5).

A similar pattern of results was seen with P_{50} values of 2.45 and 3.05 kPa. A lower P_{50} resulted in lower Pa_{O_2} and $P\bar{v}_{O_2}$ at a given Pa_{CO_2}, when the other variables were held constant. With an FI_{O_2} of 0.6, $\dot{Q}s/\dot{Q}t$ of 0.5 and $\dot{Q}$ of 5 litre min^{-1}, at any given Pa_{CO_2} in the range 0–20 kPa, the $P\bar{v}_{O_2}$ result for P_{50} of 2.45 kPa was 69–71% of the $P\bar{v}_{O_2}$ result for a P_{50} of 3.57 kPa.

Similar results were seen with $\dot{Q}$ values of 2.5 and 10 litre min^{-1}. A lower $\dot{Q}$ resulted in lower Pa_{O_2} and $P\bar{v}_{O_2}$ at a given Pa_{CO_2}, when the other variables were held constant. When $\dot{Q}$ was varied as a function of Pa_{CO_2} the pattern was different (fig. 7). Relatively small changes in $\dot{Q}$ (20% decrease in $\dot{Q}$ for a doubling in Pa_{CO_2}) virtually abolished any increase in $P\bar{v}_{O_2}$ with increasing Pa_{CO_2}, and marked decreases in $P\bar{v}_{O_2}$ were seen within the range of Pa_{CO_2} used clinically during low volume ventilation with permissive hypercapnia (Pa_{CO_2} of 5.33–20 kPa).

Hypocapnia consistently made gas exchange worse. In all the scenarios modelled, $P\bar{v}_{O_2}$ decreased as Pa_{CO_2} decreased to less than 5.3 kPa. When the shunt fraction was high, Pa_{O_2} also decreased (fig. 4).

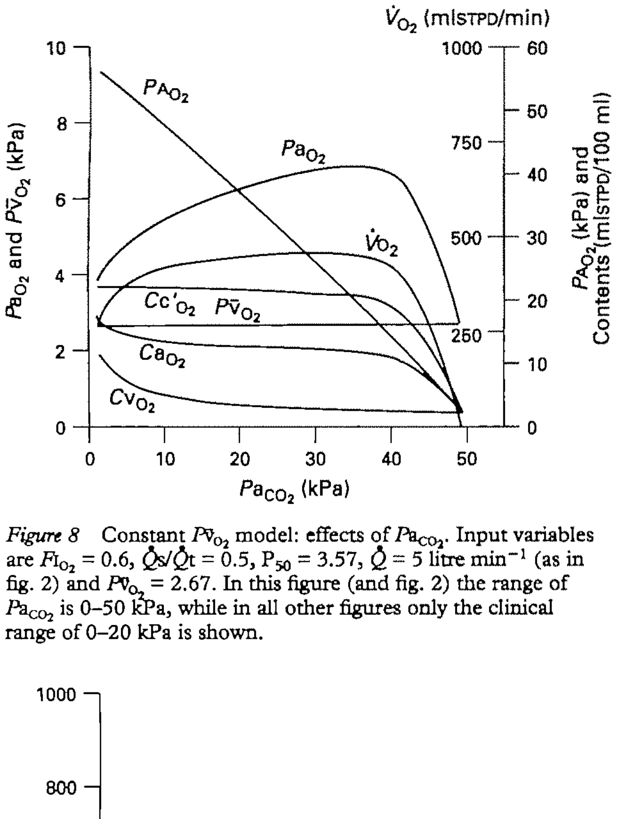

Figure 8 Constant $P\bar{v}_{O_2}$ model: effects of Pa_{CO_2}. Input variables are FI_{O_2} = 0.6, $\dot{Q}s/\dot{Q}t$ = 0.5, P_{50} = 3.57, $\dot{Q}$ = 5 litre min^{-1} (as in fig. 2) and $P\bar{v}_{O_2}$ = 2.67. In this figure (and fig. 2) the range of Pa_{CO_2} is 0–50 kPa, while in all other figures only the clinical range of 0–20 kPa is shown.

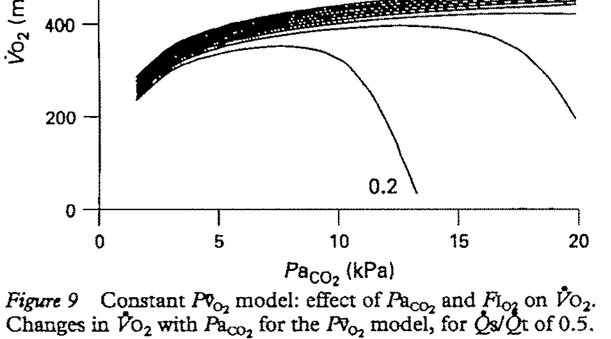

Figure 9 Constant $P\bar{v}_{O_2}$ model: effect of Pa_{CO_2} and FI_{O_2} on $\dot{V}O_2$. Changes in $\dot{V}O_2$ with Pa_{CO_2} for the $P\bar{v}_{O_2}$ model, for $\dot{Q}s/\dot{Q}t$ of 0.5. Each line of the diagram represents one FI_{O_2}. Lines from top to bottom are for FI_{O_2} 1.0, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3 and 0.2. Other input settings were P_{50} = 3.57 kPa, $\dot{Q}$ = 5 litre min^{-1} and $P\bar{v}_{O_2}$ = 2.67.

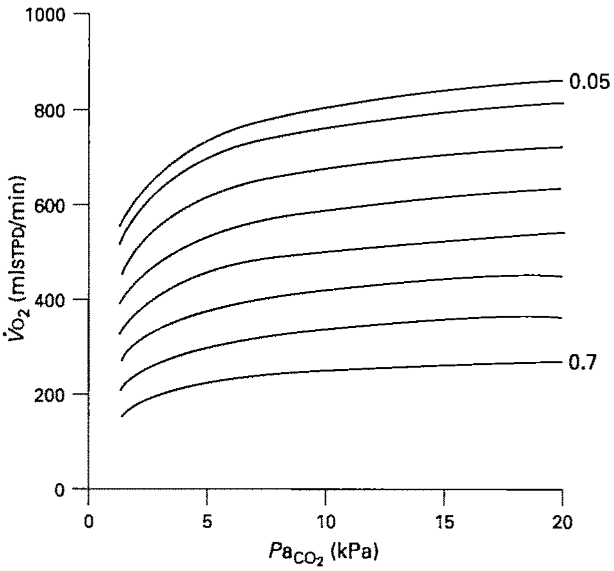

Figure 10 Constant $P\bar{v}_{O_2}$ model: effect of Pa_{CO_2} and $\dot{Q}s/\dot{Q}t$ on $\dot{V}O_2$. Changes in $\dot{V}O_2$ with Pa_{CO_2} for the constant $P\bar{v}_{O_2}$ model, for FI_{O_2} of 0.6. Each line on the diagram represents one $\dot{Q}s/\dot{Q}t$. Lines from top to bottom are for $\dot{Q}s/\dot{Q}t$ 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 and 0.7. Other input settings were P_{50} = 3.57 kPa, $\dot{Q}$ = 5 litre min^{-1} and $P\bar{v}_{O_2}$ = 2.67.

CONSTANT $P\bar{v}_{O_2}$ MODEL

The effect on $\dot{V}O_2$ and oxygen carriage of increasing Pa_{CO_2} when other input variables are held constant is shown in figure 8. The increase in Pa_{CO_2} produced an increase in $P\bar{v}_{CO_2}$. The model defines $P\bar{v}_{O_2}$ as constant, so Cv_{O_2} decreases as the increasing $P\bar{v}_{CO_2}$ shifts the dissociation curve to the right. As Pa_{CO_2} increases, there is a linear decrease in PA_{O_2} caused by increasing PA_{CO_2}. This has minimal effect on Cc'_{O_2}, until PA_{O_2} decreases below a threshold level and desaturation of haemoglobin in blood leaving the ventilated lung compartment begins. Ca_{O_2} is determined by mixing of constant proportions of blood with Cc'_{O_2} and Cv_{O_2}. Up to the threshold point, Cc'_{O_2} is relatively constant. Thus as Cv_{O_2} decreases, Ca_{O_2} also decreases but not to the same extent as Cv_{O_2}. The difference between Ca_{O_2} and Cv_{O_2} widens and hence $\dot{V}O_2$ increases. Another effect of the widening difference between Ca_{O_2} and Cv_{O_2} as Pa_{CO_2} increases is that with similar increases in PCO_2 in both arterial and venous blood, and hence similar rightward shift of the two dissociation curves, the difference between Pa_{O_2} and $P\bar{v}_{O_2}$ also increases, and Pa_{O_2} must increase as $P\bar{v}_{O_2}$ is held constant. Beyond the threshold point, $\dot{V}O_2$, Pa_{O_2}, Cc'_{O_2}, Ca_{O_2} and Pa_{O_2} decrease. The pattern of change in Pa_{O_2} as Pa_{CO_2} increases is different with low $\dot{Q}s/\dot{Q}t$ when Pa_{O_2} decreases in a similar manner to PA_{O_2}.

Figures 9 and 10 show the changes in $\dot{V}O_2$ over a range of Pa_{CO_2}. For all $\dot{Q}s/\dot{Q}t$, $\dot{V}O_2$ increases as Pa_{CO_2} increases, provided that FI_{O_2} is adequate to maintain PA_{O_2} above the threshold level for haemoglobin desaturation (fig. 10). If FI_{O_2} is not adequate, then the threshold level for haemoglobin desaturation is exceeded within the clinical range of Pa_{CO_2}, and $\dot{V}O_2$ decreases (fig. 9).

A similar pattern of results was seen with $P\bar{v}_{O_2}$ set at 1.33, 4.00 or 5.33 kPa, and with P_{50} values of 2.45 and 3.05 kPa. A lower $P\bar{v}_{O_2}$ resulted in a higher $\dot{V}O_2$ when the other input variables were unchanged. The greatest improvement in $\dot{V}O_2$ with increasing Pa_{CO_2} occurred when $P\bar{v}_{O_2}$ was high. With $P\bar{v}_{O_2}$ of 1.33 kPa there was a minimal decrease in $\dot{V}O_2$ when Pa_{CO_2} increased to greater than 17 kPa. A lower P_{50} resulted in a lower $\dot{V}O_2$ for any given Pa_{CO_2}. As can be predicted from the equations of the model, any increase in $\dot{Q}$ simply increased $\dot{V}O_2$ by the same factor.

As with the constant metabolism model, hypocapnia consistently made gas exchange worse. In all scenarios modelled, $\dot{V}O_2$ decreased as Pa_{CO_2} decreased to less than 5.3 kPa.

Discussion

It has been suggested that a rightward shift of the dissociation curve may be detrimental in ARDS, because reduction of arterial oxygen content may more than offset the amount by which venous oxygen unloading is facilitated.[2] In a pig model of hypoxaemia caused by low inspired oxygen concentration, and hypercapnia produced by high inspired carbon dioxide concentration, arterial oxygen content was increased and mortality reduced when acidosis was partially corrected by buffering. It was postulated that buffering had reduced the right shift of the dissociation curve thus improving pulmonary oxygen uptake.[2] In rats breathing air at reduced atmospheric pressure, survival was improved with a left-shifted oxygen dissociation curve.[4] A theoretical study suggested that a left shift of the oxygen dissociation curve may improve exercise tolerance at high altitude, if diffusion limitation of oxygen uptake is present.[5] However, these studies examined the response to alteration in P_{50} with hypoxaemia caused by low PA_{O_2}. In this situation it is the low PA_{O_2} which limits oxygen uptake by pulmonary blood flow and determines Pa_{O_2}. A right-shifted dissociation curve then results in decreased arterial oxygen content at this limited Pa_{O_2}, and is thus potentially detrimental. Hypercapnia has an additional detrimental effect in that it further decreases PA_{O_2}.

In contrast, when hypoxaemia results from intrapulmonary shunt, PA_{O_2} in ventilated lung remains high even with moderately high Pa_{CO_2} provided that the inspired oxygen concentration is sufficiently high. Under these conditions, blood leaving the ventilated lung compartment is fully saturated, and arterial oxygen content is determined by the shunt fraction and venous oxygen content. The effect of a right-shifted dissociation curve is then to increase Pa_{O_2} associated with this predetermined arterial oxygen content. If cardiac output and oxygen consumption do not change, then mixed venous oxygen content is unaltered and $P\bar{v}_{O_2}$ also increases. Our mathematical model confirms that in patients with pure intrapulmonary shunt causing hypoxaemia who are receiving a sufficiently high inspired oxygen concentration to ensure full saturation of the pulmonary blood flow in the ventilated lung compartment, and with other variables remaining constant, acute hypercapnia should result in an increase in Pa_{O_2} and $P\bar{v}_{O_2}$ with little change in arterial and mixed venous oxygen contents. If the increase in $P\bar{v}_{O_2}$ allows greater oxygen uptake into hypoxic tissues, this could theoretically increase tissue oxygen utilization, and the model predicts that potentially important increases could result. Our model suggests that reversing the rightwards shift of the dissociation curve by buffering may be detrimental to gas exchange.

In reality the situation is more complex, and several of the variables which were assumed to remain constant in this model may alter in patients with ARDS during low volume ventilation with permissive hypercapnia. Alterations in cardiac output affect gas exchange. Acute hypercapnia depresses the contractility of isolated myocardium,[6] although this is compensated rapidly during sustained hypercapnia, as a result of correction of intracellular acidosis.[7] *In vivo*, decreased contractility is offset by increased sympathetic stimulation, and cardiac output increases.[8] Recent studies of patients with ARDS have found that cardiac output increased in all patients during low volume ventilation with permissive hypercapnia.[9–11]

The shunt fraction may also be affected by several factors during low volume ventilation with permissive hypercapnia, including changes in mean airway pressure,[12] changes in cardiac output[13 14] and direct or autonomically mediated effects on the pulmonary vasculature or the airways.

Our model assumes that either oxygen consumption or carbon dioxide production is constant or limited by the lowest $P\bar{v}_{O_2}$ at which tissues can extract oxygen, but it is likely that acute hypercapnia has important metabolic effects. The resulting intracellular acidosis alters the activity of several enzymes, for example phosphofructokinase. Conversely, increased sympathetic activity and increased endogenous catecholamine concentrations may increase metabolic rate and $\dot{V}O_2$.

Buffering may be detrimental to gas exchange by reversing the rightwards shift of the dissociation curve and by inhibiting the potentiation of hypoxic pulmonary vasoconstriction caused by acidosis.[15] The metabolic compensation that occurs during prolonged hypercapnia shifts the curve to the left and worsens gas exchange.

Several studies have demonstrated that in patients with ARDS, hypoxaemia appears to be predominantly a result of intrapulmonary shunt,[9 16] and therefore the findings of this study should be applicable to such patients. However, there is some variability in the proportion of intrapulmonary shunt and $\dot{V}/\dot{Q}$ inequality between patients, and in those with a substantial proportion of low $\dot{V}/\dot{Q}$ regions the model is inaccurate. Another limitation of this study is that the Kelman subroutines used to calculate oxygen contents and tensions have been validated only up to a $P\text{CO}_2$ value of 20 kPa.[17] While the results at higher partial pressures are inaccurate, the results are valid over the range of Pa_{CO_2} values used in clinical practice.

The constant $P\bar{v}_{O_2}$ model examines the situation where oxygen delivery to the tissues is inadequate, so that oxygen is extracted from the blood down to a limiting level of $P\bar{v}_{O_2}$. Below a $P\bar{v}_{O_2}$ value of 2.67 kPa tissue oxygenation may be inadequate for cellular function. Our data show the level of oxygen consumption that can be supported at this $P\bar{v}_{O_2}$ value. Patients with ARDS and sepsis often have high oxygen consumption, and it has been suggested that even with normal values for oxygen delivery, oxygen uptake may be limited by its delivery to the tissues.[18]

Thus the physiological consequences and interactions after the reduction of ventilatory support and onset of hypercapnia are extremely complex, and may vary substantially between patients. Further studies of the effects of hypercapnia are needed. However, this study suggests that the effect of the right-shifted dissociation curve *per se* in patients with ARDS is likely to be beneficial rather than detrimental.

Appendix 1

MODEL EQUATIONS

Procedure used for calculating FI_{O_2} for a trial value of Pa_{O_2}

1. Ca_{CO_2} and Ca_{O_2} are calculated from Pa_{CO_2} and the trial value of Pa_{O_2} using West's modifications of Kelman's subroutines.[17 19–21]

2. *In the "constant metabolism" version of the model*

Cv_{CO_2} and Cv_{O_2} are calculated by

$$Cv_{CO_2} = Ca_{CO_2} + (\dot{V}CO_2/\dot{Q})$$

$$Cv_{O_2} = Ca_{O_2} - (\dot{V}O_2/\dot{Q})$$

In the "constant $P\bar{v}_{O_2}$" version of the model

As Ca_{O_2}, Ca_{CO_2} and $P\bar{v}_{O_2}$ are known, there is a unique set of $P\bar{v}_{CO_2}$, Cv_{CO_2} and Cv_{O_2} that will satisfy the constraint of the model that RQ = 0.8

where $RQ = (Cv_{CO_2} - Ca_{CO_2})/(Ca_{O_2} - Cv_{O_2})$. Thus $RQ = f(P\bar{v}_{CO_2})$, and $P\bar{v}_{CO_2}$ is solved by the false position method. Cv_{CO_2} and Cv_{O_2} are calculated from $P\bar{v}_{O_2}$ and $P\bar{v}_{CO_2}$ using Kelman's subroutines.

3. The contents of carbon dioxide and oxygen in blood equilibrated with the ventilated compartment are calculated by $Cc'_{O_2} = (Ca_{CO_2} - Cv_{CO_2} \times \dot{Q}s/\dot{Q}t)/(1 - \dot{Q}s/\dot{Q}t)$

$$Cc'_{O_2} = (Ca_{O_2} - Cv_{O_2} \times \dot{Q}s/\dot{Q}t)/(1 - \dot{Q}s/\dot{Q}t)$$

4. $P\mathrm{A}_{CO_2}$ and $P\mathrm{A}_{O_2}$ are calculated from Cc'_{CO_2} and Cc'_{O_2}, using Kelman's subroutines and the false position method.

5. FI_{O_2} is calculated by

$$FI_{O_2} = (P\mathrm{A}_{O_2} + (P\mathrm{A}_{CO_2}/RQ))/((PB - PH_2O) + (P\mathrm{A}_{CO_2}/RQ)\,(1 - RQ))$$

(This equation was derived by algebraic manipulation of the alveolar gas equation).

Constants used in these calculations were haemoglobin = 15 g dl^{-1}, packed cell volume = 0.45, base excess = 0 mmol $litre^{-1}$, temperature = 37.0 °C, PB = 101.3 kPa, $SVP_{(H_2O)} = 6.26$ kPa, RQ = 0.8.

Final calculations

When the solution of Pa_{O_2} for the specified value of FI_{O_2} has been found, then Ca_{O_2}, Ca_{CO_2}, Cv_{O_2}, Cv_{CO_2}, Cc'_{O_2}, Cc'_{CO_2}, $P\mathrm{A}_{O_2}$ and $P\mathrm{A}_{CO_2}$ are calculated as above in steps 1 to 4. $P\bar{v}_{O_2}$ and $P\bar{v}_{CO_2}$ are calculated from Cv_{O_2} and Cv_{CO_2} using Kelman's subroutines and the false position method.

Appendix 2

METHOD OF VARYING $\dot{Q}$ AS A FUNCTION OF Pa_{CO_2}

The effect of varying $\dot{Q}$ as a function of Pa_{CO_2} was investigated. Calculations of the constant metabolism model were followed, except that the $\dot{Q}$ to be used with the other input variables was calculated from the Pa_{CO_2}, by the equation

$$\dot{Q} = \dot{Q}5.33\ \Theta(\log_2(Pa_{CO_2}/5.33))$$

where $\dot{Q}5.33$ is cardiac output at $Pa_{CO_2} = 5.33$ kPa and is set at 5 litre min^{-1}. This equation produces an increase in $\dot{Q}$ by a factor of Θ for each doubling of Pa_{CO_2}. Thus $\dot{Q}5.33 = 5$ litre min^{-1}, $\dot{Q}10.66 = 5\Theta$ litre min^{-1}, and $\dot{Q}21.32 = 5\Theta^2$ litre min^{-1}. Values of Θ examined were 0.8, 1.0 and 1.2.

Performance of vaporizers in circle systems [III]

S. Brosnan*, B. Royston and D. White
Department of Anaesthetics, Northwick Park Hospital, Harrow

When vaporizers are used within circle systems, the temperature within the vaporizer decreases as the agent evaporates. This reduces the output of the vaporizer and may be of clinical importance.

We investigated this effect both on the bench and in theatre using a Komesaroff vaporizer, a copy of the Goldman into which a thermometer may be placed. All tests were conducted using isoflurane, the vaporizer being filled to the 30 ml level before each experiment. On the bench, gas flow rates of 4, 8 and 12 litre min^{-1} were passed through the vaporizer and the changes in temperature of the isoflurane were recorded. The greatest decrease in temperature was seen with a flow rate of 12 litre min^{-1}, the temperature decreasing from 20 to 0°C within 18 min with the vaporizer open at setting 3.

In theatre, the vaporizer was attached on the inspiratory side of a Scania circle system. Isoflurane temperature was measured at 1-min intervals using a thermistor and a record of the ambient temperatures at the start and finish of the case were made. Patients were anaesthetized with propofol and allowed to breathe spontaneously on a laryngeal mask airway. We found that the temperature in the vaporizer was related to both the vaporizer setting and the patient's minute volume. Initially, on a high inspired isoflurane concentration, the temperature decreased quite quickly, but as the anaesthetic continued and the vaporizer setting was reduced, the temperature increased (fig. 1). Also shown are minor fluctuations in isoflurane temperature related to episodes where the patient's minute volume increased in response to surgical stimulus and decreased after administration of i.v. opioids.

The maximum reduction in temperature can be calculated, using the Antoine equation, to produce a maximum reduction in isoflurane concentration of 48%. This effect is not found to be a problem in clinical practice owing to the previously described self-regulating properties of this system.[1]

Pharmacodynamics of Org 9487: onset and recovery characteristics of single and three incremental bolus doses

K. G. Mills*, J. M. Scott*, C. J. R. Parker, and J. M. Hunter
University Department of Anaesthesia, Liverpool

The need for a non-depolarizing neuromuscular blocking agent with onset and recovery characteristics similar to suxamethonium is recognized. Early reversal of residual block using an anticholinesterase would be an attractive feature of such an agent; it would be useful if attempts at tracheal intubation failed. Org 9487, the 16-*N*-allyl-β-propionate analogue of vecuronium, is a new aminosteroid neuromuscular blocking agent.[1] We compared recovery from profound block using neostigmine or edrophonium, after either a single bolus dose or a bolus plus three maintenance doses of Org 9487.

Twenty-four patients, ASA I–III, were recruited to the study. They were allocated randomly to one of four groups: Groups la and lb received neostigmine 0.05 mg kg^{-1}, la after a single bolus of Org 9487 and lb after three maintenance doses; Groups 2a and 2b were similarly reversed with edrophonium 1.0 mg kg^{-1}. Patients received lorazepam 2–4 mg orally, 2 h before operation. After induction of anaesthesia with midazolam 0.05–0.1 mg kg^{-1}, fentanyl 1–3 μg kg^{-1} and thiopentone 4–6 mg kg^{-1}, anaesthesia was maintained with nitrous oxide 70% in oxygen and incremental doses of thiopentone and fentanyl. The mechanical response of the adductor pollicis to train-of-four stimulation of the ulnar nerve was recorded using the Myograph 2000. A stabilization period of 3 min was achieved before administration of Org 9487, 1.5 mg kg^{-1} (1.5 × ED$_{90}$). Tracheal intubation was performed after 60 s. The anticholinesterase was administered in Groups la and 2a after a further 60 s. Groups lb and 2b received three further doses of Org 9487 0.5 mg kg^{-1} when T1/T0 had recovered to 25%. The anticholinesterase was given 2 min after the third maintenance dose. The recovery times after administration of the anticholinesterase in the four groups were compared using the Mann-Whitney two-tailed *U* test.

The mean (SD) lag time in the 24 patients was 34 (8.0) s, and the mean time to maximum block was 75 (33) s. The mean (SD) time to T1/T0 = 25% in Groups lb and 2b was 17.6 (4.4) min. The mean (SD) recovery times in the four groups after the anticholinesterase are given in table 1.

Rapid antagonism of profound block induced by Org 9487 1.5 mg kg^{-1} cannot be obtained using either neostigmine or edrophonium.

Effect of theophylline and forskolin on human respiratory cilia beat frequency *in vitro*

M. Alexander-Williams and T.A. Bedford
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

Mucociliary clearance represents an important protective mechanism of the upper and lower respiratory tracts. The transport of mucus is dependent on the cilia beat frequency (CBF) and coordination, and the composition of the mucus layer. Previous studies have shown that both theophylline and aminophylline increase mucus transport rate *in vivo*.[1 2] However, the exact site and mechanism of their action are unclear. Both drugs potentiate the cyclic AMP system which could affect both CBF, mucus production or both. We have investigated the effect of theophylline and forskolin (a direct adenylate cyclase activator) on the beat frequency of human respiratory cilia *in vitro*.

CBF was measured using the transmitted light technique in a previously described perfusion system.[3] Nasal turbinates from 15 patients who had undergone turbinectomy for tissue hypertrophy were used as the source of ciliated epithelium. Ciliated discs, 4 mm in diameter, cut from the turbinates were divided into four groups. Group 1 was exposed to theophylline 100 μg ml^{-1} and group 2 exposed to forskolin 100 μg ml^{-1}. Groups 3 and 4 acted as matched controls. The ciliated discs were mounted in paired perfusion chambers at 37°C and connected to a reservoir containing Hanks' balanced salt solution. The samples were perfused for 30 min before a baseline reading of CBF was made (t30). One chamber was then connected to a reservoir containing the drug solution and measurements repeated after 60 min (t90). The investigator was not aware of which chamber received the drug solution.

The results are shown in table 2.

Table 2 Mean cilia beat frequency (SD) (Hz). (**P=0.008 (increased compared with control)

Time (min)	Control	Theophylline	Control	Forskolin
30	12.16 (2.83)	11.02 (3.62)	13.23 (3.23)	11.64 (3.39)
90	11.33 (2.8)	11.58 (3.76)	12.98 (2.72)	14.71 (2.86)**

Nine pairs of ciliated discs were used for the theophylline study. There was no significant change in CBF compared with control. Six pairs of discs were used for the forskolin study. Forskolin 100 μg ml^{-1} significantly increased CBF compared with control.

Effect of carbon dioxide on cerebral autoregulation as assessed by the transient hyperaemic response test

G. Cavill*, E. J. Simpson*, R. P. Mahajan
University Departments of Anaesthesia and of Physiology and Pharmacology, Queen's Medical Centre, Nottingham

We have developed a theoretical model for the quantitative assessment of cerebral autoregulation (CA) using the transient hyperaemic response (THR) seen in the middle cerebral artery (MCA) blood flow velocity (FV) after release of a brief compression of the common carotid artery (CCA).[1] The aim of this study was to use this model to assess the effects of carbon dioxide on CA.

Seven healthy volunteers were studied in the supine position. A continuous record of cerebral blood FV in the left MCA using transcranial Doppler ultrasonography and of end-tidal carbon dioxide ($P\mathrm{E}'_{\mathrm{CO_2}}$) at the mouth was established. Each volunteer was subjected to three left CCA compressions of 10-s duration for the baseline measurements followed by measurements made while breathing via a rebreathing circuit to achieve $P\mathrm{E}'_{\mathrm{CO_2}}$ of approximately 1 kPa and then 2 kPa above baseline, and finally while voluntarily hyperventilating to $P\mathrm{E}'_{\mathrm{CO_2}}$ of approximately 1 kPa and then 2 kPa below baseline. Mean arterial pressure (MAP) was recorded non-invasively before each CCA compression. Time-averaged mean velocities from the maximal FV traces of the following MCA pulse waves were analysed: the pulse wave just preceding compression (F1); the first pulse wave after compression (F2); and the first pulse wave after release of compression (F3). The expected value of F3 was calculated as F3=F1 × MAP/P2 (where P2 stands for arterial pressure in the MCA immediately after compression of CCA, and is estimated as MAP × F2/F1). The ratio of observed F3 to expected F3 was taken as a measure of strength of autoregulation (SA).[1] A total of 97 THR tests were analysed; the correlation between SA and $P\mathrm{E}'_{\mathrm{CO_2}}$ in the pooled data is shown in figure 2.

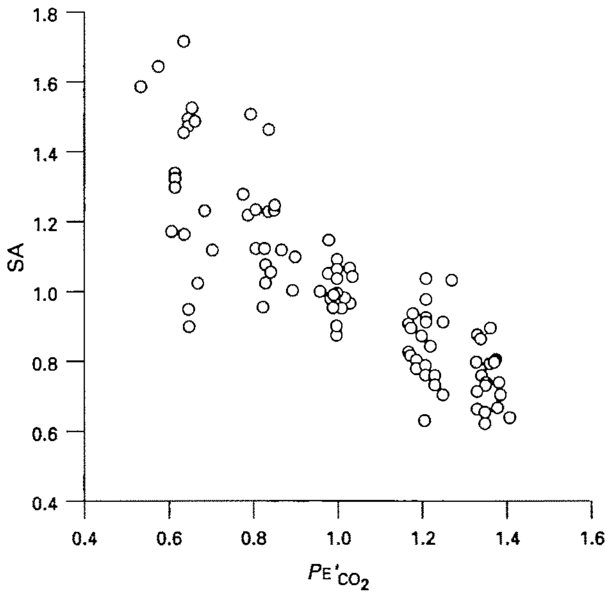

Figure 2 $P\mathrm{E}'_{\mathrm{CO_2}}$ and SA are expressed as multiples of baseline mean for each subject.

Our results demonstrate a significant negative correlation between SA and $P\mathrm{E}'_{\mathrm{CO_2}}$ (r^2=0.72; P<0.001). These findings substantiate previous claims that the autoregulatory response of cerebral vessels is attenuated during hypercapnia. In addition, we have shown that this response can be exaggerated during hypocapnia when assessed by THR test.

Comparison of the effect of intrathecal and extradural fentanyl on gastric emptying in labour

M. C. Kelly*, U. A. Carabine, D. A. Hill and R. K. Mirakhur
Department of Anaesthetics, The Queen's University of Belfast and The Royal Group Hospitals Trust

Extradurally administered opioid drugs improve analgesia in labour but have disadvantages such as nausea, vomiting and delayed gastric emptying.[1 2] Intrathecal opioids are becoming popular but their effect on gastric emptying is unknown. This study was designed to assess the effect on gastric emptying of fentanyl given intrathecally, or extradurally in standard clinical doses.

One hundred and five women with uncomplicated pregnancies and in active labour were included in the study with their informed consent and approval of the research Ethics Committee. All had been fasted for at least 3 h and had received no systemic analgesia. Patients were allocated randomly to one of three groups. Group S received fentanyl 25 μg and bupivacaine 2.5 mg intrathecally, Group E 10 ml bupivacaine 0.25% and fentanyl 50 μg extradurally and Group C 10 ml of 0.375% bupivacaine extradurally. A baseline blood sample was taken 15 min later and paracetamol 1.5 g given with 100 ml water.

Blood samples were taken at intervals over the next 3 h and analysed for paracetamol concentrations using the HPLC method. Patients received extradural boluses of 0.25% bupivacaine on request. Pain was assessed using visual analogue scores (VAS). Maximum paracetamol concentration ($C_P$max), and areas under the paracetamol concentration time curve (AUC) at 90 and 120 min were compared using ANOVA. Kruskal–Wallis test was used to compare the time to maximum concentration (tC_Pmax) and VAS. A P value of <0.05 was considered significant.

There were no demographic differences between groups. $C_P$max in Group S was significantly lower than group E, and AUC_{90} and AUC_{120} significantly smaller in S than in groups C and E (table 3). Median (range) tC_Pmax values were 120 (15–180), 82.5 (15–180) and 90 (15–180) min in groups S, E and C respectively ($P<0.05$). These results indicate delayed gastric emptying in the group given intrathecal fentanyl compared with the other two groups. The VAS scores were similar except at 30 min when the scores were significantly lower, reflecting better analgesia, in Group S. Group S also required significantly less bupivacaine.

Table 3 Paracetamol absorption (mean (SD)).(*$P<0.05$ compared with Group E; † $P < 0.05$ compared with Groups C and E)

	Group S	Group E	Group C
$C_P$max (μg ml^{-1})	13.4 (8.82)* (n=34)	17.9 (8.06) (n=34)	15.0 (6.22) (n=33)
AUC_{90} (μg ml^{-1} min^{-1})	430 (491)† (n=34)	736 (504) (n=35)	672 (453) (n=33)
AUC_{120} (μg ml^{-1} min^{-1})	649 (592)† (n=33)	1062 (627) (n=35)	1053 (616) (n=37)

Effects of alpha$_2$-adrenoceptor agonists on gastric emptying and gastrointestinal transit in the rat

T. Asai*, M. D. Vickers, W. W. Mapleson and I. Power
Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff, and Department of Anaesthesia and Pain Management, University of Sydney, RNSH, St Leonards, Australia

Opioids markedly delay both gastric emptying and intestinal transit; however, the effect of alpha$_2$ agonists, adjuncts to anaesthetics, on gastric emptying is unclear. We studied the effect of two such agonists on gastric emptying and gastrointestinal transit in the rat.

Six to 10 male Wistar rats (200–250 g) were used for most doses of each substance. Either clonidine (0.001–1 mg kg^{-1}), dexmedetomidine (0.0001–0.1 mg kg^{-1}: donated by Orion-Farmos Pharmaceuticals), morphine (0.1–30 mg kg^{-1}) or saline was injected i.p. At 30 min radiolabelled saline 1 ml was infused into the stomach. At 1 h, the animal was killed, the gastrointestinal tract was removed and the small intestine was divided into 10 equal segments. The radioactivity in the stomach and each segment of the intestine was counted, and gastric emptying and gastrointestinal transit were calculated. Gastrointestinal transit was assessed using the "geometric centre" (the centre of gravity) (= (CiSi)/ Ci, where Ci = count in segment Si).[1] In another group of rats, either yohimbine, naloxone or saline was injected with an agonist. The Mann-Whitney U test was used for comparison of substances or combinations of substances. The ED_{50} and the 95% confidence limits (CL) were determined using logistic regression of inhibition, with respect to saline, of gastric emptying and of geometric centre on log dose and the Fieller equation in the statistical package GLIM (Generalized Linear Interactive Modelling).

Dexmedetomidine 0.1 mg kg^{-1} caused strong sedation and apparent respiratory depression; therefore, this dose was given in only three rats. Clonidine significantly inhibited gastric emptying ($P = 0.001$) but the inhibitory effect was weak (95% CL for difference from saline: 8.2 and 34.9% at the maximum dose of clonidine, 1 mg kg^{-1}). Dexmedetomidine also significantly but weakly inhibited the emptying ($P < 0.05$; 95% CLs for difference from saline: 3.4 and 15.4% at the next-to-maximum dose, 0.03 mg kg^{-1}). However, both clonidine and dexmedetomidine strongly inhibited gastrointestinal transit (table 4). In contrast, morphine inhibited gastric emptying and gastrointestinal transit to a similar degree. Yohimbine significantly antagonized the inhibitory effects of both clonidine and dexmedetomidine ($P < 0.05$). In contrast, naloxone, which significantly antagonized the effect of morphine ($P < 0.01$), did not antagonize the effect of either of these agonists.

Table 4 ED_{50} (mg kg^{-1}) of clonidine, dexmedetomidine and morphine on gastric emptying and gastrointestinal transit (with 95% CL). Only lower 95% CL are shown when values are outside the range of doses used

	Gastric emptying	Gastrointestinal transit
Clonidine (n=41)	— (4.6, —)	0.080 (0.049, 0.13)
Dexmedetomidine (n=30)	— (4.3, —)	0.039 (0.027, 0.065)
Morphine (n=52)	2.8 (2.1, 3.8)	1.2 (0.87, 1.7)

Alpha$_2$-adrenoceptor agonists dose-dependently inhibit gastrointestinal transit through the alpha$_2$ adrenoceptor; however, they only weakly inhibit gastric emptying.

Key words
Gastrointestinal tract, gastric emptying. Sympathetic nervous system, alpha$_2$-adrenergic agonists.

Caesarean section; efficacy of morphine patient-controlled anaesthesia *vs* ketorolac infusion

M. A. Bewlay and A. S. Laurence
Department of Anaesthetics, The Royal Preston Hospital, Preston

Patient-controlled analgesia (PCA) with morphine can have disadvantages of drowsiness, dizziness, nausea and vomiting, which are particularly unwanted after Caesarean section. Ketorolac is known to be effective for pain relief especially in combination with opioids.[1] It is usually given by i.m. bolus doses.

Forty-one consenting patients, ASA I or II, presenting for elective Caesarean section under spinal anaesthesia were given ranitidine before operation on the night before and morning of operation. I.v. infusion was commenced and a spinal performed with a dose of 0. 5% heavy bupivacaine as chosen by the anaesthetist. Towards the end of the operation all patients were given 10 mg morphine and 10 mg ketorolac i.v. Each patient was then allocated to one of two groups.

The morphine group received a PCA pump containing morphine 60 mg + cyclizine 100 mg in 60 ml saline. Bolus i.v. doses of 1 mg with a lockout of 5 min were set with no background infusion. Ketorolac 30 mg i.m. 8-hourly was prescribed for escape analgesia.

The ketorolac group received a PCA pump with ketorolac 90 mg in 60 ml. This was run at a rate of 2.55 mg h^{-1}, with bolus dose of 0.15 mg, and lockout of 10 min was used to help blind the study (60 mg over 24 h with 30 mg available for boluses giving a maximum of 90 mg in 24 h). Cyclimorph 10 i.m. 3-hourly was prescribed as escape analgesia. Both groups were prescribed prochlorperazine 12.5 mg 8-hourly.

The pumps were continued until the morning after operation. Routine postoperative observations were made by the midwives, together with pain scores (1=none, 2=mild, 3=moderate, 4=severe), nausea/vomiting (1–4), and sedation (1–4). All patients were reviewed 24 h after operation and asked to give a satisfaction score of 1 (awful) to 5 (excellent) (table 5).

Table 5 Pain and satisfaction scores. (NS=not significant; MW=Mann–Whitney; KW=Kruskall–Wallis)

	Morphine		Ketorolac
Number of patients	21		20
Total pain events 1, 2	208/230	NS	191/218
Total pain events 3, 4	22/230	KW	27/218
Av. drug dose (mg) (range)	49 (24–71)		56 (30–71)
No. of escape doses	4 in 3 pts		10 in 8 pts
Satisfaction score			
3, 4, 5	20/21	NS	17/20
1, 2	1/21	MW	3/20

Nausea and vomiting scores, and sedation scores were surprisingly similar in both groups. The total number of unsatisfactory (score 3 or 4) pain score events was not significantly different between groups, nor were the pain scores significantly different at any time interval postoperatively (Kruskall–Wallis). The final satisfaction score was also not significantly different between the groups.

Patients for Caesarean section have less pain than those for upper abdominal surgery and, in addition, have a positive psychological factor.[2] Consequently the requirement for analgesia is less. We have shown that a ketorolac infusion plus i.m. Cyclimorph for escape analgesia provides comparable pain relief (with less opioid use) with conventional morphine PCA. (We feel that better education regarding the need for adequate escape analgesia could improve the success of the technique.)

Aspirin and the bleeding time

J. R. Sonksen* and K. L. Kong
Department of Anaesthesia, City Hospital, Birmingham and Department of Anaesthesia and Intensive Care, University of Birmingham

Aspirin is known to impair primary haemostasis by inhibiting platelet aggregation and thus prolonging the bleeding time. The ingestion of aspirin within 7–10 days is a relative contraindication to the siting of an extradural catheter, unless the bleeding time is shown to be less than 10 min.[1] The prolongation of the bleeding time in response to aspirin is variable, with 15–20 % of the adult population being hyper-responders.[2] The present study was designed to determine how the prolongation of the bleeding time, induced by low dose aspirin, changes over the first 48 h of discontinuing therapy.

Forty-eight adult ASA I volunteers were recruited from the staff of the City Hospital. After informed consent volunteers were entered into the randomized, double-blind, placebo-controlled trial, and received a 7-day course of either once daily low dose aspirin (75 mg or 300 mg), or placebo. A baseline bleeding time was performed on each volunteer before therapy and again 2, 9, 24 and 48 h after the last trial tablet. The main outcome measure was the bleeding time at 48 h (table 6).

Table 6 Mean (SD) bleeding times (s) during the 48 h after stopping aspirin. (BT = bleeding time)

Group	Baseline BT	Peak BT	48-h BT
75 mg	274 (67)	437 (145)	323 (83)
300 mg	229 (57)	479 (301)	313 (127)
Placebo	253 (60)	234 (70)	233 (88)

The mean prolongation of the bleeding time caused by 75 mg and 300 mg of aspirin was 162 and 246 s respectively. In all there were six hyper-responders. Their mean prolongation was 504 s. At 48 h the bleeding times were prolonged by 49 and 64 s respectively in the 75-mg and 300-mg groups. The mean bleeding time for the hyper-responders at this time was 72 s above baseline. In each of these groups the bleeding time at 48 h was significantly different from their respective baseline values ($P<0.05$; paired t-test). However, the bleeding time in all volunteers at 48 h was well below the 10-min limit and, importantly, the time course of effect was similar whatever the dose, and whatever the magnitude of response we saw.

For healthy volunteers, the bleeding time 48 h after stopping a 7-day course of low dose aspirin is within the normal range, and close to their baseline values.

Pharmacokinetics of atracurium after paediatric orthotopic liver transplantation

B. F. M. Chow*, M. I. Bowden*, E. Ho*, B. C. Weatherley* and J. F. Bion*
University Department of Anaesthesia and Intensive Care, Queen Elizabeth Hospital, Birmingham

Atracurium besylate is widely used by infusion in adult intensive care practice, but there is little information about its kinetics and safety in paediatric intensive care. This study was conducted in children after orthotopic liver transplantation (OLT), as a suitable model for critically ill children.

Ten children (five male) were studied after OLT on return to the ICU. The mean (range) age was 36 (7–78) months, and weight 6–24.2 kg. One child died in the ICU, and one had chronic renal impairment not requiring dialysis. Atracurium was started in theatre at induction of anaesthesia, and adjusted in the ICU according to clinical need. Neuromuscular block was measured using accelerometry (TOFguard) and TOF ratio or count. Arterial plasma samples for atracurium and metabolites taken before, every 12 h during, and at frequent intervals after, the infusion; were processed and stored using standard methods; and analysed by HPLC. Results are given as means (range).

The mean maximum infusion rate during steady state conditions was 1.44 (0.48–3.13) mg kg^{-1} h^{-1}, and the duration of infusion 36.9 (22.5–98.4) h. Tachyphylaxis was not observed. Atracurium $T_{1/2}$ was 18.8 (12–32.3) min, similar to critically ill adults[1] and paediatric surgical patients. CL_{ss} was 13.9 (7.9–20.3) ml min^{-1} kg^{-1}, and V_D 390 (124–551) ml kg^{-1}, both higher than in adults after successful OLT.[2] Laudanosine Cmax was 1190 (400–1890) ng ml^{-1} and $T_{1/2}$ 3.9 (1.1–6.7) h. Renal clearance was 1.3 (0.1–5.8) ml min^{-1} kg^{-1}, and increased with urine flow, but there was no relationship with serum creatinine. Steady state conditions could not be obtained for calculation of laudanosine CL_{ss}. EEG spikes were identified for one child only; the corresponding laudanosine Cmax was 720 ng ml^{-1}. Monoquaternary alcohol Cmax was 986 (330–1770) ng ml^{-1}, and $T_{1/2}$ 42.9 (30–57.7) h. Mean recovery time to a TOF ratio >0.75 was 23.6 (12–27) min.

Atracurium is an effective and safe neuromuscular blocking agent in this population. Laudanosine clearance is normal given satisfactory graft function.

Effect of remifentanil on the auditory evoked response and haemodynamic changes after intubation and surgical incision

R. R. McGregor*, R. Sharpe*, C. Thornton and D. E. F. Newton
Academic Department of Anaesthesia, St Mary's Hospital Medical School, Northwick Park Hospital, Harrow

The ability of remifentanil to suppress the cortical and autonomic effects of intubation and incision was investigated. We examined the effect of remifentanil in combination with either propofol or isoflurane on the auditory evoked response (AER) and haemodynamic variables. The amplitude of the early cortical AER wave (Pa) has been shown to be a sensitive monitor of depth of anaesthesia,[1] increasing in amplitude following laryngoscopy/intubation[2 3] and surgical incision.

Twelve patients undergoing hernia repair or varicose vein surgery were randomized to receive either an inhaled anaesthetic using isoflurane or a total i.v. technique using propofol. In both cases this was accompanied by an infusion of remifentanil. Anaesthesia was induced with remifentanil 1 μg kg^{-1} and propofol (mean 80 mg). Neuromuscular block was achieved with atracurium (0.6 mg kg^{-1}) before intubation. In both groups the patients' lungs were ventilated with an oxygen/air mixture. Remifentanil was administered as a continuous infusion of 0.5 μg kg^{-1} min^{-1} reducing to 0.25 μg kg^{-1} min^{-1} 5 min after intubation. Propofol was infused at 9 mg kg^{-1} h^{-1} reducing to 6 mg kg^{-1} h^{-1} after 10 min. Isoflurane concentration was maintained at 0.6% end-tidal. The AER, systolic pressure, diastolic pressure and heart rate were measured before and after intubation and incision to determine any changes in the cortical or autonomic response to these stresses.

The effects of intubation and incision on the AER and haemodynamic variables were not statistically significantly different between the remifentanil/propofol or remifentanil/isoflurane group. When the data for the two anaesthetic combinations were pooled the only significant effects were increases in the diastolic pressure and heart rate immediately after intubation (table 7). However, these were no longer seen 5 min after intubation. There were no cardiovascular responses to incision. There were no significant changes in the AER after intubation or incision.

Table 7 Mean (95% CI) of haemodynamic variables (n=12). (*Post *vs* pre-intubation, P=0.035. †Post *vs* pre-intubation, P=0.014)

	SBP (mm Hg)	DBP (mm Hg)	HR (mm Hg)
Pre-intubation	91 (82–100)	49 (43–55)	61 (56–65)
Post-intubation	103 (93–112)	58 (52–64)*	69 (64–73)†
Pre-incision	98 (88–107)	56 (50–62)	60 (55–65)
Post-incision	96 (87–105)	58 (55–65)	62 (57–67)

In previous studies increases in Pa of 36%, 53% and 60% [2 3] were seen after laryngoscopy/intubation. An increase of 29% would be detected at the 5% level of significance (assuming a power of 80%) in this study. These results indicate that the potent opioid remifentanil in combination with either propofol (6 mg kg^{-1} h^{-1}) or isoflurane (0.6% end-tidal conc) can obtund the autonomic and early cortical effects of intubation and incision.

Key words
Analgesics opioid, remifentanil. Anaesthesia, depth.

Effect of propofol on the electrocorticogram in patients undergoing cortical resection

D. L. K. Chu*, P. B. Hewitt, C. E. Polkey* and C. Binnie*
UMDS Department of Anaesthetics, Guy's Hospital, London and Academic Neurosciences Unit, King's College School of Medicine & Dentistry, London

It has been claimed that propofol can cause epileptic seizures despite contradictory evidence that it reduces the clinical effect of electroconvulsion therapy in psychiatry[1] and has anticonvulsant properties.[2] The aim of this study was to compare the effects of clinical doses of propofol with thiopentone on epileptiform activity on the electrocorticogram (ECoG) in epileptic patients undergoing cortical resection.

Fifteen patients with longstanding epilepsy were premedicated with papaveretum 0.2–0.3 mg kg^{-1} and hyoscine 0.4–0.6 μg kg^{-1}. Anaesthesia was induced with i.v. thiopentone 3–7 mg kg^{-1}. Neuromuscular block was produced with atracurium 0.5–0.6 mg kg^{-1} and maintained using an infusion of 0.3–0.5 mg kg^{-1} h^{-1}. The lungs were ventilated with 0.5–2% isoflurane in a mixture of 70% nitrous oxide and oxygen. The systolic blood pressure was maintained >100 mm Hg and mean blood pressure >60 mm Hg by adjustment of inspired isoflurane concentration and i.v. fluid administration. End-tidal carbon dioxide was 3.5–4.5 kPa and nasopharyngeal temperature 36.8–37.4°C. The drugs were administered in a crossover fashion before cortical resection; thiopentone 25 mg or propofol 20 mg was given i.v. every 30 s to a maximum of 5 mg kg^{-1} or until burst suppression. The ECoG was recorded throughout the administration and 10 min thereafter. After return of baseline ECoG, the crossover administration was performed. The recordings were assessed by a neuroelectrophysiologist (C.B.).

Activation of the ECoG was defined as either an increase of spike waves from baseline > 3 per 10 s or extension which was defined as the development of spike waves in more than one new site. All ECoG became isoelectric in patients who were given propofol at or below 1 mg kg^{-1}, while thiopentone administration up to 2.5 mg kg^{-1} produced burst suppression (table 8).

Table 8 Effect of propofol and thiopentone on activation and extension of spike waves in EcoG (No. of patients)

	Activation	No activation	Extension	No extension
Propofol	10	5	6	9
Thiopentone	12	3	5	10

Propofol and thiopentone both produced activation and had similar effects on the ECoG regarding topography and type of discharge. Propofol in the dose employed produced burst suppression more rapidly than thiopentone. Propofol did not cause more epileptiform activity than thiopentone did in epileptic patients undergoing cortical resection. Propofol uniformly induced isoelectic ECoG recording at 1 mg kg^{-1} or less, that is a subclinical dose for induction of anaesthesia. Propofol can be used as an alternative to thiopentone for activation of the EcoG before cortical resection, but the bolus doses administered should be smaller than those used in this study.[3]

Comparison of the effects of halothane and isoflurane on the electroencephalogram of the horse

C. B. Johnson* and P. M. Taylor
Department of Clinical Veterinary Medicine, University of Cambridge, Cambridge

In humans, halothane and isoflurane have both been shown to reduce median (F50) and spectral edge (SE95) frequency of the EEG and to abolish middle latency auditory evoked potentials (MLAEP). Despite these similar effects, most of the changes seen with isoflurane occur at concentrations below MAC, while progressive changes can be seen with halothane at concentrations up to approximately 2 MAC.[1] The EEG effects of these agents in the horse appear to be similar to those in humans,[2] but changes in F50, SE95 and MLAEP have not been directly compared. The aim of this study was to compare the EEG effects of isoflurane and halothane in the horse.

Eight healthy Welsh Mountain ponies weighing between 270 and 325 kg were anaesthetized on two separate occasions using i.v. thiopentone 10 mg kg^{-1} without premedication. At least 2 weeks was allowed between subsequent anaesthetics in the same animal. On one occasion anaesthesia was maintained using halothane in oxygen and on the other isoflurane in oxygen. IPPV was adjusted to keep end-tidal carbon dioxide between 5.3 and 5.9 kPa. Arterial pressure was monitored using a cannula placed in the right carotid artery which had previously been raised to a subcutaneous position. End-tidal anaesthetic agent concentration was monitored using a piezoelectric agent monitor (Kontron agent monitor 7860).

After 60 min of anaesthesia the end-tidal halothane or isoflurane concentrations were adjusted to 0.8% or 1.2% respectively corresponding to just below MAC for each agent. When the end-tidal concentration had been stable for 10 min, 15 min of single channel EEG were recorded using a dedicated preamplifier with a built-in auditory stimulus generator (Alert system, Medelec). F50, SE95 and MLAEP were calculated from the EEG for sequential 1-min epochs. The second differential of the MLAEP (DD) was calculated in order to facilitate comparison. The recording process was repeated for 1.0% and 1.2% halothane and 1.5% and 1.8% isoflurane corresponding to approximately 1.25 and 1.5 MAC. Normocarbia and the absence of hypoxaemia were confirmed from arterial blood gas samples taken at the beginning and end of each recording period.

There was a statistically significant reduction in SE95 at each subsequent end-tidal halothane concentration from 13.9 (2.6) Hz (mean (SD)) at 0.8% to 11.9 (1.1) Hz at 1.2%. In addition, the DD at 1.2% halothane (21 (6.5)) was significantly less than that at 0.8% halothane (27.6 (11.4)). The only statistically significant difference in the isoflurane data was an increase in SE95 from 10.2 (1.5) Hz at 1.5% to 10.8 (1.6) Hz at 1.8%. The value at 1.2% was intermediate. There was a progressive increase in the incidence of burst suppression with increasing isoflurane concentration. No burst suppression was seen during halothane anaesthesia. The values of SE95, F50 and DD seen at all three isoflurane concentrations were similar to those seen at 1.2% halothane.

The EEG effects of halothane and isoflurane appear to occur at different concentrations of these agents in terms of multiples of MAC.

Topographic distribution of the bispectral index

J. D. Hall* and G. G. Lockwood
Department of Anaesthesia, Hammersmith Hospital, London

The bispectral index (BIS) is a single numeric variable derived from a raw EEG signal. It is derived using an algorithm utilizing both linear and non-linear data and can therefore reflect changes in the phase, power and frequency of the EEG. The BIS is dependent upon the depth of anaesthesia and the degree of surgical stimulus. It has been used to predict movement at incision[1] and may be useful to detect awareness. Published studies have used lead arrangements (montages) which include electrodes within the hairline. These inhibit its introduction into clinical practice, but more convenient montages have not been validated and the BIS may be montage dependent.

We have compared a clinically convenient bifrontal montage with a frontocentral montage for security of lead placement, impedance, signal quality and BIS values. Electrodes were placed at F$_7$, Fp$_z$, F$_8$, C$_3$, C$_4$ and mastoid. When F$_7$ and F$_8$ lay inside the hairline, the electrodes were placed slightly medially. Frontal and mastoid sites were degreased with isopropanol, abraded with Nuprep (D.O. Weaver & Co., USA) and paediatric Ag/AgCl self-adhesive ECG electrodes (NiKo Medical Products) applied. The scalp was abraded with NuPrep and silver dome electrodes applied using Ten 20 (D.O.W) adhesive paste. The BIS and a signal quality index (SQI) were computed by an A-1000 EEG (Aspect Medical, USA) from the F$_7$-Fp$_z$ and F$_8$-Fp$_z$ pairs and from the F$_7$-C$_3$ and F$_8$-C$_4$ pairs. Anaesthesia was not controlled.

Data were collected by computer every 15 s. The median SQI for each montage was calculated for each patient. The BIS for the two montages, excluding data associated with SQI<75%, were correlated. A manual note was made when an electrode needed replacement. The electrode impedances were recorded by the computer whenever an impedance check was requested during the case, commonly when resiting an electrode. The last impedance value only from such an episode was used in the analysis.

Results are presented from 10 patients undergoing a variety of surgical procedures. The reliability of electrode replacement is summarized in table 9. The median SQI of the two montages were not significantly different. Excluding periods of poor signal

Table 9 Reliability of electrode placement

Electrode	F$_7$	Fp$_z$	F$_8$	C$_3$	C$_4$
No. of replacements needed	0	4	0	9	11
Median impedance (Ω)	2050	2200	3500	1500	3800

quality, the correlation coefficient between the BIS calculated from the frontal and the frontocentral montages was 0.75.

We conclude that a frontal montage provides a more convenient and secure EEG, but the BIS from the two sites may not be equivalent.

Assessment of frequency of audit of pain in day-case surgery

P. D. Nelson*, Z. P. Khan and M. Weisz*
Department of Anaesthesia, St Mary's Hospital, London

Pain is a potent cause of patient dissatisfaction and is the single most important factor in the delay in returning to normal activity after day-case surgery.[1] In the USA, many day surgery units routinely contact patients by telephone to assess recovery after discharge.[2] The objective of this study was to determine the incidence of assessment and audit of postoperative pain in day-case patients in the UK.

Fifty schedule one hospitals, from the document "Recognition of hospital posts under the FRCA regulations", were chosen at random. A telephone interview was conducted with a senior registrar or consultant anaesthetist involved with day-case anaesthesia in the selected hospital. It was possible to obtain completed questionnaires from all 50 hospitals.

All the hospitals performed day case surgery, although only 42 (84%) had separate day-care facilities. There was a consultant anaesthetist in charge of day-case anaesthesia in 26 (52%) of the hospitals, although only one of these had no separate day-care facilities.

Some method of assessing pain was used in 32 (64%) of the hospitals before discharge, though the majority of these (17) used an informal, bedside assessment. Of the units which used a formal type of in-hospital assessment, most (12) used a pain score out of 4 or 10. The other units (3) used a visual analogue score (VAS). By contrast, 36 (72%) of the hospitals did not routinely assess postoperative pain after discharge from hospital. Of the minority that did, most (7) phoned the patients at home on the night of surgery, while some (4) asked the patients to fill in a questionnaire and the others (3) had a nurse visit the patients at home.

Of the 50 hospitals, audit of postoperative pain was performed in 20 (40%) of the units before discharge, and in 23 (46%) of the units once the patients had returned home.

Those hospitals with a consultant responsible for day-case anaesthesia were more likely to perform audit, both in-hospital (17) and after discharge (15), than those units with no designated consultant (corresponding figures 3 and 8 respectively).

Audit is the means by which we can assess the incidence of pain after day-case surgery and then close the loop by improving clinical practice in order to reduce the incidence of this complication.

Respiratory depression following morphine and alfentanil in combination

J. A. Ramirez, R. S. Isherwood, A.S. Laurence and R. Strettle
Department of Anaesthetics, The Royal Preston Hospital, Preston and Department of Pharmacology, University of Central Lancashire, Preston

Patient-controlled analgesia could be improved if rapid onset analgesia followed the bolus administration but with a morphine-like duration of action. The equipotent dose ratio of morphine to alfentanil has been quoted as 10–15:1.[1]

Thirty consenting ASA I and II patients, aged 19–71 presenting for body surface surgery were studied in three groups of 10. All were anaesthetized with propofol, laryngeal mask and spontaneous respiration with isoflurane through a Lack circuit. Fresh gas flow was adequate to ensure there was no rebreathing.

All patients were routinely monitored in addition to end-tidal carbon dioxide (Datex Capnomac Ultima), computed minute volume (CMV) and respiratory rate (Mercury Computing Spirometer CS7) recording onto chart recorders. When stable respiration was established, patients were given an i.v. bolus of morphine 2 mg, alfentanil 0.2 mg or a mixture of both, via a syringe driver over 1 min. Recording was continued for a further 15 min after which anaesthesia was deepened before surgery.

Mean age (55.9, 46.6, 49.6 yr), weight (74.5, 75.1, 83.1 kg), and sex distribution was similar in all groups. After drug administration, there was a slow reduction in CMV in the morphine group which had reached a plateau by the end of the recording, whereas the alfentanil group showed a rapid decrease, maximal at 2 min, thereafter returning towards baseline. The combination group also showed a rapid decrease maximal at 2.5 min, thereafter similar to the morphine group (fig. 3). Mean end-tidal carbon dioxide rose by 4 mm Hg at 12 min, 5 mm Hg at 5 min and 6 mm Hg at 12 min, respectively for the three groups, and respiration rate decreased by 2 bpm at 12 min, 6 bpm at 3 minutes and 7 bpm at 5 min.

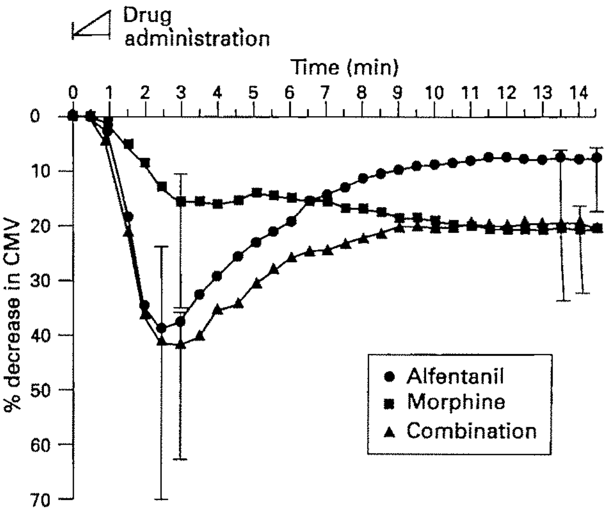

Figure 3 Mean percentage change in computed minute volume (CMV) and range.

Although the maximal carbon dioxide increase in the combination group was higher, the maximal changes in respiration rate and CMV were not markedly greater in the combination group than with alfentanil alone. The delivery of the drugs over 1 min was to simulate patient-controlled analgesia (PCA) administration. Our morphine dose was twice the commonly used PCA bolus to emphasize the respiratory effects. The objective of rapid analgesic effect[2] (implied by respiratory changes) without overshoot would have been better achieved with a lesser alfentanil ratio, although we cannot directly relate our findings to the awake patient.

Thoracic extradural infusions for pain after thoracotomy: are fentanyl–bupivacaine mixtures better than fentanyl alone?

S. V. Mahon*, P. D. Berry*, S. Thomas, K. Mills*, M. Jackson*, A. Soorae*, S. H. Pennefather* and G. N. Russell*
Department of Anaesthesia, The Cardiothoracic Centre, Liverpool

Thoracic fentanyl extradural analgesia has been shown to provide better postoperative lung function and shorter hospital stay than i.v. fentanyl and lumbar fentanyl extradural analgesia for patients after thoracotomy.[1] The quality of fentanyl extradural analgesia may be improved by the addition of low dose bupivacaine although the benefits or otherwise of this technique remain unclear.[2 3]

A randomized double-blind clinical trial was conducted on 106 patients scheduled for resection of lung tissue via thoracotomy. Preoperatively, patients had an extradural catheter inserted at the T5–6 or T6–7 intervertebral space and received a test dose of 3 ml 0.5% bupivacaine with 1 in 200 000 adrenaline. All patients received general anaesthesia for their procedures. The study extradural solution contained 0, 0.1 or 0.2% bupivacaine in combination with fentanyl 10 μg ml^{-1}. Intraoperative analgesia was provided by a 5–10-ml bolus of extradural solution delivered before surgical incision followed by an infusion of between 5 and 10 ml h^{-1} according to clinical requirements. Postoperatively, infusion rates were adjusted and boluses given according to analgesic requirements and occurrence of side effects. Analgesic adequacy at rest and during movement was assessed at 2, 4, 8, 16 and 24 h. All patients received continuous invasive haemodynamic monitoring in an HDU environment for up to 24 h with variables archived at 5-min intervals. Any episodes of respiratory depression, nausea, neurological deficit and pruritus were recorded. Analgesic efficacy was assessed using visual analogue scores (VAS), an observer/verbal ranking scale (OVRS) and by the total extradural solution used.

After patient exclusion, 95 sets of data were available for analysis. An analysis of outcome variables was performed for each time point using the Kruskal–Wallis analysis of variance. A P value of <0.1 prompted pairwise exploration using the Wilcoxon rank sum test. There was a difference in the pain scores at the 2-h (first) measurement time only with higher pain scores in the fentanyl alone group (table 10). Otherwise, there were no between-group differences in pain scores or in the total amounts of extradural solution used. There were no between-group differences in the number of episodes of hypotension or in the number of interventions for hypotension. However, the use of intraoperative vasopressor and the incidence of neurological complications were significantly higher in the 0.2% bupivacaine group. We conclude that in the early postoperative period, the addition of bupivacaine 0.1% improves fentanyl thoracic extradural analgesia without increasing the incidence of side effects.

Table 10 P values for differences in pain scores at 2 h (F= fentanyl alone; FB1 = fentanyl and bupivacaine 0.1%; FB2 = fentanyl and bupivacaine 0.2%)

	F *vs* FB1	F *vs* FB2	FB1 *vs* FB
VAS	0.03	0.08	0.6
VAS with cough	0.01	0.02	0.88

Propofol protects rat hepatocytes against an oxidant stress

V. U. Navapurkar*, D. K. Menon and J. G. Jones
University Department of Anaesthesia, Addenbrooke's Hospital, Cambridge, and Peterborough District Hospital

Propofol (2, 6-diisopropylphenol) is an i.v. anaesthetic agent with antioxidant properties.[1] Using rat hepatocyte suspensions we investigated whether pretreatment with propofol protected nucleated cells against an oxidant stress. The oxidant used was AAPH (2,2'-azobis (2-amidinopropane) dihydrochloride). This is a water-soluble free radical generator which produces maximal cell death in rat hepatocytes when used in a 50 mmol litre^{-1} concentration.[2]

Healthy, adult male Sprague-Dawley rats were killed and hepatocyte suspensions (2×10^6 cells ml^{-1}) prepared using the two-step collagenase perfusion technique.[3] The initial percentage of viable hepatocytes was measured using the Trypan blue exclusion test.[3] Hepatocyte suspensions (3 ml) were incubated and oxygenated in a shaking waterbath at 37°C with propofol (5 μg ml^{-1}) plus AAPH (50 mmol litre^{-1}) ($n = 7$), AAPH (50 mmol litre^{-1}) alone or, in a separate experiment, with 10% Intralipid (0.5 μl ml^{-1}) plus AAPH (50 mmol litre^{-1}) ($n = 6$). Each experiment had untreated control suspensions. Viabilities were measured again at 1, 2 and 3 h.

Control cells showed a decrease in viability with time. The addition of AAPH reduced the viability compared with control at all time points ($P<0.0001$). Pretreatment with propofol significantly reduced this effect at 1 h ($P=0.0013$) but no effect was observed with Intralipid pretreatment at any of the time points (fig. 4).

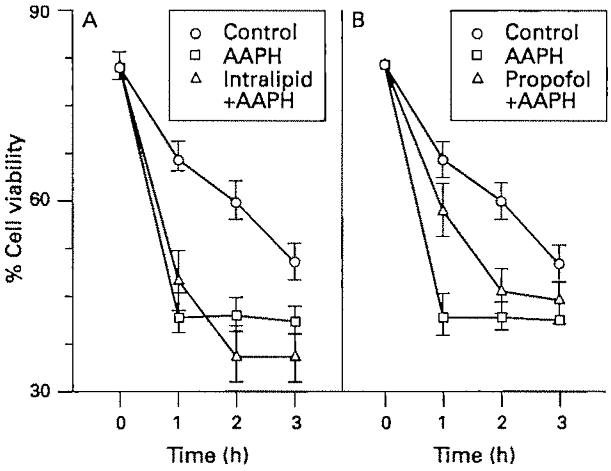

Figure 4 Survival of isolated rat hepatocytes with time in different treatment groups (see text). Bars indicate SEM.

Clinically relevant concentrations of propofol protect rat hepatocytes from an oxidant stress. To our knowledge this has not been demonstrated in nucleated cells before. Propofol may exert its effect in the cell membrane by limiting oxidant mediated lipid peroxidation although other intracellular mechanisms may also be involved.

Effects of post-injury MK-801 on behaviour and neuropeptides in the spinal cord dorsal horn of the mononeuropathic rat

M. J. Hudspith*, S. Harrison*, G. Smith*, P. J. Elliot*, P. J. Birch*, C. Bountra*, J. G. Jones, S. P. Hunt* and R. Munglani
University Department of Anaesthesia, Addenbrooke's Hospital, Cambridge, Department of Neurobiology, MRC Laboratory of Molecular Biology, Cambridge and Department of Neuropharmacology, Glaxo Research Group, Ware, Herts

In the mononeuropathic rat, loose ligation of the sciatic nerve causes loss of the neuropeptides substance P (SP) and calcitonin gene-related peptide (CGRP) in laminae 1–2,[1] and an increase in neuropeptide Y (NPY) in laminae 3–4[2] of the ipsilateral dorsal horn. Only the increase in NPY has been shown to correlate with the hyperalgesia that develops in this model,[2] and pre-emptive administration of MK-801 can delay both the development of hyperalgesia and inhibit the increase in laminae 3–4 NPY.[2] In this study we have investigated the effect of post-injury MK-801, administered after the mechanical hyperalgesia is established, upon behaviour and neuropeptide expression in the spinal cord dorsal horn.

Sciatic nerve ligation or sham operation was performed under isoflurane anaesthesia and animals were allowed to recover for up to 55 days. Animals received MK-801 0.3 mg kg^{-1} (MK group) or equivalent volumes of saline (saline group) by s.c. injection on days 28–34 after operation. Paw withdrawal thresholds to mechanical stimulus were quantified at 14, 35 and 55 day time points, after which the animals were killed and quantitative peptide fluorescent immunohistochemistry was used to analyse the L4–5 spinal cord. Data were analysed by ANOVA with Bonferroni–Dunn correction and are expressed as mean (SEM).

Ligated animals were hyperalgesic when compared with shams at 14 days and hyperalgesia persisted unchanged in the saline group to 55 days. MK-801 reduced hyperalgesia at 35 days (P=0.015), but by 55 days the hyperalgesia scores in MK-801 treated animals were indistinguishable from the saline group.

Ligated animals showed a significant loss (25–35%) of laminae 1–2 SP and CGRP at 35 and 55 days compared with shams. MK-801 had no significant effect upon CGRP at any time point. MK-801 attenuated the loss of SP at 35 days (P=0.048) but had no effect at 55 days. Ligated animals showed ipsilateral increases in laminae 3–4 NPY of 172.3 (24.9)%, 97.1 (11.2)% and 78.3 (8.0)% at 14, 35 and 55 days respectively; these increases were highly significant when compared with equivalent shams. MK-801 treatment attenuated the laminae 3–4 increase in NPY (50.3 (12.9)%) at 35 days when compared with saline group (P=0.03); attenuation was more marked at 55 days (14.4 + 4.4% increase: P<0.0001 *vs* ligated saline group) and laminae 3–4 NPY at this time point did not differ from equivalent MK-group shams.

Therefore, post-injury treatment with MK-801 has only transient effects upon hyperalgesia and neuropeptides SP and CGRP, but has long-lasting effects upon the novel NPY expression in laminae 3–4 of the ipsilateral dorsal horn. While laminae 3–4 NPY correlated with hyperalgesia at 35 days in the MK-group as previously observed with pre-emptive MK-801,[2] no correlation was evident at 55 days after ligation. This suggests that persistent elevation of laminae 3–4 NPY is not essential to the maintenance of pain behaviour in this model of neuropathic pain.

Effect of combining tramadol with piroxicam for analgesia after total hip replacement

S. ECKERSALL*, D. BOSE* AND F. DORMAN*
Department of Anaesthesia, Lister Hospital, Stevenage

Tramadol has been compared favourably with standard opioids for the control of postoperative pain.[1,2] The purpose of this study was to see whether combining the NSAID piroxicam with tramadol for postoperative analgesia after total hip replacement would reduce both the amount of tramadol needed to provide analgesia and the incidence of nausea and vomiting associated with tramadol.

Thirty ASA I–III patients scheduled for total hip replacement were randomized to receive either a 20-mg piroxicam melt (group A) or a placebo (group B) orally preoperatively. Anaesthesia was induced with fentanyl (1–2 $\mu g\ kg^{-1}$) and propofol (1–2 mg kg^{-1}). The airway was controlled with a laryngeal mask for spontaneous ventilation or tracheal tube for controlled ventilation (intubated with 0.5 mg kg^{-1} vecuronium). After induction, the patients received a subarachnoid injection of 12.5 mg of hyperbaric bupivacaine 0.5% at the level of L3–4. Anaesthesia was maintained with a mixture of 60% nitrous oxide and 40% oxygen with 0.1–1.5% isoflurane. In recovery, the patients were connected to a PCA device containing tramadol 500 mg . Pain was assessed hourly using a verbal rating scale (1–5) and the dose of tramadol used was noted. Patients were allowed to receive 10 mg of morphine i.m. if their pain score was 3 or greater. The occurrence of nausea and vomiting and the use of morphine were also recorded.

The groups were comparable for age, sex and weight. Data were analysed using Student's t-test and chi-square analysis. The mean dose of tramadol used by 12 and 18 h was significantly less in group A than group B. The number of patients requiring supplemental morphine and those complaining of nausea and vomiting were also significantly less in group A. Table 11 shows the results.

Table 11 Doses of tramadol (mg) (SEM) used to control pain.(*P < 0.05 compared with group A (Student's t-test); †P < 0.01 compared with group A (chi-square test); ††P < 0.05 compared with group A (chi-square test))

	Group A (n=15)	Group B (n=15)
Mean dose used by 6 h	182.6 (20.07)	203.3 (29.2)
Mean dose used by 12 h	278.5 (22.8)	361.3 (23.2)*
Mean dose used by 18 h	372.3 (30.2)	454.6 (18.7)**
No. requiring supplemental morphine	1	10††
No. complaining of nausea (vomiting)	3 (0)	9 (7)†

Combining tramadol and piroxicam appears to reduce the dose of tramadol needed to provide postoperative analgesia and the incidence of nausea and vomiting.

POSTER PRESENTATIONS

Ambulatory extradural analgesia in labour reduces risk of Caesarean section

A. E. MAY* AND C. D. ELTON
Department of Anaesthesia, Leicester Royal infirmary, Leicester

Extradural analgesia in labour with plain solutions of bupivacaine results in unwanted motor block precluding ambulation. Such extradurals have been associated with an increased incidence of Caesarean section.[1] It has been suggested that maintenance of the upright posture in labour is advantageous.[2] A combined spinal extradural (CSE) technique has been described[3] which delivers acceptable analgesia while maintaining ability to ambulate in labour. We describe preliminary results of work in progress to assess the benefits of maintaining mobility in labour.

Informed consent was obtained from 67 women who were randomly allocated to two groups.

In group 1 a lumbar extradural catheter was sited. A test dose of 50 mg of lignocaine in 2.5 ml was followed by 25 mg bupivacaine in 10 ml. When pain returned further extradural doses of 25 mg of bupivacaine were administered as required

In group 2 a Sprotte spinal needle (24-gauge, 120 mm) was inserted through a 16-gauge Tuohy extradural needle. Bupivacaine 2.5 mg and fentanyl 25 μg were injected into the cerebrospinal fluid. An extradural catheter was then threaded. Extradural doses of 20 μg of fentanyl and 10 mg of bupivacaine in 10 ml were administered when pain returned.

Half hourly pain scores, arterial pressure and mobilization were recorded throughout subsequent labour and delivery. Mode of delivery was recorded at follow up.

The two groups were comparable for age, parity and pain score. No patient in group 1 was able to ambulate whereas all patients in group 2 walked at some time in labour.

There was a significant increase in Caesarean section rate in patients in group 1 (plain bupivacaine group); chi-square test=3.89; $P<0.05$ (table 12).

This study suggests that CSE is associated with a lower risk of Caesarean section than a conventional extradural technique. However, further studies need to be performed to confirm these findings and allow more detailed assessment of the technique.

Table 12 Results. (CSE=combined spinal extradural technique)

Group	Vaginal delivery (spontaneous or instrumental)	Caesarean section
Group 1	26	11
Group 2 (CSE)	27	3

An explanatory model for postoperative vomiting after gynaecological surgery

A. SABRINE*, J. MORRIS* AND M.C. BELLAMY
Department of Anaesthesia, St James's University Hospital, Leeds

Postoperative nausea and vomiting (PONV) is a common event in gynaecology patients. Identifying in advance those most likely to vomit should allow targeting of treatment to increase safety and effectiveness. We have therefore studied pre- and intraoperative factors potentially predictive of postoperative vomiting.

We have collected data 48 h after operation on patients undergoing major gynaecological surgery. Information was obtained by review of case notes, prescription sheets and direct patient questioning. Postoperative vomiting (PV) and nausea were graded as present or absent; subjective questions regarding severity of symptoms were not asked. A number of potential correlates of outcome were considered: age, weight, preoperative arterial pressure, history of PV, open or laparoscopic procedure, presence of a nasogastric tube, use of nitrous oxide, use of total i.v. (propofol) anaesthesia, maximum change in arterial pressure, intraoperative fluid administration, perioperative antiemetic, administration of ondansetron, duration of surgery, cumulative morphine dose, presence or absence of droperidol added to morphine in the patient-controlled analgesia system (PCAS). Logistic regression analysis was applied to suggest predictors of PV.

We recorded data for 103 patients; 31% (22.1–39.9%, 95% confidence interval) suffered from PV. Nausea was found to be too imprecise and too common an end point (64% (54.7–73.3%)) and so was not analysed further. We suspected an interaction between ondansetron administration and PCAS droperidol; a compound variable was derived (Anaes) which was a significant predictor and improved the accuracy of the model:

Logit (p) = 8.45 (if open surgery) − 8.9724 + 1.8853 (pmh of PV) − 2.2436 (droperidol in PCAS) + 2. 0343 (anaes) − 1. 95 (if NG tube) − 1.59 (if ondansetron)

The overall accuracy of the model was 77.55% ($P<0.0001$)

We have described pre- and intraoperative factors correlating with postoperative vomiting after major gynaecological surgery. Interestingly, antiemetics, nitrous oxide and total dose of morphine seem not to be significant prognostic indicators. These may become significant in a larger data set. In our model the most significant factors in predicting vomiting appeared to be a history of PV and use of droperidol in the PCAS. An odds ratio calculation could be performed for each case according to our equation. Patients could thus be predicted as "will not vomit" or "don't know" (4% (0–9%) *vs* 40% (23–57%) risk of PV), and "high risk" patients targeted with specific antiemetic therapy. A favourable odds ratio would suggest a very low risk of vomiting and so antiemetics could be withheld saving money and avoiding potential drug side-effects.

Laryngeal mask airway is associated with reflux in the lithotomy position

C. MCCRORY* AND A. J. MCSHANE
Department of Anaesthesia and Intensive Care, St Vincent's Hospital, Dublin

The introduction of the laryngeal mask airway (LMA) to anaesthetic practice has reduced the use of face masks and tracheal tubes. The LMA may increase the incidence of gastro-oesophageal reflux,[2] and lower oesophageal sphincter tone potentiating regurgitation.[2] We investigated both the incidence of regurgitation associated with use of the LMA during general anaesthesia, and whether the LMA protected the larynx if regurgitation occurred.

Hospital Ethics Committee and patient consent were obtained. Twenty patients were included and a standardized anaesthetic technique employed. Two pH electrodes, one in the upper oesophagus, 20 cm from the anterior nares and one passed down the LMA, exiting at the aperture portion of the LMA and being fixed there, were connected to a Digitrapper which continuously recorded pH. A pH drop to <4 was defined as reflux. After induction of anaesthesia the oesophageal electrode was inserted followed by the LMA with electrode. The pH was recorded for the duration of the procedure.

Oesophageal reflux occurred in 12 patients (60%) and the LMA electrode detected reflux in four of these cases. These four patients were in lithotomy position and experienced multiple refluxes (>2). Three further patients were in lithotomy and all experienced oesophageal reflux. Five supine patients refluxed, three being multiple (table 13). No reflux occurred in the first 5 min of monitoring.

Table 13 Reflux characteristics of the supine and lithotomy positions

	No.	Oesophageal reflux	Reflux anterior to LMA	Multiple reflux
Supine	13	5	0	4
Lithotomy	7	7	4	5

Use of the LMA is associated with a high incidence of reflux. Used in the lithotomy position it was found always to cause reflux and in addition refluxed material was found anterior to the LMA in four out of seven patients increasing the risk of aspiration. Regurgitated material passing anterior to the LMA may cause aspiration, and this study suggests there is a risk of aspiration in 20% of cases where the LMA is used.

Effects of 5-hydroxytryptamine on the partially curarized rat phrenic nerve diaphragm preparation

A. T. Hindle and P. M. Hopkins
Academic Unit of Anaesthesia, General Infirmary at Leeds

5-Hydroxytryptamine has significant effects on the skeletal neuromuscular junction. Previous studies have demonstrated that 5-HT causes facilitatory and depressant effects upon the twitch responses of skeletal muscle in a number of animal models when stimulated at resting rates of stimulation.[1 2] These studies utilized millimolar concentrations of 5-HT. Micromolar concentrations have been shown to facilitate twitch responses after a tetanus, but not at resting rates of stimulation in the indirectly stimulated diaphragm.[3] We decided to evaluate the potential modulatory effects of low concentrations of 5-HT on the rat hemidiaphragm at resting rates of stimulation in a partially curarized preparation.

Phrenic nerve diaphragm preparations were removed from male Wistar rats and suspended in an 18-ml tissue bath containing Krebs Henseleit solution, maintained at a temperature of 37°C and oxygenated with oxygen/carbon dioxide mixture (95%/5%) throughout the experiment. Both hemidiaphragms were pretensioned to 4 *g* resting tension and indirectly stimulated with supramaximal square wave pulses using a 2-ms delay between pulses, a 0.5-ms pulse width and 0.3 Hz rate of stimulation. After an equilibration period, D-tubocurarine was added cumulatively in stepwise increments until all twitch responses were abolished. The concentration which produced 50% block of the twitch response was calculated (EC_{50}). The preparation was exposed to a wash cycle and allowed to re-equilibrate. The EC_{50} of tubocurarine was added to both hemidiaphragms until a stable twitch response was attained (control twitch height). 5-HT was then added in the following concentrations (0, 12.5, 25, 50, 100, 200 and 400 nmol litre^{-1}) allowing the twitch responses to stabilize between each concentration. Equivalent volumes of a control solution (Krebs) were added to the contralateral hemidiaphragm which acted as a time-matched concurrent control. The twitch response to 5-HT was expressed as a ratio over the control twitch height. The ratios were plotted against time and the area under the curve (AUC) calculated. The AUCs for test and control hemidiaphragms were compared by paired *t*-test analysis accepting a 5% significance level. The mean AUC for test (3327 mm^2) and control (4102 mm^2) were significantly different ($P = 0.003$) (fig. 5).

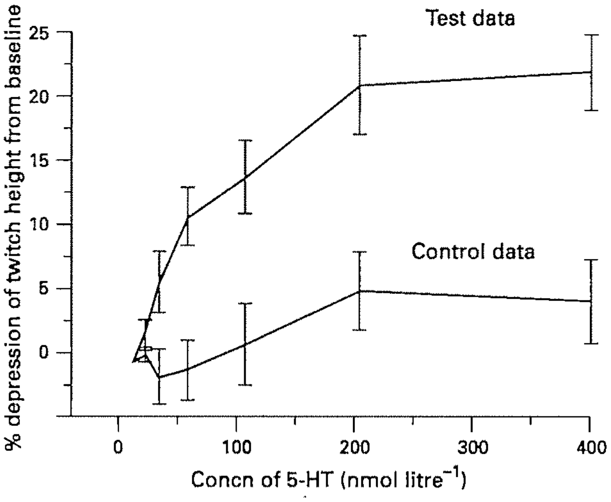

Figure 5 Effects of 5-HT on partially curarized hemidiaphragm. Data points consist of mean and SEM and represent depression in twitch height with increasing concentration of 5- HT (n=7).

We have shown that the addition of low concentrations of 5-HT to the indirectly stimulated rat diaphragm preparation causes a depression in twitch height. This is the first demonstration that 5-HT potentiates the action of curare in an *in vitro* model and gives further evidence of the neuromodulatory role of 5-HT at the neuromuscular junction. Further studies are required to identify the site of action of 5-HT.

Bispectral index is a state-specific measure of cortical arousal

I. K. Driver*, B. J. Watson*, D. K. Menon, S. K. Aggarwal* and J. G. Jones
University Department of Anaesthesia, Addenbrooke's NHS Trust, Cambridge

The bispectral index (BIS) has been developed by Aspect Medical Systems as a monitor of the hypnotic state of the brain in patients receiving anaesthetic and sedative drugs. BIS has been shown to correlate with responsiveness under sedation and anaesthesia with a variety of agents.[1 2] This study was designed to investigate whether BIS might provide useful information about cortical arousal in other brain states.

We monitored BIS (channels 1 and 2) in three groups of subjects. Group A were patients receiving general anaesthesia for routine surgery (n = 6), Group B were sleeping volunteers (n = 6) and Group C were unsedated subjects recovering from severe head injury (n = 5). Unprocessed EEG was used to confirm sleep. After a period of baseline measurement, we observed the response of BIS to an auditory stimulus, followed by a noxious stimulus (pharyngeal stimulation), in groups A and C. In group B, only the response to an auditory stimulus was monitored. Data were analysed using paired and unpaired Student's *t*-test as appropriate.

The "awake" BIS was lower in group C (46.0 (5.7), mean (SD)) when compared with the other two groups (93.6 (1.5) and 92.8 (1.4) in groups A and B respectively, P <0.01). There was a significant reduction in BIS after induction of anaesthesia in group A ($P < 0.01$) and with the onset of natural sleep in group B ($P < 0.02$). There was no significant difference between the three groups with respect to the minimum BIS (see fig. 6). The BIS in group A, was unaffected by the auditory stimulus and increased minimally after the noxious stimulus. Volunteers in group B were woken by the auditory stimulus with rapid return of BIS to pre-sleep levels. The response to stimulus in group C was inconsistent and set against a background of greater spontaneous baseline variability.

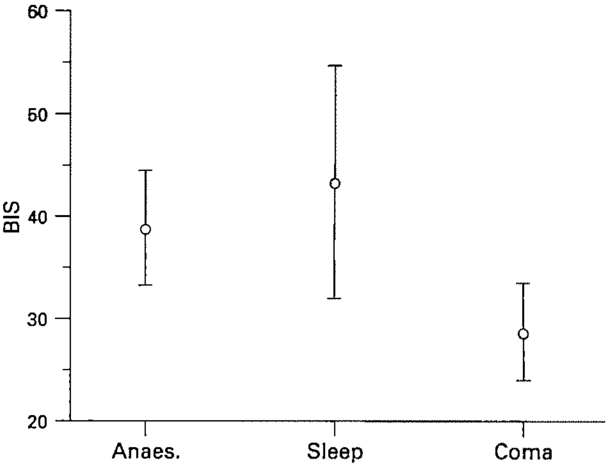

Figure 6 Minimum bispectral index (mean (SD) recorded *vs* group.

Our results demonstrate that a low BIS may occur with sleep, anaesthesia and head injury. While BIS demonstrates potential as a measure of cortical arousal in a variety of brain states, values should only be interpreted with adequate knowledge of the clinical context.

Effects of i.v. anaesthetics and lipid solutions on polymorphonuclear leucocyte chemotaxis *in vitro*

M. Leuwerl, J. Heine*, D. Scheinichen*, K. Jaeger*, S. Piepenbrock*, and A. Emmendorffer*
Department of Anaesthesiology, Hannover Medical School and Department of Immunobiology Fraunhofer Institute, Hannover Germany

Anaesthetic agents may impair the chemotaxis of polymorphonuclear cells.[1 2] In the present study we investigated the effects of propofol, thiopentone, methohexitone, midazolam and etomidate in a propylene glycol (Hypnomidate) and a lipid preparation (Etomidat-Lipuro) on *N*-formyl-methionyl-leucylphenylalanine (FMLP)-induced chemotaxis. Additionally, the lipid carriers of propofol (Intralipid 10%) and of Etomidat-Lipuro (Lipofundin-MCT 20%) were tested.

After Ethics Committee approval heparinized peripheral blood was drawn from 30 healthy blood donors. Chemotaxis test was performed as described elsewhere.[3] Briefly, the heparinized blood was mixed with HES (2:1) to enforce sedimentation of erythrocytes. After 30-min incubation the leucocyte-enriched supernatant was harvested and washed twice with phosphate-buffered saline (10 min, 250 *g*, 4°C). The remaining erythrocytes were lysed by using equal volumes of 0.83% ammonium chloride solution. After an additional washing, cells were counted and adjusted to 10^8 ml^{-1} neutrophil granulocytes. For each tested drug 1 ml of the remaining cell suspension was incubated with the respective anaesthetic or 10-fold anaesthetic plasma concentration. Additionally, the Intralipid quantities (0.6 and 6 μl ml^{-1}) which are carrying the anaesthetic and 10-fold anaesthetic propofol concentration and the same quantities of Lipofundin were studied. Random and chemotactic locomotion of the neutrophils in an agarose assay towards a gradient of FMLP (2×10^{-7} mol litre^{-1}) was investigated after a 3-h period of migration. After fixation and staining the migration towards FMLP and in the opposite direction was measured. The difference of the distances was considered to be specific migration. Student's *t*-test was applied for the evaluation of differences.

Specific migration was decreased by thiopentone at both concentrations (400 μg ml^{-1} : 0.13 (0.31); 40 μg ml^{-1}: 1.21 (0.34)) and by propofol at the 10-fold anaesthetic concentration (60 μg ml^{-1} : 1.19 (0.38)). No statistically significant effects on chemotaxis were caused by the other i.v. anaesthetics and the lipid solutions (fig. 7).

These results show that thiobarbiturales in contrast with oxybarbiturates cause a marked concentration-related inhibition of polymorphonuclear cell chemotaxis. The inhibition of migration by propofol in the 10-fold anaesthetic concentration may not be due to its lipid carrier Intralipid whose corresponding concentration had no effect. Also, equivalent quantities of Lipofundin MCT/LCT did not suppress chemotactic migration. Neither the propylene glycol nor the lipid preparation of etomidate influenced polymorphonuclear cell chemotaxis.

S-100 concentrations during hypothermic and normothermic cardiopulmonary bypass

D. Harris*, F. Gao, J. Wilson*, S. Sapsed-Byrne*, P. Smith* and K. Taylor*
Departments of Anaesthesia and Cardiothoracic Surgery, Hammersmith Hospital, London

The new assay for β β, and α β units of S-100 (Sangtec 100, Sangtec Medical) is a specific marker of glial cell damage, and is raised in patients with major neurological damage. Cardiopulmonary bypass (CPB) is associated with neuropsychometric damage in up to 80% of patients. CPB used to be performed at hypothermia (32°C), but oxygen saturation in the jugular bulb decreases during rewarming indicating possible cerebral ischaemia. Recently normothermic CPB (37°C) has been proposed to avoid the problems of rewarming, but this removes the known protective effect of hypothermia against brain damage after ischaemia. It is not yet established whether normothermic CPB improves or worsens cerebral outcome compared with hypothermia; serum Sangtec 100 could be useful in assessing the cerebral effects of CPB. We compared the concentrations of S-100 in 15 patients randomized to normothermic (7) and hypothermic (8) CPB. Eight samples were

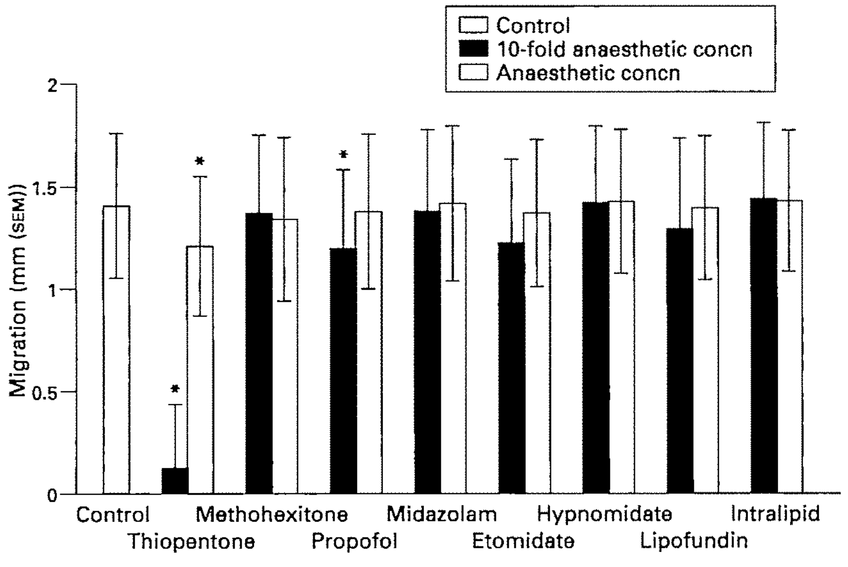

Figure 7 Results expressed as the mean distances (mm (SEM)) covered by polymorphonuclear cells during specific migration in the presence of the tested drugs in comparison with the control. (*P<0.05.)

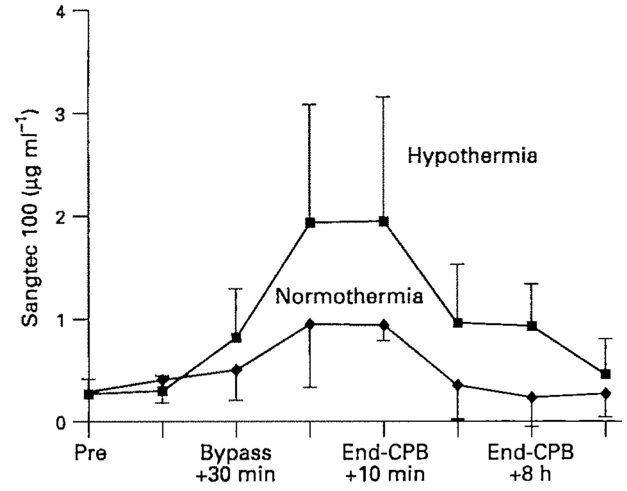

Figure 8 Sangtec 100 concentrations (mean (1 SD)) after cardiac surgery.

collected from the central venous catheter before incision, before bypass, after 30 min CPB, before the end of CPB, 10 min , 60 min and 8 h after CPB, and + 1 day after operation. Samples were spun and the serum frozen for later analysis. Results are shown in figure 8, and statistical comparisons were made by *t*-tests.

S-100 concentrations were increased after rewarming (1.88 µg ml^{-1}, $P = 0.003$) and 10 min after bypass (1.93 µg ml^{-1}), and returned to baseline by 1 day after the operation. Sangtec 100 levels were significantly lower at CPB + 10 min ($P = 0.052$) and returned to baseline 1 h after CPB.

We conclude that CPB produces an increase in S-100 indicating possible mild cerebral damage, but this returns to normal 1 h after the operation. Normothermic bypass produced a smaller increase in S-100 than hypothermic CPB, but we need to establish whether these small, transient increases in S-100 are associated with significant neuropsychometric damage.

Comparative effects of halothane, isoflurane and pentobarbitone on calcium currents in identified molluscan neurons

T. J. MORRIS*, P. M. HOPKINS AND W. WINLOW
Departments of Physiology and Anaesthesia, University of Leeds

Anaesthetics have been shown to depress calcium currents in pedal I cluster neurons of the pond snail *Lymnaea stagnalis*.[1] Here we show the comparative effects of halothane, isoflurane and the barbiturate pentobarbitone on barium currents recorded from identified neurons in the whole brain of *Lymnaea stagnalis* using the two electrode voltage clamp technique.

Snail brains were prepared in snail saline as described previously.[2] The external solution was then switched to one containing the following (mmol litre^{-1}): tetraethylammonium, 30; 4-aminopyridine, 10, Mg^{2+}, 1.5; Cs^{+}, 2; Ba^{2+}, 10; Na^{+}, 6.5; Br^{-}, 30; Cl^{-}, 23; pyruvate, 10; glucose, 5; adjusted to pH 7.8, and allowed to equilibrate for 15 min. Neurons, known as light yellow cells and lying on the ventral surface of the right parietal ganglion, were impaled with two separate microelectrodes filled with (mmol litre^{-1}): KCl, 2500; EGTA (ethyleneglycol- bis(β-amino-ethyl ether) *N*,*N*′-tetra-acetic acid), 500; adenosine triphosphate, 10; titrated to pH 7.7. Tip resistances for both current and voltage electrode were between 8 and 10 MΩ. Inward-going currents were elicited from a holding potential of −70 mV with stepped depolarizations between −50 and + 48 mV in 7-mV steps. Current amplitude was measured at 15 ms (near to the peak) to determine the current voltage relationship. Currents were seen to activate at about −40 mV, reached a peak at −15 mV and then showed only slight deactivation over the pulse duration of 100 ms.

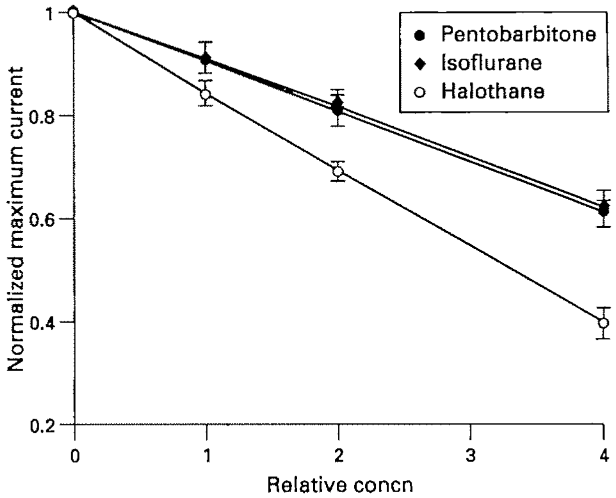

Figure 9 The normalized of peak current amplitudes are plotted against relative drug concentration: Isoflurane and halothane are at 1, 2 and 4% and pentobarbitone at 200, 400 and 800 µmol litre^{-1}. $n = 6$ for halothane. $n = 7$ for isoflurane and $n = 5$ for pentobarbitone.

Figure 9 shows a suppression of peak current both by the anaesthetics and the barbiturate. Linear regressions fitted through each data plot have r^2 values of >0.99, indicating a negative proportional relationship between drug concentration and current and suggesting a possible common pharmacological mechanism. Of the anaesthetics, halothane shows the greatest suppression of current for a given concentration. This mirrors the potency of halothane relative to isoflurane in clinical use.

CORRESPONDENCE

Volumetric analysis of aeration in the lungs during general anaesthesia

Sir,—I read with interest the article by Reber and colleagues on volumetric analysis of aeration in the lungs during general anaesthesia.[1] This is a study of radiographic density of the lung, using data consisting of picture elements (pixels) sized 0.9 × 0.9 × 4 mm. The density of the tissue in the pixel varies with the amount of air it contains, and the authors interpret these changes in two ways.

First, they use density to assess the degree of expansion of the lung tissue in terms of aeration. Second, they use changes in density during the breathing cycle to estimate regional ventilation. I would agree that the less dense the lung, the better aerated it is likely to be, because air causes less attenuation than lung tissue (or blood, which here seems to have been assumed to remain a constant fraction of the tissue). Air causes attenuation, in the scale used, of −1000 units, whereas collapsed atelectatic lung causes a much greater attenuation of −100 to +100 units. The authors argue that the distribution of pixel density indicates the distribution of poorly aerated and atelectatic lung. They suggest that the amount of lung tissue in an atelectatic area is four to five times greater than in a normally expanded part of the lung. This implies that by expansion with four times that volume of air, one atelectatic pixel would become five pixels with a normal radiographic density, as the radiographic density of air is very small compared with that of lung tissue. We are left uncertain as to how much air needs to be added to "poorly expanded" lung tissue to convert it into tissue with "reduced aeration" or "normal aeration", although these quantities would be useful for relating the current measures to previous data obtained with other methods.

This knowledge is of particular importance when it comes to drawing conclusions on "distribution of ventilation", as the authors have done in their subjects both during spontaneous breathing and mechanical ventilation. Here it is useful to remember how earlier studies of regional ventilation were performed, as this may help to elucidate some of the findings in the study of Reber and co-workers. Regional ventilation, measured with radioactive xenon, is usually expressed as ventilation in proportion to the volume of that region at total lung capacity (TLC);[2] this is done because at TLC the alveoli are nearly equal in size throughout the lung, and therefore expression of regional volumes and regional ventilation as a proportion of volume at TLC becomes equivalent to expressing these values in terms of "per alveolus". This is more useful than expressing ventilation or lung volume in terms of lung tissue at other states of inflation. If inflation of each part is unequal, then the amount of lung tissue present in each unit volume (in the present case, pixel volume) depends on the amount of distension of the lung that is being considered. Indeed, it is intuitively obvious that erroneous conclusions could result if regional ventilation were based on any other lung volume than the volume at TLC. Consider 100 ml of collapsed lung tissue which is distended by 100 ml of air. It would then have a volume of 200 ml, and if its regional ventilation were expressed as a percentage of the original tissue volume, it would have received 100% ventilation. However, this volume of atelectatic tissue can probably be fully expanded to a volume of approximately 1000 ml and hence if regional ventilation is expressed as a proportion of the volume of tissue at TLC, this ventilation would be 10%. There may be an analogous effect, of an inappropriate denominator, when radiographic density is used as a measure of aeration. This may explain some of the results when Reber and co-workers have "assumed a gas distribution in proportion to the attenuation changes" that they observed between inspiration and expiration. There may be a relationship but it is most unlikely to be a direct linear proportion between density change and regional ventilation.

They report that the radiographic density of the gravitationally upper parts of the lung is less than the density of the lower parts, in subjects at functional residual capacity. Setting aside the distinct possibility that the gradient could also be affected by a gravitationally determined gradient of pulmonary capillary distension, this observation would be expected from many previous measurements made with the isotope technique (for a succinct review, see Milic-Emili[2]). This gradient of density means that the lower pixels contain more alveoli than the upper ones. The article also reports that the lower pixels show a greater change in radiographic density than the upper ones, with a tidal volume inspiration. From an assumption that gas distribution is proportional to attenuation, the authors concluded that "distribution of ventilation" to the dependent regions is two times greater than that to the upper regions. I think that this conclusion is likely to be incorrect. First, as argued above, a change in density from −780 to −840 (approximate changes in the topmost slice) could well represent just as much, or even more, air/alveolus, as a change in density from −570 to −720. The proportional change could perhaps be better expressed as the change relative to the density difference from fully distended lung (say −900 units). If this were considered, then the topmost density change would be from (−900) − (−780) at FRC to (−900) − (−840) at end-inspiration. This gives a fractional change of density of (−60)/(−120) in the topmost level and (−180)/(−330) for the lowest level, and would lead to the conclusion that ventilation was relatively equal from top to bottom. However, this argument depends on the density value taken to represent fully distended tissue and ignores blood contribution to density.

Second, the inference of a vertically uniform distribution of ventilation agrees with findings in subjects breathing spontaneously with normal inspiratory flow rates, where the vertical distribution of ventilation in the lung depends not only on regional compliance but also on differences in airway resistance.[3] [4] A vertical discrepancy in ventilation distribution, such as Reber and colleagues conclude from their data, is only found in sitting subjects in very artificial circumstances when slow manoeuvres are undertaken so that airway resistance differences are minimized. Reber and co-workers did not report tidal volumes, inspiratory duration or ventilatory frequencies of their subjects so the mean inspiratory flow rates cannot be estimated, although these are clearly relevant.

A similar argument should probably be applied to the data obtained in subjects undergoing artificial ventilation which would result in the conclusion that ventilation is distributed preferentially to the upper regions. However, comparison of the data in subjects breathing spontaneously with those whose lungs were ventilated artificially indicates a further difficulty in the use of radiographic density to indicate aeration alone. The tidal volumes of the patients breathing spontaneously are unlikely to have been greater than those of the patients undergoing ventilation with volumes of 8 ml kg^{-1}. What is remarkable is that the change in mean lung density caused by mechanical ventilation (54 units) was smaller than the density change during spontaneous breathing (131 units), although tidal volume was probably less with spontaneous breathing. A factor that could explain this difference is a change in the volume of blood in the lungs during the 10-s breath-hold at end-inspiration necessary for the scan. This change in blood volume in the tissue may well not be uniform from the top to the bottom of the lung. This underlines the fact that factors other than ventilation can affect radiographic density, and this could affect the comparison of measurements made during spontaneous breathing with those made during mechanical ventilation.

Until these questions and uncertainties regarding the proportional relationship of radiographic density and aeration are addressed, I suggest that the inferences from CT studies should be limited to qualitative assessment of aeration, and that the expression "ventilation distribution" is not used.

Sir,—In his letter, Dr Drummond discusses some important aspects of the measurement of ventilation distribution. We agree that the calculation of ventilation "per alveolus" offers the advantage of taking into consideration the increasing amount of lung tissue, and thus of alveoli, down the lung.

One approach for depicting ventilation per alveolus is to calculate the gas/tissue ratio of a pixel, assuming that the amount of tissue in a pixel reflects the number, or size, of alveoli. In this approach, it can be seen that the difference in ventilation per alveolus of upper and lower lung regions is smaller than per pixel. Using a somewhat different approach, Dr Drummond has also shown this difference and he also pointed out that a shift of blood, either within the lung or in and out of the lung during the breathing cycle, further complicates the analysis. We thus agree with Dr Drummond on these aspects of ventilation calculations. However, relating ventilation to each alveolus is only one way of presenting the results. Ventilation can also be related to the topography of the lung and, for example, to the distribution of atelectasis. In a ventilation–perfusion scan for assessing pulmonary emboli, ventilation is related to pixels, or volume elements, as is the case in our study. These considerations taken together prompted us to present data that have been minimally manipulated.

The amount of gas within a particular pixel of a CT scan can be estimated from the attenuation value of that pixel. This implies that what is not gas is tissue with a certain attenuation value, therefore the measured attenuation is the weighted mean of gas and tissue. In our study, we used the standard scale of Hounsfield units where air has the value of −1000 Hounsfield units (HU) and water 0 HU. We have considered that lung tissue corresponds to water, an assumption that is used frequently for analysis of a CT scan. The changes in attenuation value can be measured in a particular pixel or in a region made up by a number of pixels. Therefore, the change in its gas content can be calculated, which correlates to ventilation. This is what we have done. Our data are consistent with those of Rehder, Sessler and Rodarte who used an isotope technique in awake and subsequently anaesthetized subjects.[1] Even though we agree with Dr Drummond that calculations can be made differently, we consider our conclusion, that ventilation distribution is affected by anaesthesia and mechanical ventilation, with an increase in ventilation to non-dependent regions, is correct.

Failed intubation during obstetric anaesthesia

Sir,—Hawthrone and colleagues reported an increase in the incidence of failed tracheal intubation, during Caesarean section under general anaesthesia in their unit, from 1 in 300 in 1984 to 1 in 250 in 1994.[1] As no national data are available they asked if this reflected a national trend. Since mid-1986, data on obstetric anaesthesia have been collected by hospitals in the South West Thames Region. We too have seen a decrease in the use of general anaesthesia for Caesarean section from 66.1% (range 39.8–81.9%) in 1987 to 22.9% (8.8–37.5%) in 1995. The number of general anaesthetics for Caesarean section decreased from 2198 in 1987 to 1320 in 1995. There has been a progressive increase in the incidence of failed intubation, to 1 in 173 in 1994 and 1 in 165 in 1995. Last year in the six units which performed less than 100 Caesarean sections under general anaesthesia, the incidence of failed intubation was 1 in 130; in the seven units that performed more than 100, the incidence was 1 in 188.

Our experience in South West Thames suggests that it is likely that there has been an increase nationally in the incidence of failed tracheal intubation during Caesarean section under general anaesthesia and that one probable cause is anaesthetists' decreased exposure to obstetric general anaesthesia. In the recently published Confidential Enquiries into Maternal Deaths in the United Kingdom 1991–1993, all direct deaths associated with anaesthesia for Caesarean section involved the use of general anaesthesia.[2] Any increase in the incidence of failed tracheal intubation during Caesarean section under general anaesthesia should be a cause for great concern.

The intensive care unit cost of surviving and dying

Sir,—The recent editorial by Bion and Strunin[1] introducing the issue on multiple organ failure stated that it costs twice as much to die in an intensive care unit as it does to survive, quoting a reference from 1986.[2] This is true when examining costs of all patients admitted to intensive care. In 1995 our intensive care unit cost was an average of £1997 to manage a patient who survived to leave our hospital, but more than twice this at £4116 to treat a patient who eventually died. The median APACHE II score for these patients was 15 (range 1–48).

When analysis of patient sub-groups is undertaken, however, a different picture emerges. We looked at the costs of treating a group of our most critically ill patients, namely patients referred from the specialties of renal medicine and renal transplant. In this sub-group (median APACHE II score 27 (range 14–48)) the costs, during the same period, of treating those who survived and those who went on to die were similar (£4225 and £4708, respectively).

Thus, the quoted 2:1 ratio in cost of treating survivors and non-survivors may be misleading as the overall cost of a survivor depends on the relatively larger number of less ill patients managed in intensive care who have a good chance of survival.

2. Sage WM, Rosenthal MH, Silverman JF. Is intensive care worth it? An assessment of input and outcome for the critically ill. *Critical Care Medicine* 1986; 14: 777–782.

Sir,—We are happy that Drs Thompson and Spiers agree that overall it costs at least twice as much to generate a non-survivor as it does a survivor from intensive care. For example, a 14-month study of 3600 ICU patients at Guy's Hospital showed that 15% of that population died, consuming 37% of the ICU budget in the process.[1] Of course, sub-group analysis generates exceptions to this rule, and in the article[2] which we quoted in our editorial, the authors showed this for patients undergoing elective surgery. These variations are of interest, but they do not alter our main theme, that death in intensive care is doubly wasteful of both lives and resources. It makes sense, therefore, to concentrate on prevention of multiple organ failure which was one of the main themes of the July postgraduate issue of the journal.

Aortic stent surgery

Sir,—We wish to comment on two points made in the letter of Baranowski and Adiseshiah on aortic stent surgery.[1] They noted, and appeared to accept, a mortality of 10% and put forward as a benefit of the stent procedure the fact that "the patient's trachea can usually be extubated early....".

Our own published experience of conventional elective abdominal aortic surgery using a combined general–extradural anaesthetic technique is that hospital mortality is well below 5%, with the trachea of virtually all patients being extubated immediately after surgery.[2] We believe that most centres consider a mortality rate of more than 5% unacceptable, and we support the view of Thompson and Greiff that the stent technique should be introduced with great caution.[3] In addition, fully informed consent must be obtained for all new procedures, even if they are offered to patients in whom the standard technique is considered high risk. Until the rate of conversion to an open procedure (current 35%) is reduced significantly, the stent operation should not be offered to patients who are not considered fit for conventional surgery.

3. Thompson MM, Greiff J. Aortic stent surgery. *British Journal of Anaesthesia* 1996; 76: 883.

Sir,—We agree fully with the comments of Wildsmith and McClure that a mortality rate of 10% is unacceptable and that is why we felt moved to write our letter on reading the first publication by Greiff, Thompson and Langham.[1] In that original report they did not indicate clearly the risks. We also agree that patients should give fully informed consent. It is for that reason that the consent in our hospital is obtained by consultant staff.

A recent audit of our mortality rates for open elective surgery using general–extradural anaesthetic techniques and early extubation indicated our mortality to be approximately 1%. We feel that it is inappropriate to increase the mortality risk in these patients by subjecting them to a stent procedure with a 35% conversion rate and 10% mortality risk. However, in common with many centres, we receive referrals where the local team has not been prepared to undertake an open operation as the surgical risks have been considered too great. In these patients we feel that there is an advantage to the closed technique with the mortality probably being less than that after the open approach in this specific group. We have had several such patients only spending a night on the high dependency unit as opposed to the predicted several days. A controlled study examining different techniques and risk groups needs to be carried out.

A complication of intra-arterial shunting during carotid endarterectomy

Sir,—A 68-yr old male ex-smoker presented after one episode of *amarosis fugax* affecting his right eye and lasting a few minutes. Resolution was complete and there was no residual neurological deficit. Doppler studies showed a 75% luminal obstruction in the right internal carotid and 65% in the left, and he was scheduled for right carotid endarterectomy.

In the anaesthetic room, a Floswitch 20-gauge (Ohmeda) arterial cannula was inserted in the right radial artery, after failed cannulation of the left, for continuous monitoring of arterial pressure. A typical arterial pressure trace was displayed on the monitor. General anaesthesia was induced with fentanyl, etomidate and atracurium, and maintained with isoflurane and 70% nitrous oxide in oxygen.

When dissection of the carotid artery was complete, arteriotomy was performed and a Pruitt balloon shunt inserted. Immediately, the arterial pressure trace became attenuated and the reading changed from 130/70 to 75/65 mm Hg. Flushing the cannula had no effect and free aspiration of blood was possible. Withdrawing the shunt restored a normal arterial pressure trace. It was concluded that the caudal end of the shunt was lying at the junction of the innominate and subclavian arteries and causing significant obstruction to flow of the latter (see fig. 1).

In addition to making the arterial pressure reading unreliable, this could have had a significant impact on cerebral blood flow because the right vertebral artery is a branch of the subclavian. During carotid endarterectomy this further reduction in circle of Willis supply may be crucial. On the left, the subclavian and common carotid arteries have separate aortic origins, and vertebral artery blood flow could not be compromised in a similar manner.

We suggest that the right radial pulse or pressure should be monitored when a right carotid shunt is placed, so that subclavian occlusion can be detected.

Transoesophageal echocardiography in anaesthesia and intensive care

Sir,—The delay in appearance of an editorial on transoesophageal echocardiography (TOE) in British anaesthesia literature[1] reflects the slow uptake of this tool by British anaesthetists compared with our colleagues on the continent or across the Atlantic.

TOE represents a large initial cost forcing consideration of its benefits, especially in our health system where its use does not allow immediate remuneration (as in the USA). The plethora of uses and undefined benefits to outcome has generated an impression of an expensive toy for the boys. It is now clear that its use can be largely subgrouped into a monitoring role or a diagnostic role. As anaesthetists we have concentrated initially on its monitoring role, especially in relation to regional wall motion abnormalities signifying ischaemia. Unfortunately, the "dancing doughnut", as the short axis monitoring view has been derogatorily termed, has not added significantly to other monitors available and certainly in non-cardiac surgery has not justified its expense. It is not known if the addition of colour kinesis will significantly improve its usefulness. Although many variables may be derived from Doppler data, including cardiac output and left atrial pressures, calculation is usually too cumbersome to allow routine use. However, for the first time TOE allows us to directly assess the volume status of the left ventricle[2] compared with previous indirect estimates of LV filling from pressure data. In addition, with concomitant pressure data TOE can also provide a load-independent measure of contractility.[3]

In contrast, its diagnostic role is now well established in cardiology. That this can translate to the operating room, intensive care or emergency room has now been well documented. In intensive care[4 5] and the emergency room,[6 7] TOE represents a portable easily accessible diagnostic tool. In the operating room we should differentiate between cardiothoracic surgery and other types of surgery. Despite its potential the routine use of TOE in non-cardiothoracic surgery has not been justified except possibly as a volume monitor where extensive blood loss is expected or in the diagnosis of hypotension. In cardiothoracic surgery the diagnostic role of TOE has come into its own. While its monitoring role in routine coronary artery surgery is debatable, its diagnostic role in complex valve,[8] paediatric cardiothoracic surgery[9] and artificial device implantation[10] can contribute significantly to surgical success. In addition, scanning of the aorta for atheroma plaques[11] and left ventricle for residual air pockets[12] has proved useful. After operation, its use can quickly differentiate between the main causes of hypotension and is invaluable in assessing postoperative deterioration.[13]

This diagnostic role in the intraoperative period is having a real impact on the work of cardiac anaesthetists.[14] For the first time the results of a surgical technique are being reviewed by anaesthetists and subsequent decisions based on them, including the need to go back on bypass and modify the surgery. Where these decisions are to be made, there is no doubt that the level of competence is hard to maintain for the occasional cardiac anaesthetist, who may lack credibility in dealing with surgeons and physicians who spend their time solely in a cardiac centre. This may drive us towards dedicated full-time cardiac anaesthetists, at least where complex procedures are undertaken. Indeed, some centres in the USA do not appoint cardiac anaesthetists unless they are competent in TOE.

Why then has the uptake of TOE been so slow to date in the UK? First, the enormous initial capital expense has been difficult to access. Second, there remains a fear of technological obsolescence, with many developments in the pipeline, including colour kinesis, three-dimensional reconstruction and real-time, three-dimensional views. In fact, in the 5 yr since the first editorial quoted by Townend and Hutton,[1] technology has moved from single plane probes to Doppler capability, biplane probes and now multiplane probes with automatic border detection capabilities. Third, an investment of time and training is required before competence is acquired and quality assurance is acceptable. Fourth, its role has not been defined. To these ends, the Society of Cardiovascular Anesthesiologists and American Society of Anesthesiologists have recently published guidelines[15] on perioperative TOE training and use.

In summary, the impact of intraoperative TOE on non-cardiothoracic surgery is yet to be defined. In cardiothoracic anaesthesia, its use is here to stay.

Haemodilution induces a hypercoagulable state

Sir,—Ruttmann, James and Viljoen[1] have described the effects of haemodilution on *in vitro* coagulation using the TEG, and among their conclusions suggested that 20% dilution with isotonic saline increases absolute clot strength, while at the same dilution with Haemaccel (3.5% polygeline solution) clot strength is unaltered. We have recently published similar work,[2] but with a range of dilutions (15, 30, 45, 60 and 75%). We found that both the size (clot weight) and strength (using maximal amplitude on the TEG) of clots formed *in vitro* were reduced considerably with increasing dilutions of both Haemaccel and Gelofusine (4% succinylated gelatin) compared with the same dilutions with saline or Ringer's solution. Scanning electron microscopy of these clots showed a reduction in cross-linkage with the colloids compared with dilution with saline, or controls from undiluted blood. This could be explained by an effect on fibronectin, as other workers have shown that gelatin binds to fibronectin[3] and that infusion of these fluids decreases plasma concentrations of fibronectin.[4] Although Ruttmann, James and Viljoen emphasized that their study did not examine greater or lesser degrees of dilution, our findings raise concern where large volumes of these fluids are given to patients requiring full haemostatic competence, and we endorse his suggestion that *in vivo* studies using the TEG should take place in patients receiving different fluid regimens.

4. Brodin B, Hesselvik F, von-Schenck H. Decrease of plasma fibronectin concentration following infusion of a gelatin based plasma substitute in man. *Scandinavian Journal of Clinical Laboratory Investigation* 1984; 44: 529.

Sir,—Mardel and colleagues[1] reported on a study comparing the effects of various dilutions of blood with crystalloid with those with colloid. They found some inhibition of clot maturation, as measured by clot strength, in the colloid group and attributed this effect to the binding of fibronectin to the gelatin molecule. In this respect their results are in agreement with our findings.[2]

However, we are confused by the assertion that "scanning electron microscopy of these clots showed a reduction in cross-linkage with the colloids compared with dilution with saline, or controls from undiluted blood". Careful reading of the report of Mardel and colleagues shows that their controls were diluted with saline or Ringer's lactate. Nowhere do they mention an undiluted control.

It is our contention that haemodilution with crystalloid is not inert but activates some aspects of coagulation in an as yet undefined manner. It is therefore difficult to interpret coagulation studies in which haemodilution with crystalloid is used as a control as these do not necessarily show that gelatin haemodilution *per se* causes reduced clot strength compared with the native condition.

BOOK REVIEWS

Clinical Anaesthesia. A. R. AITKENHEAD AND R. M. JONES (editors). Published by Churchill Livingstone, Edinburgh. Pp. 780; indexed; illustrated. Price £85.00.

Professors Aitkenhead and Jones, those indefatigable editors, have produced a new, short textbook of clinical anaesthesia. They argue in the preface that most textbooks have grown too large and have become too expensive, as they attempt to cover all aspects of the relevant basic sciences and clinical practice. The present text aims to provide a concise account of clinical anaesthesia in the 1990s and is intended for an international readership. Twenty-three of the 41 authors are from the UK, 10 from USA, seven from Europe and one from Australia. Among the authors are many with an international reputation: Booij, Breivik, Coriat, Cunningham, Fitch, Frost, Hug, Lindahl, Pollard, Reiz, Runciman, Sear and White, together with young co-authors who may well join this group in the future. The editors had a laudable aim and were able to recruit good authors, so does it work in practice?

The book contains 30 chapters and only 15 of these are devoted to anaesthesia for specific surgical areas, such as cardiac surgery and paediatric surgery. The other chapters cover topics such as preoperative assessment, monitoring, postoperative pain relief, safety, and audit and quality assurance. The last, short chapter by Lunn on "the quest for quality – how to keep up to date" is an idiosyncratic, but highly successful, way to finish. Most chapters are extensively referenced, and in some instances this is excessive. The prize for "referencitis" goes to Breivik and Bogod who found it necessary to use 277 references in a chapter on obstetric analgesia and anaesthesia. This is followed closely by the 264 references cited in a 10-page chapter on cardiopulmonary resuscitation. The ease of access to the anaesthetic literature does nothing to help find quality among quantity.

A few chapters are strangely unconvincing. A chapter that covers one of my major, clinical commitments gave an excellent review of the underlying physiological problems, but was of no value in dealing with common intra- and postoperative difficulties. I was left with the strong impression that the distinguished authors were lacking in recent, practical experience.

The space devoted to certain anaesthetic problems fails to reflect their current, clinical importance. Laparoscopic cholecystectomy is dealt with in half a page, which is slightly more than pancreatic surgery, but at least hepatic surgery merits two pages. Key areas of anaesthetic practice, such as anaphylaxis, are also dealt with in two pages, however the index helped in finding other relevant information about this topic. Do not rely on the index to help you learn about MH; the pages indicated will refer you to a discussion on training devices and anaesthetic simulators!

Overall, the book is competently produced with few errors and is priced competitively. I do not think that it quite hits the target. Nevertheless, the idea is thoroughly sound and I urge the editors and authors to persevere – promising but must improve.

G. M. Hall

Peripheral Nerve Blockade. C. A. PINNOCK, H. B. J. FISCHER AND R. P. JONES. Published by Churchill Livingstone, Edinburgh. Pp. 174; indexed; illustrated. Price £29.50.

There is growing interest in the application of peripheral nerve blocks for an increasing variety of surgical procedures. This book sets out to be very much a comprehensive, practical manual serving both trainee and experienced practitioner alike. The text is clear and concise, and the layout facilitates rapid access to the relevant information with great emphasis placed on the excellent line drawings. It is clear to any regional anaesthesia enthusiast that the authors themselves have considerable practical experience in this field, allowing them to give practical guidance in addition to highlighting areas of controversy as and when they occur within the text.

The first short section deals with the essentials of principles and practice, concentrating on benefits, methods and hazards, while the second section deals with the applied anatomy of the various operative sites and the possible surgical indications. Section three deals with the nerve blocks themselves. I assessed the aims of this section by looking first for a few specific "useful" blocks for day-case surgery or the medically compromised patient and was not disappointed. Field block for mesh inguinal hernia repair, inguinal canal block, arthroscopy block, ophthalmology blocks and even the sustentaculum tali block for those particularly compromised vascular patients, are all well covered.

The major nerve blocks of upper and lower limb are also well described as one would expect, although the technique of axillary block outlined is very much one of many. Techniques for using the nerve stimulator at this or the mid-humoral level could possibly have been included, although this may not have reflected the authors' own personal expertise. For the experienced practitioner it is always useful to have a handy reminder of blocks at the elbow and wrist in case one day one might need to supplement! The line drawings are particularly useful in this section. A short discussion on evolving catheter techniques outlines further possibilities for a variety of blocks with a view to postoperative pain relief, and there is comprehensive coverage of head and neck blocks.

While no substitute for practical tuition, overall this is an excellent addition to the recent publications on regional anaesthesia. As I had hoped, this book points out the major contribution of peripheral blocks in the management of postoperative pain but still concentrates on the art of regional anaesthesia as the sole technique for surgical intervention and not as a hit or miss supplement to general anaesthesia. It would clearly be invaluable to examination candidates but its concise and practical layout and size suggest that its prime location should not be the library bookshelf but the duty room of any (or every) theatre suite. I can think of few better for this purpose.

D. M. Coventry

Clinical Intensive Care. K. HILLMAN AND G. BISHOP. Published by Cambridge University Press, Cambridge. Pp. 835; indexed; illustrated. Price £35.00.

Intensive care medicine is changing very rapidly; there are changes occurring constantly in response to good science in addition to fashion and politics. Therefore, much that is written will be out of date by the time the book is published.

Of the 32 chapters of this book, the first third cover mainly general concepts. The authors lose their way here, inaccurate generalities occur and detailed dogmas that I disagree with appear often. Resuscitation procedures and specific antibiotic guidelines are not helpful. In particular when the guidelines differ from the European Resuscitation Council guidelines this could be disastrous for trainees preparing for examinations. I disagree with statements on nutrition, fluid balance, the stated importance of fluid restriction in ARDS and the importance of peripheral oedema as a problem.

The second part of the book examining particular organ systems and clinical problems was much better. The chapters on thoracic trauma, intracranial disasters and acute renal failure were very clear, readable and succinct. There are some very good axioms, and also some good tables and diagrams. Bold checklists covering some common situations are well conceived.

In its present form the book falls between two stools; as a reference text it would need further expansion and authority but it misses the mark as a handbook for trainees, and inaccuracies, repetition and unnecessary detail swamp the good material.

W. Russell

A Practical Approach to Pain Management. M. LEFKOWITZ AND A. H. LEBOVITS (editors). Published by Little, Brown and Co., Boston. Pp. 310; indexed; illustrated. Price £29.50.

This volume of some 310 pages attempts to cover the whole aspect of pain management using the "cook book" type of presentation. Consequently, because of the need for brevity, each word needs to be selected with extreme care such that each imparts the maximum information while taking up the minimum of space. In such a situation, to try and cover the whole of pain management requires extreme care on the part of the authors and utter ruthlessness on the part of the editors. Unfortunately, this volume suffers from a lack of direction and control from the latter to the former and, therefore, ends up as an uneven and somewhat uninteresting compilation.

The book is divided into two parts: therapeutic and diagnostic approaches and pain syndromes. The former is subdivided into six parts dealing with acute pain, pharmacological management, regional techniques, psychological approaches, physical techniques and other approaches to chronic pain management. The latter deals with many major areas of pain, including that due to cancer, low back and phantom limb, pain in children, herpes zoster and post-herpetic neuralgia, to mention but five of 16.

The book aims to provide the busy single specialty provider with a detailed and in depth review of the significant clinical practice approaches in pain management. On the other hand the editors write that it is not intended as a comprehensive textbook, rather it is a "how to" handbook written in outlined format. There does appear to be a hint of confusion here.

There are 46 contributing authors, nearly all of whom work in the eastern USA, thereby giving this tome a distinctive flavour. None the less, they have a good attempt at answering the editors' demands. However, as would be expected, there are both omissions and commissions. There is a plethora of words, too many of which are space wasters and do not contribute to the education of the reader. The illustrations are mediocre, basic and unnecessary taking up page space that could have been better used for good flow charts, diagrams, etc. The chapters are variable, not only in content, but also in length, references and value.

For a 1996 first edition, there is insufficient modern contemporary thought and therapy. Surprisingly, no mention is made of NMDA and substance P antagonists, bradykinin, dorsal root ganglion injections and Harkensen's technique, whereas cocaine, benzocaine and several other virtually obsolete agents feature, in some cases, with marked prominence.

Many of the tables of drugs can be obtained elsewhere and have been produced better in that situation. Also, precise descriptions of techniques are unnecessary in such a book and yet they appear, sometimes with embarrassing detail that can be better obtained from the specialist manuals that are all too rarely referenced.

Even at £29.50, this is not a book that one could encourage trainees to buy, but rather to peruse in the library and then place back on the shelf before moving on to what will inevitably be a better text

Cardiac Arrest. The Science and Practice of Resuscitation Medicine. N. A. Paradis, H. R Halperin and R. M. Nowak (editors). Published by Williams and Wilkins, Pp. 981; indexed; illustrated. Price £125.00.

This major work on the science and art of resuscitation medicine is unique in that it not only reviews the literature past and present, but also provides a reasoned description of the current state of the art and a look to the future. The is a multi-author text, drawing its writings from over 90 authors in 53 chapters. Most of the authors are from North America and are well known in the field of resuscitation. All of the authors have obviously been well briefed as to their task by the three named editors of the book and there is little repetition in the text.

The first section describes the history and epidemiology of sudden death. It is interesting that the authors of both these chapters sum up by reflecting on the lack of information available on the true physiology and pharmacology of this science. This leads neatly on to the second section where there are chapters on basic science. Most of this section reviews cell death and reperfusion. It also includes a fascinating section on the methodology of cardiopulmonary resuscitation research and provides many of the basic facts of how to carry out this form of research using modern scientific instrumentation.

Section three continues the global ischaemia and reperfusion story with seven chapters on pathophysiology and aetiology. In this section there are three detailed individual chapters on the aetiology, electrophysiology and mechanics of ventricular fibrillation, pulseless electrical activity and bradyasystolic states. Together they help to clear a path through the established jungle of anecdotal medicine associated with resuscitation. Section four deals with the therapy of sudden death and although the 17 chapters discuss all the relevant aspects of therapy, they are heavily biased towards the North American procedures and say little, if anything, about other national procedures.

Section five, special circumstances, has chapters on neonatal and paediatric resuscitation, the elderly patient, asphyxial, haemorrhagic, hypovolaemic, hypothermic and toxicological sudden death. It also deals with cardiac arrest during anaesthesia and in pregnancy, in the drowned and in the electrocuted patient. This is one of the best sections in the book as the authors have managed to assimilate and digest a wide range of publications and viewpoints and bring them together into a well-reasoned argument on the therapy of these rarer resuscitation scenarios. Section six has six chapters on post resuscitation disease. It includes a chapter on post-resuscitation prognostication and the declaration of brain death. It highlights the difficulties found at the sharp end of clinical practice of deciding when to stop resuscitation and how to deal with the initial resuscitation success which subsequently turns into the long-term intensive care patient. Its arguments are useful to those who have to battle against colleagues who declare all resuscitation events as failures despite their aetiological background.

The final section and chapter deals with the future and development of informational guidelines for practising and reporting resuscitation events. It points out that despite there being a single foundation of published research, national bodies have produced different regimens, often depending on internal political pressures. An international body does exist to rectify this matter and this chapter formulates the basic strategy on which this body is now formulating international recommendations on resuscitation.

The book is extremely well written, referenced and indexed. It is illustrated appropriately and each illustration is fully referenced. If I must have one criticism it is, as stated above, that it is biased heavily to the science and art based around the North American regimens. This may account for the complete lack of any reference to the use of the laryngeal mask airway in resuscitation. It is harder to explain the inclusion of only one and one half columns on automated external defibrillation as this is one of the foremost developments in this field; it may reflect how rapidly resuscitation has moved forward during the time of compiling and publishing this text.

This is a must for everyone interested in or researching resuscitation. Although its price is high, this can be justified as it is one of the most complete reference sources on resuscitation in the current published literature. In fact, it has hardly sat on my library shelf as I find myself constantly referring to it for both references and comments. I highly recommend this book.

D. A. Zideman

Core Curriculum for Professional Education in Pain, 2nd Edn. H. L. Fields (editor). Published by IASP Press, Washington. Pp. 123; indexed. Price $25.00.

This is the second edition of *Curriculum for Education in Pain*; the first addition apperared in 1991. The document was developed by a task force of international specialists from a broad discipline base in pain management, including neurology, oncology, rehabilitation medicine, psychiatry, rheumatology and the basic sciences. It is aimed for use as a reference for other curricula for designing training programmes and as a basis for rationalizing and planning patient services.

The curriculum is divided into chapters, each covering various topics from the pharmacology of pain transmission and pain measurement, through to specific disease states, including low back pain, myofascial pain and cancer pain. Its format consists of headings and lists of relevant areas in each topic. There is a helpful chapter on designing, reporting and interpreting clinical trials in the management of pain, and a good, up-to-date bibliography.

The book is an improvement on the first edition and takes account of the brisk pace of expansion of the knowledge base in the field of pain research in recent years. It is a useful publication for those responsible for designing training programmes and patient services in pain management.

EDITORIAL I

Ether anaesthesia comes to London. December 1846

In October of this year, 1996, the sesquicentenary of the first successful public demonstration of ether anaesthesia by William Thomas Green Morton was celebrated in Boston, in appropriate style. It is rare for any discovery to be attributable to only one individual and the very different roles of Crawford Long, Horace Wells and Charles T. Jackson have been well aired over many years. Morton, nevertheless, was the figure of the day. Described by Jacob Bigelow as "not a human of much cultivation or science", one can easily conjure a picture of a relatively humble journeyman dentist arriving by invitation at the Massachusetts General Hospital for a demonstration that, in the light of previous failure by others, might not attract a totally confident assembly. Dr Barbara Duncum[1] quotes from N.P. Rice's *Trials of a Public Benefactor* published in 1859:

"He (Morton) had taken the precaution to request Mr Frost to accompany him, to conduce in some way to his relief, in case of failure and act as a voucher as regards his statements of what he had already accomplished. At this moment his mind was in one great whirl of doubts and conflicting emotions."

Morton was ambitious but he was also brave.

In Britain, news of ether anaesthesia did not arrive until the penultimate week of the year. Against today's sophisticated communications the use of Francis Boott as an intermediary between Jacob Bigelow and Robert Liston, by this time a leading surgeon of London, seems unusual. Yet Boott acted effectively and swiftly. Not only did Liston operate successfully under ether anaesthesia within the space of 5 days but Boott's association with James Robinson, a leading London dentist, led to Robinson's successful demonstration on December 19, the Saturday before Liston's successful operation on the following Monday. It is customary to note the "Dumfries claim" in which the news was brought to Scotland, faster than to London, by a local doctor who had travelled from Boston to Dumfries via Liverpool. Sadly the outcome, whatever is was, adds nothing to either science or medicine as the public announcement was some 20 years delayed and there is no trace of the patient!

Before the year ended, John Snow who became the leading figure in the development of ether anaesthesia had attended one of Robinson's administrations. James Young Simpson, the Professor of Midwifery at Edinburgh, had journeyed in the Christmas holiday period to London, probably to visit Liston, for the specific purpose of learning about ether anaesthesia. Simpson took the news north and, with the shared interest of several of his contemporaries at Edinburgh, became an immediate enthusiast for anaesthesia and moved quickly, if controversially, to the use of ether for the relief of the pain of difficult labour.

By today's standards it seems quite remarkable that Robinson, and soon Snow, appeared so rapidly and effectively in print on their contributions and perceptions in respect of the new discovery. While the unfortunate Morton's star was soon in decline as he struggled unsuccessfully to assert his ownership of, and explore a patent for, ether, John Snow was the man in the right place at the right time to develop the scientific basis of anaesthesia which he did to superb effect. There can be little doubt that the explanation for this zeal and success lay not only in Snow's rather puritanical character but equally his strong motivation to ensure that as a doctor in 19th century England he was equipped with the highest academic qualifications. In time for the sesquicentenary of ether anaesthesia, Dr David Shephard, from Prince Edward Island, Canada, has produced a new biography of John Snow which, although populist in places, provides an excellent resource on an important medical pioneer.[2]

Of the British pioneers, Robinson, Snow and Simpson, it is notable that all three were leaders in their profession and would have enjoyed such a position even if they had made no contribution to anaesthesia. At a time when dentistry could offer very little in the way of control of the quality of practice, Robinson enjoyed the highest reputation as a practitioner, with a distinguished clientele which included Prince Albert The Prince Consort. Indeed it is interesting to consider that Albert's contact with Robinson would have been at least one reliable source of intelligence about anaesthesia which ultimately led to chloroform analgesia being sought by Queen Victoria from John Snow in 1853 and again in 1857, although on the second occasion either the Queen was early or Snow was late. He arrived to find Prince Albert administering the chloroform!

Snow as a respected practitioner in Soho and as an enthusiastic participant of medical and scientific societies is, or should be, remembered for his study and recognition of putrid water as the source of cholera several years before Pasteur. Similarly, Simpson advocated "hospitalism" based on the recognition that a fever developed after injury was often less serious outside compared with inside a hospital. He, too, was several years ahead of Lister, with strongly expressed views on how hospitals should be designed (and regularly destroyed and rebuilt); all this in addition to his laying the foundations of gynaecological practice and his distinction as an antiquarian. Perhaps it was because of these polyglot characteristics among the pioneers that the "science" of anaesthesia in Britain was subject to stewardship of a high order, and the general acceptance of the clinical use of anaesthesia, although occasionally the subject of controversy, was remarkably trouble free.

EDITORIAL II

Is it always necessary to antagonize residual neuromuscular block? Do children differ from adults?

Use of an anticholinesterase at the end of surgery, to antagonize residual neuromuscular block induced by a non-depolarizing drug, is commonplace; it is easy to forget that such drugs were not always given routinely. When the clinical use of "Intocostrin" (a biologically standardized extract of curare) was first described in 25 patients by Griffith and Johnson in 1942, it was only recommended that an ampoule of the antidote, prostigmine, be readily available[1]; there was no mention of administering the antagonist. Indeed, it is difficult to determine how anticholinesterases came into regular use.[2] Neostigmine was noted only to be given "seldomly" by Prescott and colleagues in 1946, in doses of up to 5 mg, even though these workers were using tubocurarine 0.4 mg kg^{-1} for abdominal surgery.[3] Undoubtedly, failure to use an anticholinesterase was a factor in the morbidity associated with the use of small doses of non-depolarizing neuromuscular blocking drugs in patients breathing spontaneously, and a reason why such techniques fell into disrepute in the early 1950s.[4] Unfounded fears of neostigmine causing cardiac arrest were probably a reason for its omission.[5] With the increasing use of larger doses of tubocurarine or pancuronium and controlled ventilation many, although not all, clinicians began to administer neostigmine 5 mg to adults.[5 6] Large doses of anticholinesterase were used in children at this time: neostigmine 0.08 mg kg^{-1} was given to antagonize tubocurarine in neonates, who were thought to need an even higher dose than adults to obtain reliable recovery.[7]

With the advent of the intermediate-acting non-depolarizing agents, atracurium and vecuronium, the need for such high doses of anticholinesterase was questioned.[8] Clinicians soon realized that recovery from these agents was more rapid than with tubocurarine or pancuronium. The greater clearance of the newer drugs from plasma, and hence a more rapid decrease in relaxant concentration at the post-synaptic nicotinic receptor allowed, on some occasions, for the omission of an anticholinesterase. This has some benefits; nausea and vomiting may be less common in patients who are not given neostigmine after the use of a non-depolarizing drug.[9] Any detrimental effect of neostigmine on a newly created gut anastomosis can also be avoided.[10]

But careful monitoring of neuromuscular block is always necessary if anticholinesterases are not used. It is well recognized that even the clinicians most experienced in using monitoring techniques cannot detect decrement of the train-of-four twitch response by visual or tactile means, when the fourth twitch of the train has recovered to more than 40% of the first.[11] It is essential therefore for all anaesthetists to quantify the train-of-four ratio if they are considering not using an anticholinesterase. Double burst stimulation, which consists of two or three bursts of 50 Hz tetanus, 750 ms apart, is thought to be more useful in detecting fade by visual or tactile means than the train-of-four response, although the differences are marginal.[12] In addition, it is now thought that 80% recovery of the train-of-four ratio T4/T1 (and not 70% as first described[13]), is a more reliable indicator of adequate recovery if electromyographic monitoring is used.[14] This degree of spontaneous recovery may take much longer than is appreciated, even with atracurium or vecuronium. For example, the average time to spontaneous recovery of T1/T0 to 95% after atracurium 0.5 mg kg^{-1} is 68 min.[15] But it is probable that with atracurium and vecuronium, neostigmine 2.5 mg in adults is an unnecessarily large dose to antagonize residual block, if greater than 20% recovery of T1/T0 has already occurred.[16 17] Doses of neostigmine 1.25 mg are almost as effective. Even neostigmine 0.625 mg accelerates recovery after atracurium, although not after vecuronium.[17]

The introduction of mivacurium, which is metabolized by plasma cholinesterase, again raised the question of whether or not it was always essential to antagonize residual block. Neostigmine, although not edrophonium, was known to inhibit plasma cholinesterase activity,[18 19] and it was therefore postulated that neostigmine may *potentiate* mivacurium-induced neuromuscular block. There has been little evidence of such an effect,[20] although neostigmine would only seem to speed recovery from mivacurium-induced block by a few minutes.[21] The mean time for spontaneous recovery of T1/T0 from 25 to 75% (the recovery index) after a constant infusion of mivacurium is 7.7 min; if neostigmine 35 $\mu g\ kg^{-1}$ is administered at 20% recovery of T1/T0, the recovery index is only reduced to 4.7 min. However, a few minutes add up to a long time if 10 laparoscopies are performed on a half-day list!

Plasma cholinesterase activity is greater in children than in adults and this is thought to explain the more rapid spontaneous recovery from mivacurium-induced neuromuscular block in the young.[22 23] Whether mivacurium is given as a single bolus dose or by constant infusion in children, the benefit of using an anticholinesterase to speed recovery is questionable (if neuromuscular monitoring is being used), and edrophonium is a more appropriate agent than neostigmine to antagonize any residual block.[24]

The longer-acting, non-depolarizing agents which are cleared more slowly from plasma have, of necessity, been antagonized routinely. But in children, Fisher and colleagues demonstrated that the dose–response curve for neostigmine, although not edrophonium, used to antagonize residual block from tubocurarine, was shifted to the left of that in adults,[25 26] for the first time disputing the belief that larger doses of anticholinesterase were needed in the younger age group. As the distribution volumes and distribution half-lives of neostigmine and edrophonium are similar in all age groups, these differences cannot be explained easily by a pharmacokinetic mechanism.[25 26] It was postulated that local differences at the neuromuscular junction in children, such as the number of nicotinic receptors, amount of acetylcholine reserve or acetylcholinesterase activity, may be the causes of the lower dose requirements for anticholinesterases in paediatric patients.[26] In addition, a more rapid circulation time in children speeds both delivery of anticholinesterase to the neuromuscular junction, hastening onset of effect, and also increases its rate of removal, shortening the duration of action. There is evidence, however, that it is the more rapid removal of the *relaxant* from the neuromuscular junction that is responsible for the more rapid recovery from block in children.[24]

Antagonism of neuromuscular block induced by pancuronium or doxacurium may be achieved with relatively smaller doses of neostigmine or edrophonium in children than in adults.[27] Recovery rates from both blockers were similar in this study but in children, only half the weight-related dose of neostigmine or edrophonium used in adults was needed to produce the same effect. In an older study of recovery from pancuronium-induced neuromuscular block in children and adults, recovery of T1/T0 was found to be faster after large doses of edrophonium (1.43 mg kg^{-1}) than after a large dose of neostigmine (0.071 mg kg^{-1}) in all ages of children.[28] Whichever anticholinesterase was used, recovery was more rapid in children than in adults.

In this issue, recovery from rocuronium-induced neuromuscular block is reported in children and in adults during isoflurane anaesthesia, using varying doses of neostigmine.[29] Small doses of neostigmine after rocuronium 0.6 mg kg^{-1} have a more marked effect in children aged 2–10 yr; for example, 5 μg kg^{-1} produced as rapid a recovery of T4/T1 to 0.7 in children as neostigmine 50 μg kg^{-1} in adults. These findings are impressive and, if substantiated, could alter paediatric anaesthetic practice significantly. Unlike mivacurium,[24 30] spontaneous recovery in children and adults after rocuronium was at least twice as long as that induced by neostigmine 50 μg kg^{-1}. In children aged 1–5 yr during halothane anaesthesia, spontaneous recovery of T4/T1 to 0.75 after rocuronium 0.6 mg kg^{-1} had previously been shown to occur in a mean time of 41.9 min, which is a shorter time than in adults.[31] Of note is the wide range of recovery of T4/T1 to 0.75 (26.5–57.7 min). Such wide variation with the aminosteroid neuromuscular blocking agents is an indication for always using at least a small dose of anticholinesterase when these drugs are administered. It has been suggested, in an interim report, that recovery from rocuronium-induced neuromuscular block is slower in young children aged 1–4 yr than in older children aged 5–10 yr during halothane anaesthesia.[32] Neostigmine administered at 25% recovery of T1/T0 again halved the recovery index (25–75% T1/T0) in both age groups. Further work is necessary on the pharmacokinetics and pharmacodynamics of rocuronium in children of all ages.

Nevertheless, it is becoming clear that, after administering the newer neuromuscular blocking agents, anaesthetists should again question if they are using too much neostigmine. If neuromuscular block is being monitored, and recovery is established (e.g. all four twitches of the train-of-four response are present), neostigmine 2.5 mg may be unnecessary in an adult who has received atracurium or mivacurium. Neostigmine 1.25 mg may be preferable. Decreasing the dose of the anticholinesterase may reduce its side effects. In children, smaller doses of anticholinesterase are necessary, even after using the aminosteroid neuromuscular blocking drugs, and especially with mivacurium, when they may not be needed at all!

CLINICAL INVESTIGATIONS

Dose–response relationships for neostigmine antagonism of rocuronium-induced neuromuscular block in children and adults

M. ABDULATIF, H. MOWAFI, A. AL-GHAMDI AND M. EL-SANABARY

Summary

Dose–response relationships for the antagonism of intermediate-acting neuromuscular blocking agents have not been evaluated previously in children. We have examined the dose–response relationships for neostigmine antagonism of 90% rocuronium-induced neuromuscular block in children and adults, during nitrous oxide–1 MAC of isoflurane anaesthesia. We studied 40 children, aged 2–10 yr, and 50 adults, aged 18–60 yr; all received a single bolus dose of rocuronium 0.6 mg kg^{-1} and accelerometry was used to monitor neuromuscular transmission. When the first twitch of the train-of-four (TOF) response (T1) recovered to 10% of its control (T0), one of five doses of neostigmine 0, 5, 10, 20 or 50 μg kg^{-1} was given by random allocation to each of the study groups (*n*=8 children and *n*=10 adults). Recovery of T1 and TOF ratio (T4/T1%) was recorded for 10 min after initial administration of neostigmine. Onset time of rocuronium-induced block was faster in children than in adults (mean 64.6 (95% confidence intervals 57.7–71.5) s *vs* 83.7 (70.7–96.6) s; $P<0.05$). The time to 10% recovery of T1/T0 was shorter in children than in adults (25.4 (22.9–27.9) min *vs* 38.8 (36.1–41.4) min; $P<0.001$). Spontaneous and antagonist-assisted recovery were more rapid in children than in adults. Adequate recovery (T4/T1 of 80%) occurred in children at 4, 5 and 8 min after neostigmine 50, 20 and 10 μg kg^{-1}, respectively. Adequate recovery was not produced in adults by any dose of neostigmine within 10 min. The effective doses of neostigmine required to achieve a TOF ratio of 80% (ED_{80}) after 10 min in children and adults were, respectively, 7.10 (5.2–9.8) μg kg^{-1} and 56.56 (45.5–71.9) μg kg^{-1} ($P<0.001$). There was no advantage in administering doses of neostigmine greater than 20 μg kg^{-1} to antagonize 90% rocuronium-induced neuromuscular block in children. In contrast, it appeared prudent to use neostigmine 50 μg kg^{-1} or more for adequate antagonism of a similar degree of block in adults. (*Br. J. Anaesth.* 1996; **77**: 710–715)

Key words
Anaesthesia, paediatric. Antagonists neuromuscular block, neostigmine. Neuromuscular block, rocuronium. Age factors. Pharmacology, dose–response.

In the past, there was an undocumented belief that higher doses of neostigmine were required for adequate antagonism of long-acting neuromuscular blocking drugs in children.[1] Later dose–response studies, however, showed that the dose of neostigmine required to antagonize tubocurarine-, pancuronium- or doxacurium-induced blocks in children was in the range of 25–50% of the adult value.[2 3] Also, in a recent dose–response study of mivacurium antagonism, Bevan and colleagues[4] reported that, compared with adults, children had a very rapid rate of spontaneous recovery to the extent that 10 min after antagonism with edrophonium or neostigmine, recovery in children was not very different from spontaneous recovery. In a subsequent study, the same group proved that it was safe to omit antagonism at the end of mivacurium-induced neuromuscular block in children but not in adults.[5]

Several dose–response studies have evaluated antagonism of intermediate-acting neuromuscular blocking drugs with anticholinesterases in adults.[6 7] Single-dose studies of neostigmine antagonism of vecuronium-induced block have demonstrated that the rate of recovery is age-dependent, being more rapid in children than in infants and adults.[8] However, single-dose comparisons between adults and children may be misleading and dose–response studies are a more appropriate alternative.[6] To date, antagonist dose–response studies have not been carried out for intermediate-acting neuromuscular blocking agents in children. Therefore, this study was designed to construct and compare the dose–response curves for neostigmine antagonism of an equivalent degree of neuromuscular block induced by the recently introduced intermediate-acting non-depolarizing neuromuscular blocker, rocuronium, in children and adults under similar anaesthetic conditions.

Patients and methods

We studied 40 children, aged 2–10 yr (mean 5.3 yr) and weighing 10–30 kg (mean 18.4 (SD 5.5) kg) and 50 adults aged 18–60 yr (mean 31.8 yr) and weighing 45–89 kg (mean 64.8 (9.8) kg), ASA I or II. All

patients were undergoing low-risk elective surgery. This study was approved by the hospital Ethics Committee and all children's guardians and adult patients gave written informed consent. We excluded any patient suffering from cardiac, vascular, respiratory, hepatic, renal, neuromuscular disorders or small joint arthritis. Patients receiving medications known or suspected to affect normal neuromuscular transmission were also excluded.

All children were premedicated with midazolam 0.5 mg kg^{-1} orally, 20–30 min before surgery. Adult patients were premedicated with diazepam 10–15 mg orally, approximately 90 min before surgery. In the operating room, an i.v. infusion of warm 5% glucose in half normal saline solution was given at a rate of 4–6 ml kg^{-1} h^{-1} via a peripheral arm vein. The ECG was monitored continuously and arterial pressure was measured every 5 min. Anaesthesia was induced with propofol 3–5 mg kg^{-1} in children and with 2–3 mg kg^{-1} in adults, and alfentanil 20 μg kg^{-1}. Tracheal intubation was performed without the use of neuromuscular blocking agents. Anaesthesia was maintained with 70% nitrous oxide in oxygen and an age-adjusted end-tidal isoflurane concentration of 1 MAC, excluding nitrous oxide (1.4–1.6% in children and 1–1.2% in adults).[9] Incremental doses of alfentanil 10 μg kg^{-1} were given as required. Ventilation was controlled to maintain normocapnia (end-tidal carbon dioxide partial pressure 4.6–5.3 kPa).

The temperature of the skin overlying the adductor pollicis muscle was monitored and maintained at 32–33 °C. Nasopharyngeal temperature in the two age groups was maintained at 36–37 °C by the use of a warming mattress. Concentrations of isoflurane, nitrous oxide, carbon dioxide and oxygen saturation were monitored continuously by a multiple-gas analyser (Capnomac Ultima-SVI, Datex Instrumentarium Corporation, Helsinki, Finland). The ulnar nerve was stimulated supramaximally at the wrist with square pulses of 0.2 ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz repeated every 15 s. An acceleration piezo-electric transducer (Biometer International, Odense, Denmark) was fastened to the volar surface of the distal phalanx of the thumb contralateral to the site of i.v. fluid infusion. For both children and adults, the arm was immobilized in a splint and free movement during evoked thumb adduction was ensured by fixation of the extended four ulnar fingers by an elastic bandage or adhesive tape. Registration of evoked thumb acceleration, in response to adductor pollicis contractions, was carried out using a TOF Guard neuromuscular monitor (Biometer International, Odense, Denmark). After stabilization of the evoked TOF responses, each patient in the two age groups received a single i.v. bolus of rocuronium 0.6 mg kg^{-1}.

The onset time of rocuronium-induced neuromuscular block, the time interval between the end of injection of rocuronium and the development of maximum block, and the time required for spontaneous recovery of the first twitch in the TOF response (T1) to a value of 10% of its control (T0), were determined for all patients. Neostigmine antagonism was induced at T1/T0 of 10%. Patients in the two age groups were allocated randomly using closed envelopes to one of five equal dose blocks ($n=8$ for children and $n=10$ for adults). Patients in each age group received either no antagonist (control) or one of four doses of neostigmine (5, 10, 20 or 50 μg kg^{-1}). Atropine 5–20 μg kg^{-1} was given as appropriate. No other antagonist was given for the next 10 min and the end-tidal isoflurane concentration was not altered. First twitch height and TOF ratios (fractional height of the evoked fourth twitch in the TOF response in relation to the first twitch height T4/T1) were then recorded continuously for 10 min in the control and after the different doses of neostigmine. Additional doses of neostigmine and atropine were given if a TOF ratio of 80% was not achieved at the end of the 10-min period. All information derived from the acceleration transducer was recorded on a memory card and subsequently a computer printout was obtained using TOF Guard Reader software (Biometer International, Odense, Denmark).

Dose–response curves were constructed using log dose *vs* probit transformation of antagonist-assisted recovery of TOF ratios. Antagonist-assisted recovery was defined as total recovery minus spontaneous recovery that would have taken place in the absence of neostigmine. This was calculated by subtracting from the total recovery of the TOF ratio mean spontaneous recovery observed in patients who did not receive neostigmine. The result was expressed as a percentage of the maximum possible antagonist-assisted recovery, which is equal to 100% minus percentage mean spontaneous recovery.[6 7] Linear regression analyses of the dose–response curves were used to calculate the effective doses of neostigmine required to achieve 50% and 80% recovery of the TOF ratio (ED_{50} and ED_{80}, respectively), every minute for 10 min after initial administration of neostigmine. Regression lines were compared using analysis of covariance. First we tested the lines to determine if they deviated from parallelism; if they did not, the F test was applied to determine if the elevations were different. If so, Newman–Keuls multiple comparison test was applied to determine which line differed in elevation.[10] Unpaired t test was used to compare the two age groups with respect to: overall onset times, times to 10% recovery of T1/T0, T1 and TOF ratio at 5 and 10 min in the control and after different doses of neostigmine. For each age group, Dunnett's test was used to compare the degree of recovery of T1 and TOF ratio recorded at 5 and 10 min after different doses of neostigmine to the corresponding values recorded in the control group.[10] Unless otherwise specified, all results are expressed as mean (95% confidence intervals) and were considered statistically significant when $P<0.05$. Most of the statistical analyses were performed using SPSS 6.0 statistical package for Windows.

Results

All patients in the two age groups developed 100% neuromuscular block in response to the bolus doses

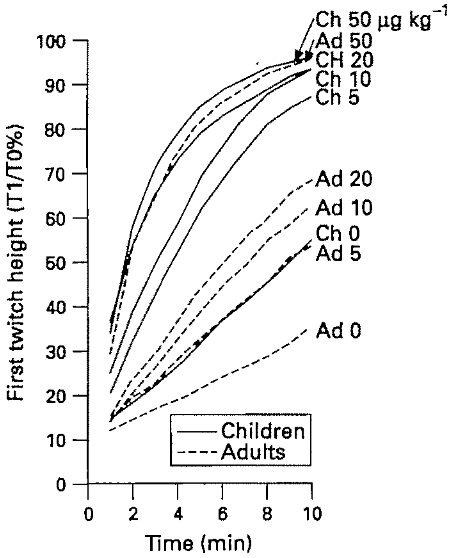

Figure 1 Mean total recovery of the first twitch height *vs* time after administration of various doses of neostigmine to antagonize 90% rocuronium-induced neuromuscular block in children (Ch) and adults (Ad). Error bars were omitted for the sake of clarity.

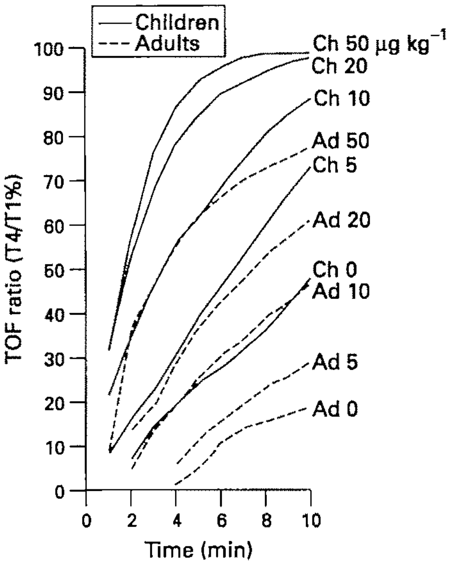

Figure 2 Mean total recovery of the train of four (TOF) ratio (T4/T1%) *vs* time after administration of various doses of neostigmine to antagonize 90% rocuronium-induced neuromuscular block in children (Ch) and adults (Ad). Error bars were omitted for the sake of clarity.

of rocuronium. The overall onset time of rocuronium-induced neuromuscular block in children was faster than that in adults (64.6 (57.7–71.5) s *vs* 83.7 (70.7–96.6) s; $P<0.05$). The time required for 10% spontaneous recovery of T1/T0 after rocuronium was shorter in children than in adults (25.4 (22.9–27.9) min *vs* 38.8 (36.1–41.4) min; $P<0.001$).

At the end of surgery, first twitch height always recovered to baseline in the two age groups. Spontaneous and antagonist-assisted recovery were more rapid in children than in adults. The courses of T1 and total recovery of the TOF ratio over the 10-min period in the control and after different doses of neostigmine in children and adults are shown in figures 1 and 2, respectively. Doses of neostigmine in the range 10–50 μg kg⁻¹ resulted in more than 90% recovery of T1 and adequate total recovery of the TOF ratio (80% or more) by the end of the 10-min period in children (table 1). A level of 80% TOF ratio was achieved in children at 4, 5 and 8 min after initial administration of neostigmine 50,

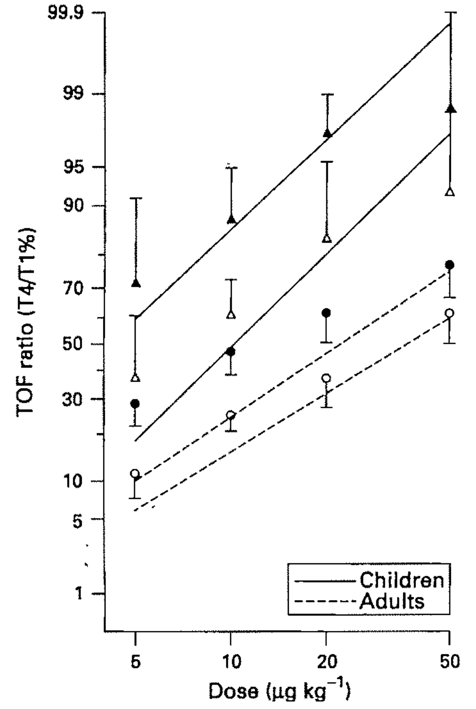

Figure 3 Dose–response curves of train-of-four (TOF) ratio recovery (probit scale) constructed at 5 and 10 min (▲, △= children and ●, ○=adults) *vs* dose of neostigmine (log scale) during antagonism of 90% rocuronium-induced neuromuscular block. Individual points represent mean values of antagonist-assisted TOF ratios attained with each dose of neostigmine. Error bars represent 95% confidence intervals.

20 and 10 μg kg^{-1}, respectively (fig. 2). In contrast, only the highest dose of neostigmine (50 μg kg^{-1}) resulted in substantial recovery of T1 to reach a value of 95.8 (94.0–98.3) % after 10 min in adults. However, adequate total recovery of 80% TOF ratio was not achieved with any of the four doses of neostigmine in adults within the same time interval (table 1, fig. 2). It is interesting to note that with respect to TOF recovery, neostigmine 5 μg kg^{-1} in children was as effective as 50 μg kg^{-1} in adults after 10 min (table 1, fig. 2).

The dose–response curves for antagonist-assisted TOF ratio recovery at 5 and 10 min were parallel in the two age groups (fig. 3). For each group, the lines constructed at 10 min were shifted significantly to the left from those constructed at 5 min ($P<0.001$ in children and $P<0.05$ in adults). The dose–response curves for children were shifted significantly to the left compared with those for adults ($P<0.001$). The effective doses of neostigmine required to achieve 50% (ED_{50}) and 80% (ED_{80}) antagonist-assisted recovery of the TOF ratios at 10 and 5 min were significantly lower in children compared with adults (table 2). The values for ED_{50}, ED_{80} in children and ED_{50} in adults are expressed as a function of time in figure 4. The ED_{50} values for adults were consistently higher than the ED_{50} and ED_{80} values in children.

Discussion

Antagonism of non-depolarizing neuromuscular block may depend on several factors including: type and dose of anticholinesterase,[6 7 11] degree of block at the time of antagonism,[12–15] anaesthetic technique used,[16] rate of spontaneous recovery and type of neuromuscular blocking drug.[6 17 18] In this study, most of these factors were standardized for the two age groups. The anaesthetic and neuromuscular monitoring techniques were similar and equal doses of neostigmine were used to antagonize 90% neuromuscular block after single standard intubating doses of rocuronium. Despite these apparent similarities, children had a more rapid onset and a shorter duration of rocuronium-induced neuromuscular block. A more rapid rate of recovery was also produced with substantially lower doses of neostigmine in children compared with adults. These age-related differences in response to rocuronium-induced neuromuscular block and its antagonism with neostigmine may have a kinetic or dynamic basis, or both.

Fisher and colleagues[2] demonstrated that the steady state volume of distribution for neostigmine in infants and children is not different from that in adults. However, infants and children have shorter elimination half-lives for neostigmine and more rapid clearance rates than adults. Therefore, the age-related differences in the rate of recovery and antagonist requirements do not seem to have a neostigmine-related kinetic basis.[19] Local differences at the neuromuscular junction such as acetylcholine reserves, acetylcholinesterase enzyme activity or the quantity of receptors at the neuromuscular junction have been suggested as possible contributing factors for the lower dose requirements of anticholinesterases in paediatric patients.[20] In contrast,

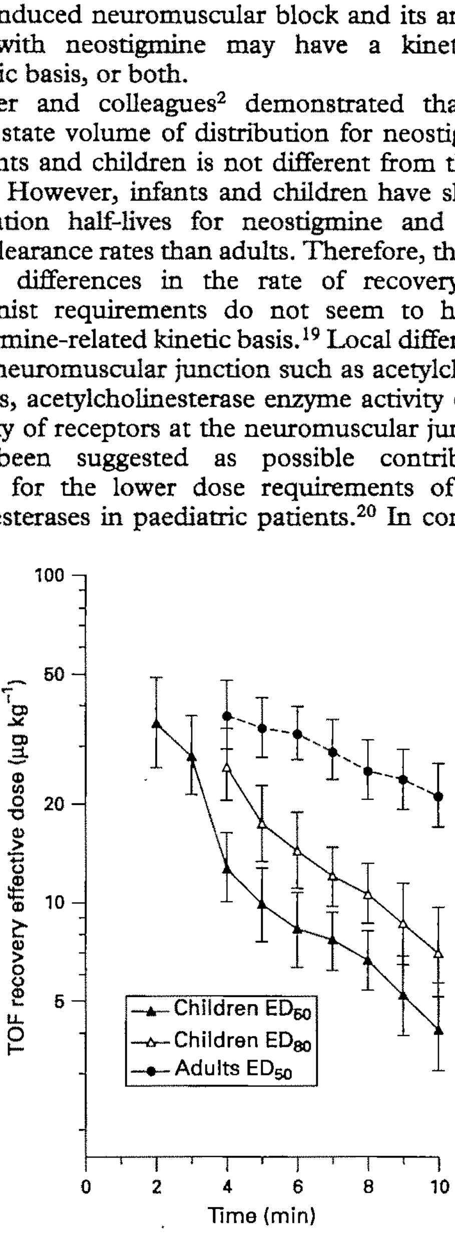

Figure 4 Effective doses for 50% (ED_{50}) and 80% (ED_{80}) antagonist-assisted train-of-four (TOF) ratio recovery *vs* time for neostigmine antagonism of 90% rocuronium-induced neuromuscular block in children and adults. Error bars represent 95% confidence intervals. Time 0=time of administration of neostigmine. The ED_{80} values for adults are not presented because they fell outside the range of the doses tested and were too high to be of clinical relevance.

it is well known that there are age-related pharmacodynamic and pharmacokinetic differences in the response to non-depolarizing neuromuscular blockers.[1 21–23] The more rapid circulation time and increased cardiac output in children are expected to expedite drug delivery to the neuromuscular junction and its removal.[23–25] Clinically, this results in acceleration of onset of neuromuscular block, more rapid rate of spontaneous recovery and reduction in duration of block in children. This was confirmed with the use of rocuronium in this and other studies.[26] In common with other neuromuscular blocking drugs, children have a shorter elimination half-life for rocuronium.[27] Smith, Donati and Bevan[6] suggested that the use of intermediate-acting neuromuscular blocking agents is associated with rapid reductions in their concentrations at the biophase. This implies that, with time, fewer receptors are occupied by the neuromuscular blocking drug with a consequent improvement in both total and antagonist-assisted recovery. This was probably the case in this study, as the effective doses of neostigmine were reduced progressively with time (fig. 4). Therefore, it appears more likely that the more rapid rate of spontaneous recovery from the effects of rocuronium-induced neuromuscular block was the predominant mechanism to explain the reduced neostigmine dose requirements and the more complete recovery observed in children.

Our results are in agreement with previously reported trends for antagonism of long-acting neuromuscular blockers, tubocurarine, pancuronium and doxacurium, in the two age groups.[2 3] However, the effective doses of neostigmine required for adequate TOF recovery were reduced considerably when rocuronium rather than longer-acting neuromuscular blockers were used.[3] Differences between the effectiveness of neostigmine antagonism of long- and intermediate-acting neuromuscular blockers have been recognized previously in adults and were attributed to different rates of spontaneous recovery.[28 29]

Rocuronium has a relatively longer duration of action than mivacurium in both adults[30 31] and children.[27 32] Therefore, at a comparable degree of neuromuscular block, anticholinesterases are expected to be more effective in antagonizing the effects of the latter.[29] However, Bevan and colleagues[4] reported recently that 10 min after administration of neostigmine 0, 5, 10, 20 and 50 μg kg^{-1} to antagonize approximately 90% mivacurium-induced block in children during nitrous oxide–propofol–fentanyl anaesthesia, the TOF ratio had recovered to mean 83.7 (SD 5.2) %, 79.3 (6.9) %, 92.8 (8.1) %, 92.2 (6.3) % and 97.0 (2.7)%, respectively. Our corresponding mean values for neostigmine antagonism of rocuronium in children were: 48.0 (95% confidence intervals 39.0–57.9) %, 73.0 (54.8–91.9) %, 88.5 (81.7–95.2) %, 97.7 (94.9–99.0) % and 98.7 (96.1–99.9) %, respectively. It is clear that when no antagonist was given, spontaneous recovery was more pronounced during recovery from mivacurium- than rocuronium-induced neuromuscular block. Therefore, the presence of comparable degrees of antagonist-assisted recovery may reflect a more effective neostigmine antagonism of rocuronium than mivacurium-induced neuromuscular block in children. This finding may appear surprising, however, factors other than anticholinesterase activity at the acetylcholine receptor level may be considered in the return of neuromuscular activity after administration of neostigmine. Szenohradszky and colleagues[33] reported recently that neostigmine was less effective in antagonizing the neuromuscular effects of mivacurium than vecuronium when administered during a continuous infusion of each blocker. In the same study, administration of neostigmine was associated with increased plasma concentrations of mivacurium. The authors suggested that the neostigmine-induced increase in mivacurium plasma concentrations may be responsible for the less effective antagonism compared with vecuronium. Neostigmine is a potent inhibitor of the butrylcholinesterse enzyme which is important for spontaneous recovery from mivacurium-induced neuromuscular block.[34 35]

In this study, inhalation of isoflurane was continued during the reversal process to ensure adequate depth of anaesthesia and prevent accidental patient movement in response to surgery, peripheral nerve stimulation, or both. This may be partly responsible for the increased dose requirements of neostigmine in adults. Other investigators have also reported that neostigmine doses in the range 40–50 μg kg^{-1} were required for adequate antagonism of 90% neuromuscular block induced by other intermediate-acting neuromuscular blockers during enflurane anaesthesia in adults.[36 37] Maintenance of anaesthesia with enflurane or isoflurane has been reported to impede the reversal process.[16] In clinical practice, however, inhalation anaesthetics are usually discontinued at the time of antagonism. This has been shown to reduce but not eliminate impairment of the reversal process.[38]

Comparison of the effects of mivacurium on the diaphragm and geniohyoid muscles

G. D'HONNEUR, V. SLAVOV, J.-C. MERLE, K. KIROV, J.-M. RIMANIOL, L. SPERRY AND P. DUVALDESTIN

Summary

Although subjects often report difficulty with swallowing shortly after receiving neuromuscular blocking agents, difficulty with swallowing during recovery from neuromuscular blocking agents appears to be infrequent. We have used electromyography to compare onset and recovery at the diaphragm and geniohyoid airway muscles after an intubating dose of mivacurium (0.2 mg kg^{-1}) to determine if the geniohyoid muscles were particularly sensitive to neuromuscular blocking agents. Twelve adults undergoing elective surgery were anaesthetized with propofol and fentanyl and the trachea intubated without neuromuscular blocking agents. The left hypoglossal and right phrenic nerves were stimulated with percutaneous needle electrodes and the electromyogram recorded with surface electrodes. EMG responses were measured after a bolus dose of mivacurium 0.2 mg kg^{-1}. Recordings were also made of the mechanical response of the adductor pollicis to supramaximal ulnar nerve stimulation. There was no difference in the rate of onset of block for geniohyoid muscles and the diaphragm, but recovery to 25% and 90% of the control response was shorter at the diaphragm (median 14.5 (95% confidence limits 12.9–15.3) min and 23.8 (21.7–26) min) than at the geniohyoid muscle (19.4 (15.6–20.1) min and 29.2 (26.3–31.4) min), respectively ($P < 0.05$). When the train-of-four ratio of the mechanical response of the thumb reached 70%, the diaphragm and geniohyoid muscles had recovered completely in all patients. (*Br. J. Anaesth.* 1996; **77**: 716–719)

Key words
Neuromuscular block, mivacurium. Muscle skeletal, diaphragm. Muscle skeletal, geniohyoid.

A degree of neuromuscular block that does not affect quiet breathing may impair upper airway muscle function, interfering with airway patency and swallowing, and the responses that protect against aspiration. Clinical reports suggest that during onset of neuromuscular block, the muscles of the tongue are more sensitive to blockers, and swallowing can be affected by small doses, of the magnitude used for "priming".[1] During recovery, the tongue has a response similar to that of the hand muscles.[2] Such reports suggest that inadvertent residual block may affect the upper airway and hand muscles more markedly than the diaphragm, but few data are available which have compared the relative sensitivity of these muscles to non-depolarizing neuromuscular blocking agents.

We have compared the evoked responses of the diaphragm and geniohyoid muscles during onset and recovery from mivacurium. We hypothesized that there would be a more prolonged effect on the geniohyoid. We chose mivacurium to reduce the likelihood of large variation in recovery times between subjects.[3]

Patients and methods

After obtaining local Ethics Committee approval and informed consent, we studied 12 patients (eight men), ASA I or II, undergoing elective surgery. Patients were aged 31–62 yr and had no history of previous abnormal response to neuromuscular agents. No premedication was given. Before induction of anaesthesia, a venous blood sample was obtained for analysis of plasma pseudocholinesterase activity using butyrylthiocholine as substrate (normal values 3000–7000 iu $litre^{-1}$). Anaesthesia was induced with propofol 2.5 mg kg^{-1} and fentanyl 2 μg kg^{-1} and tracheal intubation was performed 2 min later without the use of neuromuscular blocking agents. Anaesthesia was continued with 60% nitrous oxide in oxygen and a continuous i.v. infusion of propofol 3–7 mg kg^{-1} h^{-1} supplemented by bolus doses of fentanyl 1 μg kg^{-1} every 30 min. Ventilation was controlled to maintain an end-tidal carbon dioxide concentration of 3.5–4.5%. The patient was placed supine with the head fixed firmly in a neutral position, and covered with a warm air heating blanket (Bair Hugger, Augustine, La Praye, Switzerland).

The right phrenic nerve was stimulated using percutaneous insulated needle electrodes (Xomed, Jacksonville, FL, USA) inserted at the inferolateral

edge of the sternomastoid muscle, 1.5–3.5 cm deep. The electrode was inserted anterior to the scalene muscles at the level of the cricoid cartilage and directed inferiorly, anteriorly and medially. Satisfactory stimulation of the nerve caused a hiccuping movement of the right hemidiaphragm, with no activity of muscles supplied by the brachial plexus. The electrode was fixed in position with adhesive tape. The activity of the diaphragm was measured by placing two silver–silver chloride surface electrodes, 2 cm apart, in either the seventh or eighth intercostal space between the right anterior axillary and midclavicular lines where the response was maximal.

The left hypoglossal nerve was stimulated with the same type of percutaneous electrodes placed to a depth of approximately 1 cm under the angle of the mandible and directed anteriorly.[2] The activity of the geniohyoid muscles was measured with surface electrodes, placed 2 cm apart, midway between the mentum and the hyoid bone, between 0.5 and 1.5 cm lateral to the midline on the same side as the stimulating electrodes. Supramaximal stimuli (20–35 mA) were applied at 0.1 Hz and the rate of mechanical ventilation was adjusted so that the stimuli occurred at the end of expiration.

The activity of the muscles was amplified and recorded with a gated EMG amplifier using a latency of 2 ms and a window of 10 ms (Viking 2, Nicolet Instruments, Trappes, France). We measured the peak-to-peak amplitude of the compound action potential.

The left ulnar nerve was stimulated supramaximally at the wrist with surface electrodes using train-of-four (TOF) stimulation every 12 s. The force of contraction of the adductor pollicis was measured with a force transducer (Entran, Clayes sous Bois, France).

After steady responses for each muscle had been present and recorded for 3 min, a single dose of mivacurium 0.2 mg kg^{-1} was given i.v. over 10 s and the evoked EMG responses and force of contraction of the thumb recorded until full recovery. The times to 90% and maximum effect during onset, and to 5, 10, 25, 50, 75 and 90% of the control response during recovery were measured for all muscles. We calculated the recovery index as the time taken to recover 25–75% of the evoked response. We noted the time that the thumb TOF ratio (fourth to first response) became 70%.

Onset and recovery times were compared between the geniohyoid and diaphragm muscles with the Wilcoxon rank sum test, using the SIPHAR statistical program (Simed, Creteil, France). $P < 0.05$ was considered significant. Times are reported as median (95% confidence intervals).

Results

Mean age of the patients was 50 (range 31–72) yr and mean weight 70 (SD 12) kg. Plasma pseudocholinesterase activities were within the normal range, with a mean value of 4390 (SD 990) iu $litre^{-1}$. There were no adverse events or clinically important changes in heart rate or arterial pressure during the study.

The times to 90% and maximal depression of response were similar for the diaphragm and geniohyoid muscles. Figure 1 shows the time course of recovery of muscle responses after mivacurium, and the times of onset and recovery are given in table 1. Recovery times for the diaphragm were significantly less than those for the geniohyoid. Recovery indices of the diaphragm and geniohyoid muscles were similar and significantly less than the values for the thumb. At 70% TOF for the thumb, the responses of the geniohyoid muscles and diaphragm had returned to control values in all subjects.

Recovery of the electromyogram signal was usually complete. At full recovery, the absolute percentage differences between the responses measured after administration of the neuromuscular blocking agent, compared with the response obtained before the drug, were 3.5 (0.8–18.8) % for the geniohyoid and 3.0 (0.5–7.1) % for the diaphragm.

Discussion

We used the evoked response of the EMG to measure neuromuscular block in the diaphragm and geniohyoid muscles, because estimation of the mechanical responses of these muscles is complex and invasive. When resting muscle length is constant (i.e. preload is constant) and length during contraction does not alter (i.e. the transducer used has a large elastance), neural activation of a muscle, the evoked EMG activity, and the tension developed are closely related. Under experimental conditions, diaphragmatic contraction assessed by transdiaphragmatic pressure correlated well with the EMG signal[4] and it is likely that under the conditions of this study both measurements would have yielded similar results. In some circumstances EMG assessment of neuromuscular transmission, such as we used, may not indicate true functional state of the muscle. It is necessary to separate the effects on transmission, force generation and mechanical activity (lengthening or shortening). Measurement of an evoked response to a single stimulus is not affected by factors such as fade, which may be present when the muscle is activated with natural neural frequencies. However, if both EMG and mechanical response are measured in these circumstances, these responses are likely to be equally affected by factors that affect transmission, such as fade. Factors that alter muscle contractility or coordination may adversely affect airway protection and stability, even when neuromuscular transmission is satisfactory, and neuromuscular transmission has also to be assessed at physiological frequencies to be certain that this is so.[5]

We studied the geniohyoid muscle with EMG surface electrodes, and it is possible that activity from other facial muscles could have caused interference. However, because unilateral selective stimulation of a hypoglossal nerve is unlikely to cause significant activation of other muscles, and the position of the recording electrodes was close to the muscles studied, we are confident that the method allowed specific assessment of the mylohyoid–geniohyoid muscle complex. These muscles act to maintain airway patency[6] and are involved in the initial phase of swallowing. Impairment of neuromuscular transmission of these muscles can impair pressure generation during swallowing[7] but the timing of muscle activation does not appear to be reduced, indicating that coordination is less affected.

The dose of mivacurium chosen caused complete paralysis of the diaphragm in 11 of 12 subjects, despite resistance of this muscle to the action of non-depolarizing neuromuscular blocking agents. As the dose chosen was 2.5–3 times the ED_{95} for the thumb,[3] when given during nitrous oxide–opioid anaesthesia, it is not surprising that it caused rapid and almost complete paralysis of the diaphragm.

With this large dose, the onset of action at the geniohyoid muscles and diaphragm was similar, probably reflecting similar kinetic factors, such as muscle blood flow.[8] The onset of facial and diaphragm paralysis are similar and measurement of orbicularis oculi responses has been suggested as a good index of the time necessary for intubation.[9] In this study, loss of transmission for both the geniohyoid and diaphragm occurred at the same time, reinforcing the value of facial paralysis as a marker of adequate relaxation for intubation, which requires good relaxation of both diaphragm and pharyngeal muscles. Onset of neuromuscular block at the arm takes longer, indicating a smaller blood flow to the arm than to the diaphragm.[10]

Although during onset of action the importance of kinetic factors is great, during recovery the relative potencies of blockers at the two sites becomes more relevant as blood and tissue concentrations decrease progressively and in parallel.[11] In some studies, although the dose–response relationship was not assessed formally, relative transmission during recovery has been taken as a reasonable index of relative potencies,[9] particularly for longer-acting agents. During steady state neuromuscular block and recovery, sparing of the diaphragm relative to other muscles is well described.[12] The differences between the diaphragm and geniohyoid muscles in this study showed that the diaphragm has a greater margin of safety than the geniohyoid muscles, although this difference was not marked with mivacurium.

We tested the hypothesis that the actions of the neuromuscular blocking agent, mivacurium, would differ during onset of effect and recovery from effect, and that recovery of the geniohyoid muscles would be slow and similar to that of the thumb. Previous studies performed under similar conditions have suggested that the airway muscles are much more sensitive to neuromuscular blocking agents than the diaphragm, and hence patients may be unable to overcome airway obstruction or to clear the airway of foreign material despite respiratory muscle activity adequate for ventilation alone. Isono and co-workers showed in dogs that geniohyoid block was more intense than diaphragm block during onset and recovery from the action of vecuronium.[13] In patients, the same group or investigators found that partial neuromuscular block disturbed swallowing even though ventilation was adequate.[7] However, there has been no study in humans where simultaneous recovery of the two muscle groups has been assessed using the same method.

Although we found some difference, this was less than might have been predicted. Recovery after mivacurium may be more dependent on kinetic factors than recovery from other agents. Although blood flow may not normally affect recovery with agents such as atracurium and vecuronium, it may be a more important factor in the termination of action of agents with a very short half-life, such as mivacurium, leading to a faster recovery and shorter recovery index in the geniohyoid muscles because they seem to have a large blood flow.

When the TOF ratio for the thumb was 70%, no residual depression of either the diaphragm or geniohyoid muscle was present, showing that recovery from an intubating dose of mivacurium confers a greater safety margin for the geniohyoid muscles than for atracurium and vecuronium.[2]

Concentration-related effects of propofol on the auditory evoked response

M. A. TOOLEY, G. L. GREENSLADE AND C. PRYS-ROBERTS

Summary

We have studied the effects of propofol, as the sole agent, at blood concentrations of 1–10 μg ml^{-1}, on the first 100 ms of the auditory evoked response (AER) in 41 women before gynaecological surgery. AER were recorded with the patients awake and then after 30 min of one of seven stepped infusion regimens. Each patient was studied at only one blood concentration. The recordings were edited and processed off-line by coherent signal averaging, to obtain reliable estimates of each AER. We measured standard features, such as amplitudes and latencies of brainstem wave V and the mid-latency waves Na, Pa and Nb. In addition, we studied several composite indices, intended to give a more global characterization of the AER. We derived relationships between the doses and blood concentrations of propofol, features of the AER and response to eyelash stimulus and venepuncture. Nb latency was better than either concentration or dose rate of propofol in providing a confident explanation of the likelihood of eyelash response (which parallels the response to command). A cut-off value of 53 ms had a sensitivity of 100%, a specificity of 96% and an overall correctness of 98% as a discriminator of eyelash response *vs* no response. Several alternative AER-derived indices provided more than 90% correctness in discrimination, as did a dose rate of propofol of 6.3–7.8 mg kg^{-1} h^{-1} or a blood concentration of 2.9 μg ml^{-1}. We conclude that the concentration and dose of propofol were good discriminators of response to venepuncture, while the latency of the Na wave was the most successful of the AER features. (*Br. J. Anaesth.* 1996; **77**: 720–726)

Key words
Anaesthetics i.v., propofol. Brain, electroencephalography. Monitoring, evoked potentials. Monitoring, electroencephalography.

Graded changes in the auditory evoked response (AER) occur as concentrations of anaesthetic agents are altered, mainly in the mid-latency waves (15–80 ms).[1] Brainstem components are said to be unchanged by anaesthetics, while later components (>80 ms) are probably too affected by mental activity[2 3] to allow the effects of anaesthetics to be discerned accurately. Several workers have tried to demonstrate loss of implicit/explicit memory during anaesthesia, correlating it with the AER, but results so far are inconclusive.[4 5]

Previous studies of AER during anaesthesia have included the effects of several drugs in combination[6–9] and have been limited to small numbers of patients (i.e. 6–10 patients) or short exposure times that may not have allowed steady states to be established in brain or blood. Forrest and colleagues[10] found that the changes in the electroencephalogram (EEG) were unstable during the first 10–15 min of a targeted propofol infusion regimen. Only after 20 min did a steady neurophysiological state emerge. In this study we used propofol as a sole agent in patients free from surgical stimulation. We attempted to determine how the shape of the transient AER varied with a range of stable blood concentrations. The responsiveness of patients to standardized stimuli was assessed. Each patient was subjected to only one concentration of propofol.

Patients and methods

With approval from the local research Ethics Committee and written informed consent, we studied 41 healthy women, ASA I or II, median age 40 (range 25–71) yr. The patients were undergoing elective gynaecological surgery and receiving no medication other than hormone replacement therapy or oral contraceptives. We attached two sets of bipolar silver–silver chloride electrodes in a conventional configuration.[11] One set was placed on the vertex (positive) and 2 cm above the inion (negative), and the other on the vertex (positive) and the earlobe (negative), with the forehead as reference. We applied them in the ward and ensured stable impedances below 5 kΩ. In the anaesthetic room we sited an i.v. cannula and started routine clinical monitoring with ECG, non-invasive arterial pressure measurement and pulse oximetry.

We made a set of baseline AER recordings (see below) with patients awake and relaxed, with eyes lightly closed. Patients then received propofol from a

calibrated infusion pump (Graseby 3400 series) according to one of seven different manually controlled infusion schemes (table 1). These were intended to achieve and maintain a range of stable blood concentrations of propofol[12] between 1.0 and 10.0 $\mu g\ ml^{-1}$, with corresponding states of responsiveness between light sedation and deep unconsciousness.[13] The infusions were allocated openly and sequentially in blocks of seven (i.e. first patient to group 1, second patient to group 2, ... seventh patient to group 7, eight patient to group 1, etc.). Patients breathed spontaneously. Sedated patients received oxygen 4 litre min^{-1} through a Hudson mask. Anaesthetized patients received 40% oxygen from an entrainment T-piece via a laryngeal mask airway.

We made repeat recordings of AER at 10, 20 and 30 min after the start of the propofol infusion. Only recordings at 30 min were considered for this study. Immediately after the 30-min recordings, we recorded each patient's responses to the instruction "open your eyes", stroking an eyelash and venepuncture. We obtained venous blood samples from the contralateral arm to the infusion, which were stored in oxalate tubes for subsequent assay by high pressure liquid chromatography (HPLC).[14] This had a coefficient of variation of 7.3% at a propofol concentration of 2.0 $\mu g\ ml^{-1}$. The laboratory staff were unaware of the dose regimen. Anaesthesia for surgery was then provided by the anaesthetist covering the operating list.

AER RECORDING EQUIPMENT

We used an 80486 computer (Elonex plc, London, UK) to control two signal processing microprocessors (CED 1401 plus, Cambridge Electronic Design Ltd, Cambridge, UK), one as a flexible auditory stimulator and the other for data acquisition. The stimulator unit contained software (AUDPLUS, Cambridge Electronic Design) that allowed preprogramming of the qualitative and quantitative characteristics of the stimuli. These were delivered from a fixed-gain buffer amplifier via insert headphones at amplitudes 80 dB above the normal hearing threshold. Each set of recordings contained the responses to 500 bursts of a 2-kHz tone of 5 ms duration, followed by 500 rarefaction clicks of 0.5 ms duration.

We recorded a "sweep" of raw EEG data lasting 128 ms after each stimulus on a high quality, patient-isolated EEG amplifier (CED 1902). Its settings (gain, calibration and filtering) were controlled by the computer acquisition software. The amplifier had second-order, high-pass and low-pass filters set, respectively, to 3 dB points of 15 and 200 Hz. Data acquisition software (SIGAVG, Cambridge Electronic Design) controlled the repetition rate of the auditory stimulus (5.9 Hz), duration of "sweep" (128 ms) after each stimulus and sampling frequency of the EEG signals (1 kHz) during each sweep. Each sub-set of 500 sweeps took approximately 90 s. A monitor displayed the real-time coherent average AER and the sweeps were stored on disk for definitive off-line processing.

AER PROCESSING (OFF LINE)

Off-line processing of each sweep consisted of iterative loops of editing and coherent averaging (to obtain the most reliable estimate of the AER) followed by feature extraction from the best estimate. Editing was done semi-automatically using custom-designed signal processing software (SPIKE 2 language, Cambridge Electronic Design). Additionally, all sweeps were digitally filtered by a 15-Hz high-pass filter to remove low frequency EEG.

Editing and coherent averaging

Coherent averaging is a signal processing strategy for extracting a small response from a background of random overwhelming noise in sweeps of recorded signals after a repeated stimulus. As a running average is obtained of the values of a signal after each stimulus, the positive and negative deflections of the noise (background EEG activity, muscle activity, 50 Hz from mains, etc.) should cancel each other out. However, the consistent deflections produced by a contained response should reinforce one another ever more strongly as successive sweeps contribute to the average. This method fails if there are major incidents that rise above ordinary noise. These could distort the final AER or make it totally incorrect. Our previous unstimulated EEG studies during propofol anaesthesia[10] taught us that such incidents were liable to occur. These included movement artefacts in unanaesthetized patients, ECG spikes and spontaneous "burst" activity in patients receiving higher concentrations of propofol (fig. 1). Some patients also showed time-locked myogenic responses to auditory stimulation. Many of these incidents in the EEG have frequency contents so close to the important frequencies in the AER that it is not feasible to remove them by filtering. Editing is a reasonable alternative.

We identified these incidents by the program, producing compressed time displays of three features of the EEG during the 500 sweeps of recording: the first simply showed the maximum amplitude (used for rejecting noise spikes), the second the integral of the rectified waveform (used for rejecting high propofol concentration effects) and the third the maximum differential value of the waveform (used for rejecting ECG signals). Thresholds were determined by inspection to differentiate the normal background activity from incidental transients of unwanted data. A coherent average was then made using those sweeps that were below the chosen thresholds. The others were rejected. The quality of the resulting average was checked by examining the width of the confidence limits that contained the best estimate of the time course of the AER. The best estimate, with that edition of sweeps, was compared with the estimates produced from the first and second half of the file of edited sweeps. Its shape was also compared with that of the best estimate produced by the tone stimuli. A further test of the editing and data-processing was that the coherent average of a similarly edited batch of 500 sweeps of the contemporaneous background EEG, with no auditory stimulus, should show a flat trace. Failure to achieve a confident estimate of the AER by any of the above criteria required the cycle of editing and coherent averaging to be repeated until a satisfactory estimate was obtained. Otherwise the analysis was abandoned and the information discarded. The final satisfactory estimates of the AER were stored as separate files.

Feature extraction from the best estimates of the AER

The simple features that were extracted consisted of amplitudes (measured from the preceding peak or trough) and latencies (from the stimulus) of the peaks or troughs of the conventionally labelled components of the AER (brainstem wave V, Na, Pa, Nb). These were measured by applying cursors to the screen display of each satisfactory estimate of the AER. Several empirically devised composite measures of the complete AER wave were also recorded, including: (i) integral of the rectified waveform between 15 and 70 ms (summation index); (ii) integral of the rectified smoothed differential of the waveform between 20 and 70 ms (differential index); (iii) reciprocal of the difference between Na and Nb latencies (basic frequency index); (iv) index of the superimposability of each waveform on that of the grand average of several patients' baseline (awake) AER waveforms (amplitude, at each time, of the AER waveform under investigation was multiplied by the corresponding amplitude of the grand average, and the successive product terms were summed over the first 50 ms).

STATISTICAL ANALYSES

The groups were not randomly allocated, and therefore we used analysis of variance to examine for bias in ages, weights and baseline arterial pressures: we also examined the haemodynamic effects of the different doses of propofol, 30 min after the start of the infusions. Relationships between dose and concentration, and between concentration and the values of the features extracted from the AER, were determined by non-linear curve-fitting programs (Sigma Plot for windows 5, Jandel Scientific, Erkrath, FRG and Unistat for windows). A stepwise multiple logistic regression (LOGIST, SAS version 6, for windows. SAS institute Inc, Cary, NC, USA) was used to identify explanators of the patient's responses to eyelash and venepuncture. The conventional AER amplitudes and latencies and the composite indices were offered as potential explanators, together with the dose and concentration of propofol. The LOGIST procedure can output sensitivity, selectivity and correctness if different cut-off probabilities are used to classify responses as present or absent. Data on verbal response were not examined formally. They could be inaccurate because the insert headphones interfered unpredictably with hearing through normal channels. However, the responses achieved were virtually superimposable on the eyelash responses, as in our other studies.[10 13] A probit analysis (SAS for windows version 6, SAS Institute, Cary NC, USA) was used in addition, to estimate (with confidence limits) the values of the single and composite AER features and the doses and concentrations of propofol that corresponded to 50% and 95% probability of no response.

Results

There were no significant differences between the seven groups in age, weight or arterial pressure, either at baseline or after 30 min of infusion.

SAMPLING AND EDITING OF AER

For the period of propofol infusion, data from six

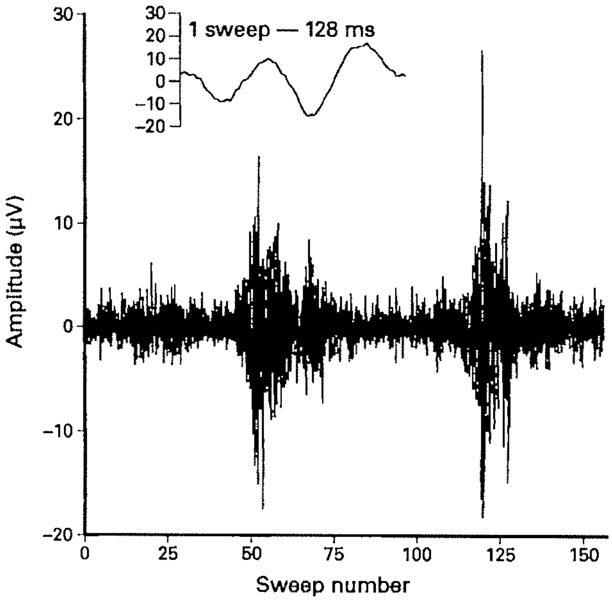

Figure 1 A compressed time display of 150 sweeps of raw data during which auditory stimuli were being given. The inset shows a single sweep (No. 52) of raw data containing both AER and EEG, with the stimulus given at the vertical axis and the sweep lasting 128 ms.

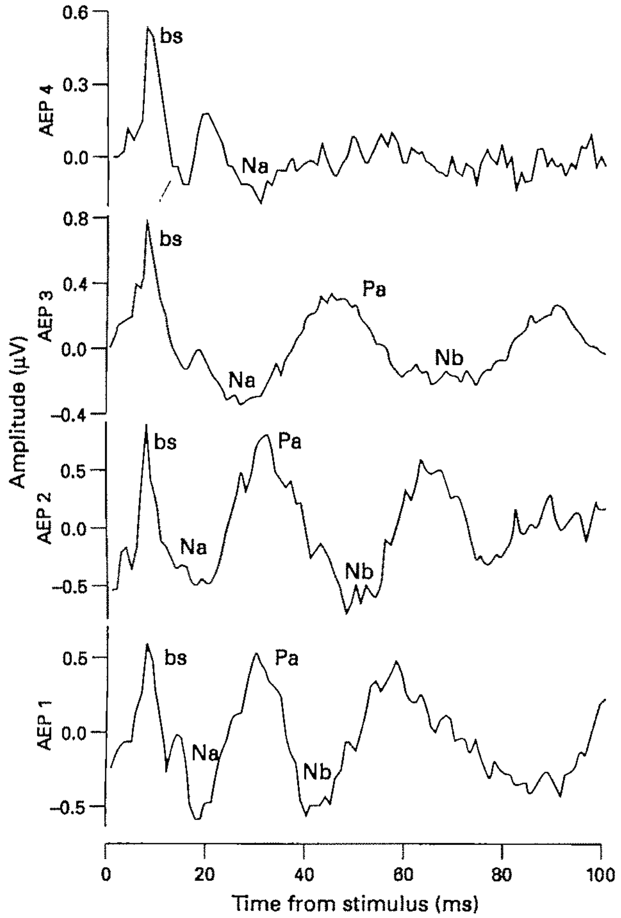

Figure 2 Example AER estimates for wakefulness (AEP 1) and at three different infusion rates of propofol, giving blood concentrations of propofol of 1.5 $\mu g\ ml^{-1}$ (AEP 2, eyelash response present), 3.8 $\mu g\ ml^{-1}$ (AEP 3, no response to eyelash or venepuncture) and 8.9 $\mu g\ ml^{-1}$ (AEP 4). Each trace has a different amplitude scale.

patients could not be included in the analysis: two coughed uncontrollably on the allocated dose of propofol (groups 3 and 4); two produced time-locked myogenic responses that overwhelmed the AER estimate; in one patient, the coherent average of the unstimulated EEG did not tend to zero; the EEG from the last patient was too heavily contaminated with artefact to provide a confident estimate of the AER. Therefore, there were 35 estimates remaining after 30 min of propofol infusion. In these 35 patients, only 16 estimates were obtained of awake AER. The estimates that were made required a variable amount of editing to exclude incidents and artefacts from the coherent average.

Figure 1 is an example of a compressed time display of the first 150 sweeps in a set of 500, and shows what can happen at the infusion rates of propofol that produce blood concentrations of more than 3 $\mu g\ ml^{-1}$. Periodic increases in amplitude are reminiscent of the spindling in burst suppression, but the increases are much greater and the contained frequencies (indicated in the insert of a single sweep) are higher, overlapping with the principal frequencies in the AER. Features similar to this appear in the presence or absence of auditory stimulation and necessitated the editing described in the methods.

Figure 2 shows four example AER from three patients, illustrating qualitatively the progression from awake (AEP 1) through to the effects of three dose rates of propofol that span the range used in this study. It shows the reduction in amplitude and delay of the mid-latency components, with relatively little effect on the brainstem response.

DOSE–CONCENTRATION EFFECTS

The relationship between dose rate and concentration of propofol was described as well by linear regression as by one with higher terms in infusion rate:

$$\text{concentration } (\mu g\ ml^{-1}) = -1.12 + 0.53 \times \text{final infusion rate } (mg\ kg^{-1}\ h^{-1})\ (r^2 = 0.83)$$

CONCENTRATION–AER EFFECTS

Figure 3 shows the relationships between propofol concentration and two of the measured features of the AER. The relationship with Na latency was almost linear, whereas that for Nb was non-linear. There was an apparent ceiling effect at approximately 70–80 ms which was reached normally at propofol concentrations greater than 6 $\mu g\ ml^{-1}$. Higher concentrations attenuated the responses to an extent that made Nb latency difficult to judge. This also occurred with four AER recorded at propofol concentrations less than 6 $\mu g\ ml^{-1}$. Data for Nb were fitted significantly better by a quadratic than by a linear equation in concentration. The

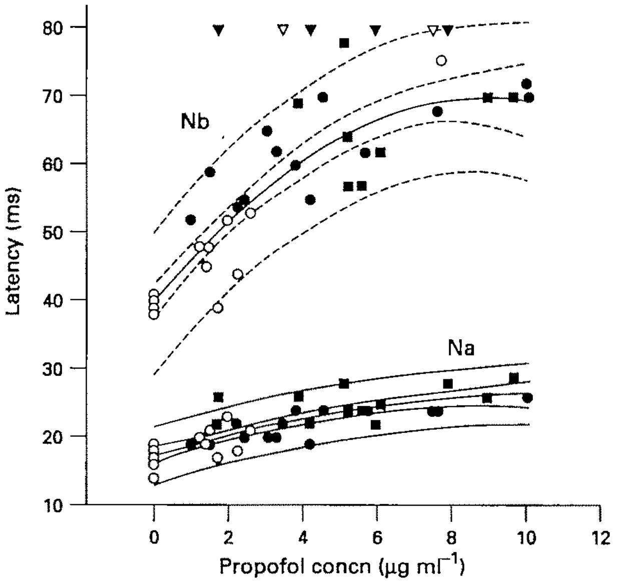

Figure 3 Relationships between Nb latency, Na latency and whole blood propofol concentration. The overlapping open circles at zero concentration represent the distributions of 13 values for Nb (mean latency 39.6 (SD 1.0) ms) and eight values for Na (mean latency 17.0 (1.5) ms) obtained from awake patients. All other values were obtained at 30 min after the start of infusion. ○=Patients responding to eyelash and venepuncture stimuli; ●=patients responding to venepuncture stimulus only; ■=patients not responding to eyelash or venepuncture; ▼=patients not responding to eyelash or venepuncture and also the AER was too suppressed to allow estimation of Nb; ▽=patients responding to venepuncture only and the AER was too suppressed to allow estimation of Nb. The 95% confidence limits for the best fit regression line and for individual data points are superimposed on each plot.

Table 2 Relationships between blood propofol concentration (conc.) and conventional and composite features of the AER, with coefficients of determination (r^2)

Variable	Equation	r^2
Nb latency	$=39.9+6.7\text{ conc.}-0.37\text{ conc.}^2$	0.83
Nb amplitude	$=1.19-0.26\text{ conc.}-0.016\text{ conc.}^2$	0.44
Pa latency	$=28.5+3.9\text{ conc.}-0.2\text{ conc.}^2$	0.79

relationships for the other features that were extracted are summarized in table 2 as quadratic equations in concentration.

DOSE, CONCENTRATION AND AER EFFECTS ON RESPONSIVENESS TO STIMULI

When offered all possible AER explanators together (conventional and composite features) the stepwise multiple regression process identified only Nb latency as a significant explanator of the occurrence of an eyelash response. If Nb latency was not offered, stepwise multiple logistic regression process identified several other AER features as partial alternative explanators. A similar process was carried out with propofol concentration and dose rates. In the corresponding analyses for the venepuncture response, Na latency itself gave as complete an explanation as the total set of offered AER explanators, although others also had partial explanatory effect that was overlapped by that of Nb.

Table 3 summarizes the relationships between likelihood of suppressing eyelash or venepuncture responses and the values of various AER and non-AER features. The values for 50% and 95% probability of no response were estimated by probit analysis.

The logistic regression process produces values for sensitivity, specificity and correctness in discrimination that would be obtained if different probabilities (or the corresponding value of the explanator in a single explanator regression) were to be used as cut-off points for classification of response *vs* no response. For example, an Nb latency of 53 ms had a sensitivity of 100%, a specificity of 96% and a correctness of 98% as a discriminator of eyelash response. This is confirmed in figure 3: if a horizontal line is placed at 53 ms, all eyelash responders are below it and 20 of 21 non-responders are above it. For concentration, the best discriminator, a vertical line placed at 2.9 μg ml^{-1} shows all responders to the left but only 15 of the 21 non-responders to the right. Table 4 lists the threshold values of the seven best discriminators of eyelash and venepuncture responses, ranked in order of correctness, with the associated values of sensitivity and specificity in discriminating responders from non-responders.

Table 3 Estimated values (95% confidence limits) of a selection of AER and non-AER explanators that are required to have 50% or 95% probability of suppressing the eyelash or venepuncture response in the sample. Dose=final infusion rate of propofol, concentration=blood propofol concentration

Variable	50% probability of no response	95% probability of no response
Eyelash:		
BS latency (ms)	7 (6.6–7.5)	8.2 (7.7–14)
Na latency (ms)	20 (16–23)	24 (22–48)
Nb latency (ms)	52 (46–56)	60 (56–79)
Frequency (Hz)	32 (29–39)	28 (16–31)
Concentration μg ml^{-1}	1.9 (1.4–2.7)	3.3 (2.5–5.5)
Dose (mg kg^{-1} h^{-1})	5.8 (4–7.5)	8.2 (6.9–15.6)
Venepuncture:		
BS latency (ms)	7.8 (7.4–8.7)	9 (8.3–12.3)
Na latency (ms)	24 (23–26)	29 (26–37)
Nb latency (ms)	67 (62–75)	85 (76–122)
Frequency (Hz)	23 (17–27)	14 (2–18)
Concentration (μg ml^{-1})	6.5 (4.4–12.7)	13 (9–32)
Dose (mg kg^{-1} h^{-1})	13.2 (10.6–18)	23 (18–37)

Discussion

The conditions of the study were not typical of clinical anaesthesia, but the design allowed examination of the effects of propofol as a sole agent, without the confounding effects of surgery. The relationship between the infused dose rate and 30-min propofol concentrations was consistent with that found in our previous study on unstimulated EEG[10] which also indicated that 30 min was the minimum time needed for the stepped infusions to produce a stable neurophysiological state.

Great care was needed to obtain confident estimates of the AER. Awake, unpremedicated patients were often tense, despite all efforts to relax them. More than 50% of their AER were contaminated by time-locked muscle responses, such as the post-auricular response. The remaining reliable awake AER had a fairly consistent waveform which was also similar to many awake AER recorded in subsidiary studies on volunteers. Much of the contamination (including, in all patients, the post-auricular response) disappeared during infusion of propofol, but could be replaced by other activities, such as in figure 1, for which careful empirical analysis seemed the only solution. For applications of AER recording to on-line feedback of anaesthetic depth, methods of automating the editing process are needed, unless the contaminating activity can be removed directly, for example by some pharmacological adjuvant. Latencies and amplitudes of the various waves are accepted simple features with which to characterize the form of the AER, but there are alternatives[15] to our chosen method of measuring the amplitudes by reference to the preceding peak.

The concentration-related changes in the form of the AER, after 30 min of anaesthesia or sedation with propofol alone, were qualitatively similar to those found by others. However, complete suppression of the AER waveform required greater propofol concentrations than have been described previously.[8 9] This may be attributable to polypharmacy, different filtering of the EEG or pharmacodynamic instability in their studies. Although the brainstem wave V changed much less with propofol

Table 4 Correctness, sensitivity and specificity of the seven best discriminators for the eyelash and venepuncture responses. Dose=final infusion rate of propofol, concentration=blood propofol concentration

AEP variable	Correctness (%)	Sensitivity (%)	Specificity (%)	Threshold

concentration than the later waves, we noticed some changes in its latency (table 2), unlike in other reports.[7 8]

In the absence of particular explanations, such as deafness or hysteria, failure to acknowledge or respond to verbal instructions is probably the simplest indicator of the threshold between consciousness and unconsciousness or anaesthesia. Verbal responses were tested in all patients, but concern about the possible distracting effects of the insert headphones led us to place more reliance on the analysis of eyelash reflex, which has very similar pharmacological and EEG correlates.[10]

With a sensitivity of 100% and specificity of 96%, a threshold Nb latency of 53 ms discriminated between the presence and absence of an eyelash reflex better than any other simple feature and as well as any of the composite features. The scope for improvement seems small, although this may apply only to this particular set of data. For an EEG feature to be useful in clinical monitoring or feedback control, sensitivity in detecting awareness is probably more important than selectivity. False positives (arising from unselectivity) would result in an overdose of anaesthetic agent. This happens in daily anaesthetic practice without being particularly troublesome. In contrast, false negatives (arising from insensitivity to awareness) would leave some patients aware during surgery, a much more serious error. Other workers have also suggested that Nb latency is a useful discriminator[16] but with a threshold value of 44 ms, which would have had a sensitivity of only 43% (although a specificity of 100%) in detecting eyelash responders in our patients. In our work on the unstimulated EEG,[10] a median power frequency of 8.3 Hz had a sensitivity of 94% and specificity of 84%.

One might reasonably expect composite measures to provide better information on the overall form of the AER. The reciprocal of the difference between Na and Nb latencies is the basic low frequency component of the AER. It is related closely to the latency of Nb itself (which accounts for its high discriminating power (table 4)). The awake value of approximately 40 Hz is also the steady state frequency of the awake AER.[17] If auditory stimuli are repeated at a fixed frequency of 40 Hz as sedative or anaesthetic drugs are given, the amplitude of the steady state AER is reduced,[18] presumably because the basic frequency no longer resonates with the stimulating frequency. If the stimulation frequency is changed to match the change in the basic frequency, the amplitude of the steady state AER can be better maintained and the frequency required to do so, "the coherent frequency", is yet another possible correlate of anaesthesia.[19] The first[20] and second[15] differential of the waveform have also been used empirically to describe the transient AER. None of our composite measures seemed to offer any advantage over the simpler Nb latency, although composite measures could be more robust in an automatic analysis environment, such as closed loop control. If any particular single or composite feature in the AER or EEG is to be proposed as a universal predictor of the risk of awareness, it is important that its value be constant in the face of variations. These include the pharmacopoedia to produce anaesthesia and the levels of arousal brought about by surgery or other noxious stimuli. This was not tested in our study.

Our study took approximately 90 s to collect the data for analysis. Although acceptable with stable blood concentrations, it is too long for periods when blood concentrations are changing rapidly. A faster method of obtaining estimates of the AER is needed.

AER features ranked more highly than dose and concentration of propofol as discriminators for the eyelash response. However, the opposite was true for the response to venepuncture (table 4). The observation that the brainstem wave V latency has some discriminatory value for the response to venepuncture accords with the evidence that responses to superficial pain (such as venepuncture) are mediated well below the cortical level.[21] With faster sampling of the EEG signal to resolve the first 10 ms more accurately, the discriminating potential of brainstem responses for pain could possibly be improved.

Better characterization of the AER correlates of different clinically observable responses may improve our understanding of the hierarchy of responsiveness that is challenged by anaesthesia.

Acknowledgements

We thank Mrs A. Dye and Mrs S. Gorman for assaying blood propofol concentrations, Dr Chris Day for his help and advice with the statistical analysis and Dr Andy Black for his help and advice with the final editing.

Comparison of patient-controlled sedation with either methohexitone or propofol

S. K. HAMID, N. MCCANN, L. MCARDLE AND A. J. ASBURY

Summary

We studied 42 patients undergoing oral surgery under local anaesthesia with i.v. sedation, allocated randomly to receive either methohexitone (group M) or propofol (group P) for patient-controlled sedation (PCS). Group M patients self-administered 2.5-mg (0.5 ml) bolus doses of methohexitone and group P, 5-mg (0.5 ml) doses of propofol, without a lockout. The 0.5-ml bolus dose was delivered over 7.2 s for both drugs. The procedure was completed satisfactorily in all patients. Patients in both groups achieved their desired levels of sedation. No patient lost verbal contact. Group M patients had higher heart rates during the procedure. The lowest Sp_{O_2} values recorded were 92% and 95% for group P and group M, respectively. Immediately after operation patients in group M reported that they felt more sleepy than those in group P ($P < 0.01$) but there were no differences at subsequent times. The results of the psychomotor tests were comparable for the two groups after operation, except for the "posting box task" at 15 min after operation when the mean decrement (compared with preoperative performance) was −3% for group P and −13% for group M ($P < 0.05$). More patients in group P complained of pain in their hand. We conclude that methohexitone is a suitable alternative drug to propofol for PCS. (*Br. J. Anaesth.* 1996; **77**: 727–730)

Key words
Anaesthetics i.v., methohexitone. Anaesthetics i.v., propofol. Sedation, patient-controlled. Surgery, oral.

Patient-controlled sedation (PCS) has been reported using either midazolam or propofol. However, they are not comparable in pharmacokinetics. Oversedation may be a problem with midazolam as it has a relatively slow onset and the patient may make additional demands for drug boluses before adequate time has elapsed for the earlier boluses to produce an effect. The use of methohexitone for PCS has not been described. It is cleared rapidly from the body and is cheaper than propofol.[1] Studies of psychomotor function after induction doses of propofol or methohexitone suggest that there is faster recovery of psychomotor performance after propofol.[2–4] However, MacKenzie and Grant showed that propofol produces a slightly greater decrease in the critical flicker fusion threshold than methohexitone.[5] A comparison of psychomotor performance after sedation with propofol or methohexitone has not been performed.

Methohexitone may be a more suitable alternative than midazolam for day-case PCS. The objective of this prospective, randomized study was to compare PCS with either methohexitone or propofol.

Patients and methods

Approval was obtained from the hospital Ethics Committee and we studied 42 unpremedicated patients, ASA I or II, aged 16 yr or more, undergoing oral surgery under local anaesthesia with i.v. sedation. Patients gave informed consent. Exclusion criteria included patients who were taking sedative medication, those who were pregnant and those who had previous adverse reactions to propofol or methohexitone. After a full explanation, patients were allocated randomly to receive PCS with either methohexitone (group M) or propofol (group P). Randomization was performed using sealed envelopes. Each drug was self-administered by the patient from a Graseby 3300 infusion pump. The bolus dose administered was 0.5 ml for both drugs. The concentrations of drugs used were 10 mg ml^{-1} for propofol and 5 mg ml^{-1} for methohexitone; hence group M patients received 2.5 mg of methohexitone and those in group P received 5 mg of propofol on demand. No lockout time was used but as the infusion rate was 250 ml h^{-1}, it took 7.2 s to infuse the 0.5-ml bolus. Demands made for drug during this period resulted in no drug being administered.

Patients were instructed in the use of the infusion pump before sedation and were told that they could press the demand button as often as they liked to produce the level of sedation they desired but that the pump would not administer another dose for a

period of approximately 7 s. A maximum of 8 doses per minute could be administered, giving a maximum of 20 mg of methohexitone or 40 mg of propofol per minute. Before sedation and surgery, immediately after operation and at 15 and 30 min after the end of the procedure, patients were asked to rate their anxiety, pain and somnolence on a four-point scale (none, mild, moderate and severe). They were also asked to complete a Corah dental anxiety questionnaire before operation.[6]

Patients performed psychomotor tests before operation and again immediately on completion of the procedure and at 15 and 30 min. These tests consisted of a "posting box task" (PBX) which involved the patient putting 15 shaped bricks through appropriately shaped holes of a box as quickly as possible using one hand.[7] The best time for two attempts for the PBX task was taken. The other test consisted of a choice reaction time (CRT) which was measured using a programme implemented on a hand-held Psion organizer.[8] Before the CRT test itself, preliminary instructions scroll across the screen, prompted by key presses by the patient. The final message is "Are you ready?—press the Y key to go on". After the patient presses the Y key, one of six letters (A–F) appears on the screen in random order and after a randomized time interval. The patient has to press the corresponding letter on the keyboard. This process is repeated 30 times. This test gave two results: a choice reaction time score (CRTS), that is the percentage of choices made correctly, and a mean choice reaction time (CRTM), that is the mean time taken to react. At the end of the test, the Psion displays the results which are stored and can be transferred subsequently to an IBM-compatible computer for manipulation by word-processing and spreadsheet programmes.

When the patient was settled in the dental chair, monitoring (non-invasive arterial pressure, heart rate and pulse oximetry) was established and continued throughout the procedure. A 20-gauge cannula was inserted into a vein on the dorsum of the patient's hand. For event timing, time 0 was taken as the time of administration of the first dose of drug. The patient's deepest level of sedation was recorded using a modified published five-point scale.[9] This was recorded every 1 min for the first 16 min, every 2 min for the next 15 min and every 5 min until the end of the dental procedure (table 1). Local anaesthetic infiltration (2% lignocaine with adrenaline 1:80 000) was performed by the dentist when the patient was ready.

After completion of the dental procedure, the patient was transferred to a recovery area. Before discharge home, patients were questioned on nausea, pain in the hand, recall of intraoperative events, if they had managed to achieve their desired level of sedation and if they would be prepared to have the same method of sedation again. Patients and the dentist were asked to evaluate the acceptability of the sedation technique using a four-point scale (poor, moderate, good or excellent). The dentist was also asked to evaluate patient cooperation during the procedure.

Table 1 Sedation scoring used

1=Fully awake
2=Drowsy with eyes open and/or brisk response to command
3=Drowsy with eyes closed and/or slow response to command
4=Eyes closed but rousable with mild physical stimulus
5=Eyes closed and unrousable with mild physical stimulus

Minitab for DOS release 7 was used for statistical analysis. The Mann–Whitney test was used for ordinal data, and chi-square test for nominal data. A probability (P) of less than 0.05 was considered to be statistically significant.

Results

Forty patients were included in the data analysis; two patients were excluded, one in group M had a cannula resited during the procedure and the other patient in group P had to be given a general anaesthetic to reduce a dislocated jaw. There were 20 patients in each group. Fourteen patients in group M had third molar teeth extractions, two had extraction of other teeth, two had apicectomies, one had excision of a granuloma of the mouth and one had removal of a salivary calculus. Six patients in group P had third molar teeth extractions, eight had extraction of other teeth and six had apicectomies. The proposed dental procedure was completed satisfactorily in all patients (table 2).

The lowest oxygen saturation value recorded was 92% for a group P patient and 95% for a group M patient. Group M patients had higher heart rates during the procedure. Mean arterial pressures remained within acceptable clinical limits and were similar in the two groups. The ratio of successful to unsuccessful demands was similar in both groups.

No patient in either group lost verbal contact. Table 3 shows the deepest level of sedation achieved by the patients. All patients were discharged approximately 30 min after the end of the procedure. Immediately on arrival in the recovery area patients in group M reported that they felt drowsier than those in group P ($P < 0.01$). However, there were no

significant differences at 15 or 30 min after operation. Table 4 shows how sedated patients said they felt immediately after, 15 min and 30 min after the procedure.

Table 5 shows the results of psychomotor testing. Group M patients showed a greater decrement in the PBX task at 15 min than those in group P. However, there were no significant differences in performance times immediately after or 30 min after the procedure. CRTS and CRTM were not significantly different between the two groups at any time after operation.

Two patients in group M had some fine tremor-like movements of their limbs of short duration but this did not upset the patient or dentist. Four patients in group M and nine patients in group P complained of pain in their hand but this was not statistically significant. Eleven patients in group M and 12 in group P had amnesia for certain intraoperative events. One patient in each group had amnesia for recovery room events. No patient complained of nausea or vomited. All patients said that they had managed to achieve their desired level of sedation. All patients thought their sedation was either good or excellent. Patient cooperation was rated as excellent in 19 patients and poor in one patient in group M and excellent in 15 and poor in one patient in group P.

Discussion

Our study has shown that methohexitone compared favourably with propofol when used for patient-controlled sedation. However, patients who received methohexitone reported that they felt more drowsy immediately after the procedure than those who received propofol. Fifteen minutes after surgery both groups felt less drowsy and there was no difference between the groups at this time or subsequently. More patients in the methohexitone group had wisdom teeth extractions. This could have resulted in an increased demand for sedation by this group.

The methohexitone group performed the PBX more slowly than the propofol group 15 min after the procedure. Immediately and 30 min after the procedure there were no significant differences in performance times. However, this is a fairly insensitive test.[10] There were no differences between the two groups in CRTM and CRTS at any time after operation.

All patients were discharged home escorted 30 min after operation with written instructions. Studies comparing PCS with propofol or midazolam suggest faster recovery of psychomotor function in patients who received propofol.[11 12] The amnesic effects of propofol and methohexitone appeared to be similar when used for sedation in this study, with the most marked effect being amnesia for intraoperative events. Amnesia is more likely to persist for recovery events with midazolam.[12] Hence methohexitone and propofol would be more suitable agents for day-case patients requiring sedation.

More patients in the propofol group complained of pain in the hand but this was not statistically significant. The lower incidence of pain in the hand than would have been expected for the methohexitone patients may have been because of the more dilute concentration (0.5%) of methohexitone used in this study.

Patients were allowed to start and maintain their own sedation. The amount of drug administered was limited by the drug concentration and the time taken to infuse each dose. The infusion rate of the pump used in this study was 250 ml h^{-1}. If a pump capable of infusing at a faster rate had been used, then a faster onset time for sedation would have been achieved. However, this may have risked the patient being oversedated. No patient lost verbal contact and all patients were satisfied with their level of sedation. An initial bolus dose of drug was not administered because of individual patient requirements for depth of sedation.

The anaesthetist who carried out the intraoperative sedation assessment and the dentist were not blinded and this may have resulted in some bias of the intraoperative results but the anaesthetist who carried out the postoperative assessments was blinded to the agent used.

It must be stressed that although we were able to maintain verbal contact with all patients throughout the procedure, it is imperative that personnel skilled in airway management and resuscitation are present during sedation procedures. Equipment and drugs used for resuscitation must be at hand.

Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation†

A. MALLICK, S. N. SMITH AND A. R. BODENHAM

Summary

Patients in the intensive care unit require large doses of sedative/analgesic drugs to tolerate the presence of a tracheal tube and other unpleasant stimuli. The ideal regimen for sedatives and analgesics has not yet been found. We have investigated the effects of topical local anaesthesia to the pharynx and airway on sedative/analgesic requirements in 30 ICU patients (25–75 yr old) with no obvious brain injury, undergoing mechanical ventilation. Oral tracheal tubes were changed to a modified tube which allowed instillation of local anaesthetic solutions onto the pharyngeal, laryngeal and tracheal mucosa. Lignocaine 1% (5 ml) or 5 ml of 0.9% saline were instilled hourly for 12 h each for a total of 24 h, in a double-blind, randomized crossover design. Baseline sedation was maintained with propofol or alfentanil infusions, or both, which were titrated to patient comfort and to maintain an optimum sedation score throughout. Twenty-five patients completed the study. Mean total propofol and alfentanil requirements were 766 (SD 524) mg and 17 (7.6) mg, respectively, during 12 h of lignocaine instillation, and 1321 (862) mg and 25 (11.4) mg, respectively, during 12 h of saline instillation. There was a significant reduction ($P<0.05$) in the requirements for both agents during the period of lignocaine instillation. (*Br. J. Anaesth.* 1996; **77**: 731–734)

Key words

Anaesthetics local, lignocaine. Intensive care, sedation. Anaesthetics i.v., propofol. Anaesthetics i.v., alfentanil. Ventilation, artificial. Airway, mucosa.

Translaryngeal tracheal intubation is the standard technique for early airway management of patients requiring assisted ventilation. Most patients require anaesthesia or significant amounts of sedatives/analgesics to tolerate a tracheal tube for the first few days in the ICU.[1 2] This requirement is unimportant during surgery but is often a major drawback in patients requiring intensive care as these drugs often accumulate in the critically ill patient, and may increase the length of stay, morbidity and mortality.[3]

Tracheal intubation can be performed in awake patients using topical local anaesthesia to the airway in difficult intubation situations.[4] We were interested to determine if topical lignocaine delivered via a modified tracheal tube (LITA tube—laryngotracheal instillation of topical anaesthesia) to the pharyngeal, laryngeal and tracheal mucosa could improve comfort, and thereby reduce requirements of sedative and analgesic drugs in ICU patients. Topical lignocaine via an LITA tube has been reported to reduce the incidence of tracheal tube-induced coughing during emergence from general anaesthesia.[5] The use of this tube has not been described previously in patients requiring intensive care.

Patients and methods

After obtaining approval from the local Ethics Committee and written informed consent from the patients' relatives, we enrolled 30 patients (23 males) requiring ventilatory support in the ICU. We excluded patients requiring analgesia in the immediate postoperative period and those with obvious brain injury. Oral tracheal tubes were changed to an LITA tube of 8 mm id in females and 8.5 mm id in males (fig. 1) after administration of an i.v. bolus of propofol 0.5–1.5 mg kg^{-1} and atracurium 0.5 mg kg^{-1}. The study began 2 h later.

The LITA tube (Sheridan Catheter Corp., Argyle, NY, USA) differs from a conventional tracheal tube only in that it contains an additional small-bore channel incorporated into the wall of the lesser curvature of the tube (fig. 1). The proximal end of this channel has a Luer-lock syringe connector and has 10 small perforations on its distal segment. Local anaesthetic, injected under pressure, sprays the mucosa both proximal and distal to the inflated tube cuff. It is designed so that the spray of local anaesthetic deflects off the anterior wall of the larynx and trachea and by gravity runs down to bathe the entire circumference of the mucosa.

Syringes containing 5 ml of either 1% lignocaine or 0.9% saline were prepared by the hospital pharmacy. The authors and the nursing staff were blinded to the nature of the solutions.

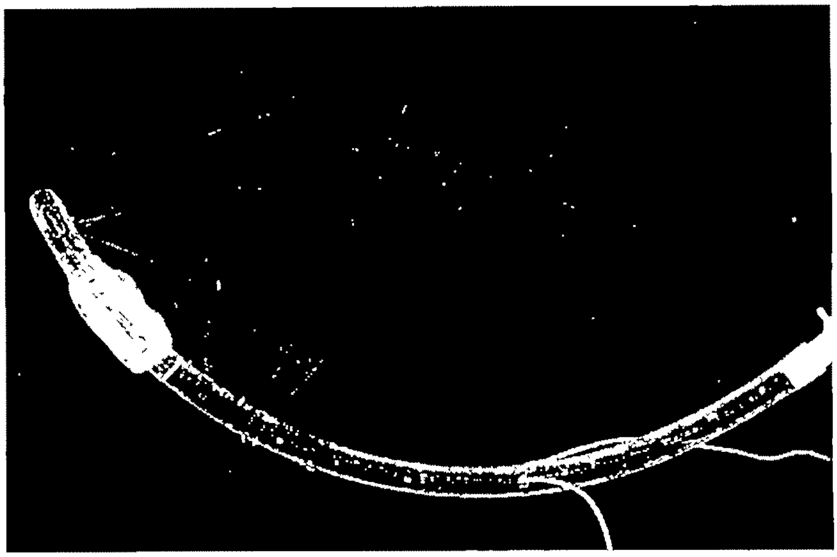

Figure 1 Local anaesthetic injected via the delivery channel of the the LITA tracheal tube exits through the holes in a fine spray both proximal and distal to the cuff.

Table 1 Sedation score

Level 1	= Patient restless, agitated or anxious, compromising ventilation and oxygenation, showing signs of distress on physiotherapy, tracheal suction, oropharyngeal suction and handling in general.
Level 2	= Patient awake but needs sedation for physiotherapy and other nursing or invasive procedures.
Level 3	= Patient just asleep, responds to speech and touch, needs additional sedation to cover handling and physiotherapy or any other procedures.
Level 4	= Patient asleep, handles well and tolerates care, showing response to speech and to touch by either squeezing the nurses hand or by blinking.
Level 5	= Patient asleep, has dull/sluggish response to any form of stimulation, for example tracheal suction
Level 6	= Patient asleep showing no sign of response to stimulation of any kind.

Randomization was carried out by the pharmacy according to a computer-generated table so that each patient received an hourly instillation via the LITA tube of either 1% lignocaine for the initial 12 h and saline for the ensuing 12 h or vice versa. Each patient acted as their own control. We chose the 1% lignocaine solution as we know that this acts on bronchial mucosa during fibreoptic bronchoscopy and we wished to avoid potential local anaesthetic toxicity from absorption of more concentrated solutions.

Sedation was maintained with baseline infusions of propofol 0.2–1 mg $kg^{-1} h^{-1}$ or alfentanil 10–20 μg $kg^{-1} h^{-1}$, or both. We chose these particular agents for their short duration of action and ability to rapidly titrate doses for a desired effect. The level of sedation was monitored hourly using a sedation scale (table 1) with six levels of cognitive neurological function, similar to the Ramsay sedation scale.[6] Monitoring of sedation and adjustment of propofol and alfentanil infusions to maintain a target score of 3–4 (table 1) were carried out throughout the entire study. If at any time sedation was assessed to be outside the target level, nurses achieved the target sedation levels either by administering additional boluses of either propofol 10 mg or alfentanil 200 μg or by altering the infusion rates. Episodes of coughing and gagging, desaturation (Sa_{O_2}<90%) and hypertension (increase in systolic arterial pressure >20% above baseline) were recorded during the study. Patients who were awake enough were questioned about the discomfort caused by the presence of the tracheal tube or by pulmonary suctioning. The paired *t* test in SPSS version for MS Window release 6.1 was used to assess statistical significance between sedation requirements during the different periods, and significance was taken at $P<0.05$.

Results

We studied 30 patients, aged 25–75 yr; the male:female ratio was 3.3:1. Patients were of a mixed group (table 2) and they had no significant organ dysfunction except respiratory failure. No problems were encountered during change of the tracheal tube to an LITA tube. Five patients were excluded from subsequent analysis because the study was not completed: in two of these the trachea was extubated, one after 3 h and a second after 8 h from the start of the study, one required neuromuscular block 5 h after the beginning of the study because of deterioration in oxygenation, one was transferred to another hospital and another developed bronchospasm during the period of saline instillation. Thirteen of the remaining patients received lignocaine instillations for the initial 12 h followed by 12 h of saline instillation. The remainder started with saline instillation. Eight patients received a propofol infusion, eight patients an alfentanil infusion and another nine patients received both concurrently during the study. The total amount of propofol and alfentanil used for each patient was recorded for the 12-h pre-study period, for lignocaine instillation and for the 12 h of saline instillation. Mean requirements of propofol and alfentanil are shown in table 3. There was a significant reduction (30–40%) in the requirements of both drugs during lignocaine instillation compared with the pre-study and saline periods. There was no significant difference between the requirements for

propofol or alfentanil in the pre-study and saline periods. We analysed a subgroup (table 3) of 13 COAD patients. Three received both a propofol and an alfentanil infusion, four a propofol infusion and another six patients received an alfentanil infusion during the study. This group was found to have a more marked reduction in requirements for propofol and alfentanil (40–50%).

Mean sedation scores during the 12 h before entering the study were 4–6 while a score of 3–4 was maintained during the study. Nine patients were awake and co-operative (sedation score of 2) during the study. They appeared to be less bothered by pulmonary suctioning during the period of lignocaine instillation compared with saline instillation. We noted that patients also tended to cough and were transiently restless in response to tracheal instillation of saline. No episode of desaturation ($Sa_{O_2}<90\%$) or hypertensive response (increase in systolic arterial pressure by more than 20% from baseline) was reported during periods of lignocaine or saline instillation.

Discussion

Patients undergoing mechanical ventilation are subjected to many noxious stimuli attributable to diagnostic, therapeutic and physical nursing interventions. The presence of a tracheal tube and frequent tracheal suctioning are very unpleasant. An optimal level of sedation is a fundamental requirement to facilitate delivery of ICU care. Although essential, sedation and analgesia in this group of patients produce many side effects; cardiovascular instability, delayed weaning from mechanical ventilation, impaired tolerance of enteral feeding, tolerance and withdrawal symptoms, and other complications of immobility.[3] These effects may persist because of accumulation of the parent drugs and their metabolites in critically ill patients.

Various strategies have been adopted to reduce sedative and analgesic requirements, and hence their side effects, without compromising patient comfort. These include tracheotomy, non-invasive ventilation, regional nerve block to wounds whenever appropriate, and synchronization of mechanical ventilation. Tracheotomy is generally claimed to be tolerated better in patients undergoing ventilation.[7 8] Non-invasive ventilation in patients with respiratory failure has a better outcome compared with intubation and conventional IPPV.[9] However, at the present time, most patients in the ICU require a tracheal tube in order to achieve adequate ventilation and provide access to the lower airway for removal of secretions.

In this study, we have demonstrated that propofol and alfentanil requirements were significantly lower (overall reduction 30–40%) during the period of hourly laryngotracheal instillation of lignocaine via an LITA tube than during the period of saline instillation. The results in a subgroup of 13 COAD patients showed more marked reduction in the total amount of sedatives during 12 h of lignocaine instillation. We believe this could be ascribed to the absence of any major stimuli (e.g. wounds) in these patients other than the tracheal tube and frequent tracheal suction.

During awake tracheal intubation and bronchoscopy, a higher concentration (4% or 10%) of local anaesthetic is used for airway anaesthesia. Lignocaine 1% instilled via an LITA tube has been shown to decrease the incidence of coughing and bucking during emergence from general anaesthesia.[5] A survey of the literature gives very little information on topical airway anaesthesia, including optimal choice of drug, dose and frequency of administration. This study was the first of its type and so we had to choose the doses empirically. We used 1% lignocaine to reduce potential lignocaine toxicity and to instill a larger volume (5 ml hourly) to allow spread throughout the tracheal and laryngeal mucosa. This would not have been possible with a smaller volume of 4% lignocaine.

We chose propofol or alfentanil, or both, as the sedative/analgesic agents in this study to allow rapid titration of the level of sedation when used as an i.v. infusion, either alone or in combination.[10] Propofol potentiates the analgesic effects of alfentanil and the latter potentiates the sedative action of propofol.[11] Infusion of alfentanil was used alone in eight patients who were haemodynamically unstable and propofol infusion was used alone in another eight patients in whom nasogastric aspirate was high and who showed intolerance to nasogastric feeding.

The patients' levels of sedation and anxiety were assessed using a six-point scale similar to the Ramsay sedation scale. Monitoring the degree of sedation in the ICU is inexact. However, the Ramsay scale is the most widely used scoring system in clinical studies in critically ill patients. This scale evaluates the patient either in the awake or asleep state but does not convey information on the quality of sedation. Other authors have commented on the need for a new validated tool and scale to measure the efficacy of sedation in the ICU.[12]

Saline may not be a true control as patients cough and become restless for a few minutes in response to its instillation. However, it did not increase the requirement of sedatives during the period of saline instillation compared with the pre-study period. Bronchospasm developed in one patient who had an acute exacerbation of COAD during the period of saline instillation and this may have been precipitated by the saline. Hence, we felt that it was reasonable to use saline as a control as otherwise it would have been difficult to carry out the study in a blinded fashion.

The total dose of lignocaine was 600 mg over 12 h. The dose of lignocaine used for treatment of ventricular arrhythmias is significantly greater[13] and we believe it is unlikely that toxicity would occur given the dose and duration of this study. Lignocaine is known to be absorbed rapidly from the tracheobronchial mucosa. We cannot exclude the effect of systemically absorbed lignocaine from our findings. However, studies investigating the effects of i.v. lignocaine as an antitussive and an agent to attenuate the cardiovascular response to intubation are inconclusive.[14 15] The short period of this study did not allow us to assess if tolerance to the local anaesthetic occurred. Local anaesthetics with a longer duration of action (e.g. bupivacaine) may be beneficial but there is a paucity of data on the mucosal use of such drugs.

Comparative effects of thiopentone and propofol on respiratory resistance after tracheal intubation

R. S. C. Wu, K. C. Wu, D. C. W. Sum and M. J. Bishop

Summary

To compare the effects of propofol and thiopentone on tracheal intubation-induced bronchoconstriction, 37 patients were allocated randomly to anaesthesia with either thiopentone 4 mg kg^{-1} followed by a 15-mg kg^{-1} h^{-1} continuous infusion or propofol 3 mg kg^{-1} followed by a 9-mg kg^{-1} h^{-1} continuous infusion. Intubation was facilitated by vecuronium 0.1–0.2 mg kg^{-1}. Respiratory system resistance (*R*rs) was measured by a CP-100 pulmonary function monitor, 5 min after intubation. The 5-min post-intubation *R*rs values were significantly lower in the propofol group (8.5 (SD 1.5) cm H_2O litre^{-1} s^{-1}) than in the thiopentone group (10.9 (3.2) cm H_2O litre^{-1} s^{-1}). Thirty minutes after commencing isoflurane–nitrous oxide anaesthesia, *R*rs declined by 17.5 (SEM 3.6) % from baseline in the thiopentone group, but by only 1.6 (2.6) % in the propofol group. We conclude that the dose of propofol administered provided more protection against tracheal intubation-induced bronchoconstriction than an induction dose of thiopentone. (*Br. J. Anaesth.* 1996; **77**: 735–738)

Key words
Anaesthetics i.v., propofol. Anaesthetics i.v., thiopentone. Intubation tracheal. Complications, bronchospasm.

Bronchoconstriction may occur after tracheal intubation[1–3] and occasionally may be severe enough to produce life-threatening decreases in gas flow. Because induction is the period of highest risk for bronchospasm it is important to identify induction agents which minimize the bronchoconstrictor response to tracheal intubation.

The effects of thiopentone on airway resistance remain controversial. Early studies indicated that thiopentone releases histamine and constricts airways.[4–6] However, thiopentone may also inhibit vagal reflexes,[7] and at higher concentrations produce bronchodilatation.[8] The effects of propofol on human bronchomotor tone are also inconclusive. There are studies reporting bronchospasm during propofol induction[9] but there are also some stating otherwise.[10] Mehr and Linderman, comparing the effects of propofol on peripheral airway responsiveness with the effects of thiopentone and halothane, showed that propofol afforded no benefit over thiopentone or halothane.[11] Cheng and colleagues recently found that *in vitro*, propofol did not produce smooth muscle relaxation.[12] However, a study comparing the incidence of wheezing in asthmatic patients induced by different i.v. anaesthetic agents found that fewer patients wheezed after receiving propofol compared with a barbiturate.[13]

The purposes of this study were to compare the effects of propofol and thiopentone on tracheal intubation-induced bronchoconstriction and to investigate how the addition of an inhalation anaesthetic further influences bronchomotor tone after intubation.

Patients and methods

This study was carried out with the approval of the Human Subjects Review Board of Chang Gung Memorial Hospital. All patients underwent surgery of the extremities and were of normal body habitus, ASA I or II.

After obtaining informed consent, 37 patients, aged 20–50 yr, were allocated to one of two groups. Induction was performed by an anaesthetist who did not participate in the study. The induction agent chosen was according to a random number design which was not revealed until the start of induction. The anaesthetist recording the resistance measurement was unaware of the medication used for induction. Anaesthesia in the thiopentone group was induced with thiopentone 5 mg kg^{-1} i.v. There was a variance allowed of 1 mg kg^{-1} depending on the response of the patient. Vecuronium 0.1–0.2 mg kg^{-1} was given to facilitate oral tracheal intubation using a 7.5-mm tube. After intubation, an i.v. infusion of thiopentone 15 mg kg^{-1} h^{-1} was started immediately to maintain an adequate anaesthetic level until the end of the study. Anaesthesia in the propofol group was induced with 2.5 mg kg^{-1} and a bolus dose of vecuronium followed by a continuous infusion of propofol 9 mg kg^{-1} h^{-1} for maintenance

of anaesthesia. Patients' lungs were ventilated with 100% oxygen using a Drager Narkomed II ventilator (North American Drager, PA, USA) at a tidal volume of 650 ml, an inspiratory flow rate of 0.6 litre s^{-1} with a rectangular wave pattern and a ventilatory frequency of 10 bpm. Mean end-tidal $P\mathrm{CO_2}$ was 4.6 kPa in the thiopentone and propofol groups. All patients were positioned supine.

Resistance of the respiratory system (*R*rs) was measured 2 and 5 min after intubation with a CP-100 pulmonary function monitor (Bicore, Irvine, CA, USA). The CP-100 pulmonary function monitor is a monitoring device consisting of a flow transducer (VarFlex) and an oesophageal balloon catheter which allows breath-by-breath measurement of tidal volume ($V\mathrm{T}$), airway flow ($\dot{V}$), transpulmonary pressure (airway − oesophageal pressure) and airway pressure (*P*aw). The flow transducer was connected to the ventilation system between the tracheal tube and the Y-piece. The oesophageal balloon catheter was left exposed to ambient pressure to measure *R*rs. Measurement of *R*rs was based on pressure and flow measurements in the airway. Resistance measurements were calculated using the isovolume method (the difference in airway pressure divided by the sum of the flows taken at the same volume during both inspiration and expiration)[14–17] and included resistance of the tracheal tube. The CP-100 monitor is equipped with self-diagnostic hardware tests which perform self-calibration of the measuring system.

After the 5-min period during which the patient received only the induction agent, inhalation anaesthesia was begun with 1.3% isoflurane and 50% nitrous oxide in oxygen, as monitored by end-tidal concentrations. Inspired concentrations of isoflurane were adjusted to 5% initially to achieve this end-tidal concentration as rapidly as possible and were then adjusted using the end-tidal monitor. Respiratory measurements were repeated 30 min after initiation of inhalation anaesthesia.

As secretions in the trachea may affect resistance data, the trachea was suctioned 1 min before every *R*rs measurement to remove any sputum that might influence the resistance measurement. Suctioning was performed with a 10-ml sputum trap attached between the suction catheter and the vacuum source. The total volume of mucus collected during the study was used to categorize patients *post hoc* into two groups: mucus producers (>1 ml) and non-mucus producers (<1 ml).

STATISTICAL ANALYSIS

Comparisons of differences between groups were made using the two-tailed Student's *t* test for unpaired data. Comparisons within groups between different times were made using analysis of variance (ANOVA) and comparisons within subgroups at different times using the Student's *t* test for paired data and Bonferroni's correction to identify specific differences. $P<0.05$ was considered significantly different.

Results

Patients were allocated randomly to one of two groups: propofol ($n=19$, mean age 29 (range 20–45) yr) and thiopentone ($n=18$, mean age 33 (20–49) yr) (table 1). Patients with a history of pre-existing chest disease were excluded. There was no correlation between mucus production and smoking.

Two and 5 min after intubation, *R*rs values were 8.5 (SD 1.5) cm H_2O litre^{-1} s^{-1} and 8.5 (1.4) cm H_2O litre^{-1} s^{-1} in the propofol group, respectively, but 10.9 (3.2) cm H_2O litre^{-1} s^{-1} and 11.0 (3.4) cm H_2O litre^{-1} s^{-1} in the thiopentone group (fig. 1) ($P<0.01$, Student's *t* test for the effect of the drug).

Thirty minutes after initiation of isoflurane–nitrous oxide anaesthesia, *R*rs had declined significantly (to 8.6 (SEM 1.3) cm H_2O litre^{-1} s^{-1}; $P<0.001$, Student's *t* test paired data comparing *R*rs after intubation and 30 min after inhalation anaesthesia) by a mean of 17.5 (3.6) % in the thiopentone group ($P<0.01$) compared with after intubation, but had declined (to 8.3 (1.0) cm H_2O litre^{-1} s^{-1} ; $P<0.002$, Student's *t* test) by only 1.6 (2.6) % in the propofol group (fig. 2) ($P<0.001$ for percentage decline of thiopentone *vs* propofol). *R*rs in the propofol group 30 min after initiation of inhalation anaesthesia did not differ from *R*rs after intubation.

In our 37 patients there was a clear difference in *R*rs between mucus and non-mucus producers. *R*rs

Non-mucus producers	11	8.6 (0.5)	7.9 (0.6)**
Propofol			
Mucus producers	5	10.2 (2.0)††	8.7 (0.9)**††
Non-mucus producers	14	8.0 (0.8)	8.1 (1.0)

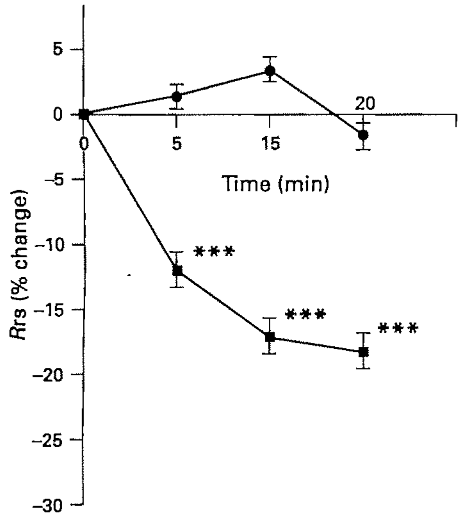

Figure 2 Percentage change in total respiratory system resistance (*R*rs) from baseline (5 min after intubation) to 5, 15 and 30 min after initiation of 1.3% end-tidal isoflurane–50% nitrous oxide after induction of anaesthesia with thiopentone (■) and propofol (●) (mean, SEM). ***$P<0.001$ *vs* propofol.

of mucus producers was significantly higher than non-mucus producers (Student's *t* test for unpaired, $P<0.01$) (table 2). *R*rs values were consistently high regardless of sputum volume among mucus producers suggesting that mucus production is a marker for hyper-reactivity in our patients.

Analysis of the subgroups, mucus *vs* non-mucus producers, demonstrated that propofol and thiopentone mucus producers had significantly higher *R*rs values at both 5 min after intubation and 30 min after initiation of inhalation anaesthesia than non-mucus producers. A significant reduction in *R*rs 30 min after initiation of inhalation was noted for thiopentone and propofol mucus producers together, in addition to thiopentone non-mucus producers, but not for propofol non-mucus producers.

For mucus and non-mucus producers, *R*rs 30 min after administration of the inhalation agent was not different between thiopentone and propofol.

Discussion

The important findings of this study were that compared with thiopentone, propofol attenuated the intubation-induced bronchoconstrictive response. Mucus production was a marker of airway reactivity. In patients with normal airways, propofol provided protection against the intubation-induced bronchoconstrictive response equivalent to 30 min administration of end-tidal 1.3% isoflurane–50% nitrous oxide anaesthesia. In mucus-producing patients however, propofol did not provide full protection but was still better than thiopentone.

We chose to use vecuronium because of the lack of histamine release,[18] and the lack of drug interaction between vecuronium and propofol.[19]

The isovolume method of measuring respiratory resistance used in this study includes the resistance of the tracheal tube. At the flow rates used with a 7.5-mm tracheal tube, this would have resulted in a consistent overestimation of resistance of approximately 4 cm H_2O litre^{-1} s^{-1}.[14] While the exact effect of the tracheal tube on the value depends on expiratory flows and would vary slightly from patient to patient, inter-patient variation would be very small. If the value of 4 is subtracted from all patients, the mean values for the propofol and thiopentone groups become 5 and 7 cm H_2O litre^{-1} s^{-1}, suggesting an approximate 40% increase in resistance if thiopentone is used for induction.

Although the Bicore pulmonary function monitor provides measurements of the resistance of the lung (R_L), *R*rs was used to study the response because of its reproducibility and simplicity of measurement, requiring only airway pressure and flow data. Supine position may influence oesophageal pressure readings and decrease accuracy, and technical difficulties because of oesophageal secretions and catheter movement may make measurements of R_L less reproducible. Under anaesthesia and neuromuscular paralysis, there is a correlation of 0.9998 between R_L and *R*rs in rabbits.[20] Given the inherent difficulties of the oesophageal catheter, *R*rs provides more reliable data. Therefore, we left the oesophageal catheter port of the Bicore open to air so that we measured *R*rs.

Our results suggesting a beneficial effect of propofol on the airways are consistent with several recent studies. Pizov and co-workers showed that the incidence of wheezing was significantly greater in asthmatic patients receiving a barbiturate for induction of anaesthesia than in patients receiving propofol.[13] However, they made no measurement of respiratory resistance. Cigarini and colleagues demonstrated that propofol prevented fentanyl-induced bronchoconstriction in surgical patients.[21] Pederson anecdotally reported that sedative doses of propofol inhibited postoperative bronchospasm in two patients with hyper-reactive airway disease.[22] Prien demonstrated that moving patients from the supine to the lithotomy position, airway impedance was unchanged for patients anaesthetized with propofol, but it increased significantly for patients anaesthetized with thiopentone.[23] Our objective findings after airway stimulation provide further evidence of a protective effect of propofol.

A secondary finding of the study was that a subgroup of patients had significant mucus production after intubation, and that the greatest increase in respiratory resistance occurred in this group of patients. Our finding agrees with others as mucus production has been shown previously to be a marker of airway irritation.[24] Production of 1 ml represents 10% of the normal daily production of the airways and appears to have been a marker for patients with more reactive airways. Among mucus producers, *R*rs 5 min after intubation was significantly higher in the thiopentone group than in the propofol group suggesting that propofol is significantly better than thiopentone in providing protection against the increase in airway resistance in these patients with more reactive airways.

Our finding that there was no correlation between mucus production and smoking agrees with the results in our previous study on the effects of fenoterol on the airway resistance response to tracheal intubation.[25]

Inhalation anaesthetics have been shown to cause bronchodilatation in a dose-related manner.[26 27] Our results in the thiopentone mucus and non-mucus producers confirmed this effect. The addition of end-tidal concentrations of 1.3% isoflurane–50% nitrous oxide after propofol produced a further slight decrease in the mucus producers (significant difference P=0.049 for two-tailed and 0.025 for one-tailed), but not in the non-mucus producers, suggesting that propofol provides bronchodilatation almost equivalent to that provided by inhalation anaesthetics. However, as the number of mucus producers studied was relatively small, interpretation of the decrease in *R*rs 30 min after inhalation anaesthesia for the propofol mucus producers must be made with caution. The magnitude of the additional bronchodilatation after isoflurane was relatively small, implying that even in mucus producers, propofol produced substantial protection.

Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics

W. HABRE, I. MATSUMOTO AND P. D. SLY

Summary

Propofol may cause histamine release and alter airway tone and reactivity. Although its use has been reported to be safe in asthmatics, there is a lack of information on its effect on lung function in children with asthma. We measured respiratory mechanics after i.v. or inhalation anaesthesia in 60 children, aged 2–12 yr, with or without asthma. Anaesthesia was induced with propofol 3 mg kg^{-1}, fentanyl 1 μg kg^{-1} and atracurium 0.5 mg kg^{-1} and maintained with an infusion of propofol 10 mg $kg^{-1}h^{-1}$ and 50% nitrous oxide in oxygen. Halothane was administered subsequently at a concentration of 1 MAC. Respiratory mechanics were measured by applying a single-compartment model using multi-linear regression analysis to calculate dynamic compliance (Crs,dyn) and respiratory system resistance (Rrs), based on: $P\text{ao} = V/C\text{rs,dyn} + \dot{V}\, R\text{rs} + P\text{A,EE}$, where Pao = airway opening pressure, PA,EE = alveolar pressure, V = volume and $\dot{V}$ = flow. The two groups were comparable in age, weight and ventilation variables (tidal volume and peak pressure). Respiratory mechanics during propofol anaesthesia were comparable in normal and asthmatic children (Rrs = 20.5×10^{-4} (SD 5.2×10^{-4}) *vs* 21.5×10^{-4} (5.7×10^{-4}) kPa ml^{-1} s^{-1} (ns) and Crs,dyn = 247.5 (76.5) *vs* 235.1 (63.8) ml kPa^{-1} (ns)). Halothane produced a minimal decrease in Rrs and a minimal increase in tidal volume in both groups without changes in Crs,dyn. In conclusion, respiratory mechanics were comparable after propofol anaesthesia in both children with and without asthma. Changes in Rrs after halothane administration were not clinically relevant. (*Br. J. Anaesth.* 1996; **77**: 739–743)

Key words
Anaesthesia, paediatric. Anaesthetics i.v., propofol. Anaesthetics volatile, halothane. Asthma. Ventilation, mechanics. Lung, mechanics. Lung, function.

With the worldwide increase in the prevalence of asthma[1–3] an increased number of asthmatics are likely to require anaesthesia for surgical procedures. As asthma is characterized by increased airway reactivity to different stimuli, the choice of anaesthetic technique should consider the increased risk of bronchospasm in children with asthma. Anaesthesia may induce changes in airway resistance, alter ventilation distribution, produce atelectasis and reduce lung volume,[4] any of which may result in hypoxaemia.

Propofol has several advantages for use in paediatric anaesthesia. It has been shown to reduce the incidence of airway obstruction at induction,[5] shorten recovery time and allow earlier discharge for outpatients,[6 7] and to reduce postoperative emesis.[8 9] However, propofol has been reported to induce histamine release in healthy[10] and atopic patients.[11] Excessive histamine release may provoke bronchoconstriction in asthmatic patients and would limit its usefulness in this group. While propofol has been reported to be safe in asthmatic patients,[12–14] there is a lack of information on its effect on lung function in asthmatics, particularly children. Objective lung function data are required before recommending the use of propofol in asthmatic children.

This study was designed to measure respiratory mechanics in children with asthma undergoing mechanical ventilation during (i) induction of anaesthesia with propofol and (ii) maintenance of anaesthesia with halothane in children with and without asthma. For practical reasons respiratory mechanics were measured during propofol anaesthesia first, followed by measurements during halothane anaesthesia.

Patients and methods

After obtaining institutional Ethics Committee approval and parental informed consent, we studied 60 children, aged 2–12 yr, undergoing elective surgery requiring general anaesthesia and mechanical ventilation. Based on the medical history during preoperative anaesthetic assessment, children were

classified as having asthma (children with a history of physician diagnosed asthma, stabilized under medical treatment before undergoing surgery) or not (children with normal lungs and no history of asthma, hay fever or allergies). Children with a history of upper respiratory infection within 4 weeks, and children with acute or chronic respiratory disease other than asthma were excluded.

All children had EMLA cream applied on both hands 1 h before surgery, and received oral midazolam 0.25–0.35 mg kg^{-1}, 30 min before induction of anaesthesia with propofol 3 mg kg^{-1} and fentanyl 1 μg kg^{-1}. Propofol was then continued at a rate of 10 mg kg^{-1} h^{-1} in the presence of 50% nitrous oxide in oxygen while respiratory mechanics were measured. A tracheal tube was inserted after administration of atracurium 0.5 mg kg^{-1}. The size of the uncuffed tracheal tube was chosen to avoid leak at the pressures encountered during mechanical ventilation. If a leak was detected around the tracheal tube, a throat pack was inserted or cricoid pressure was applied, or both, during measurements. The lungs were ventilated mechanically with a volume-controlled ventilator (Air-Shields Ventimeter Controller) and ventilatory frequency was titrated to achieve an end-tidal carbon dioxide concentration of approximately 4.6 kPa. After respiratory measurements were obtained during infusion of propofol, anaesthesia was subsequently maintained with 1% halothane and 50% nitrous oxide in oxygen.

The measurement equipment, consisting of a pressure port and transducer (Microswitch 142 PC01D) to measure airway opening pressure (Pao) and a pneumotach (Hans Rudolph Inc. K.C., MO, USA) to measure flow ($\dot{V}$) was placed between the patient's tracheal tube and the ventilator circuit. Pao and $\dot{V}$ signals were amplified (Applied Measurement, 022A), low- pass filtered (cut-off frequency 10 Hz, Applied Measurement, 043) and stored on computer. All data were collected and analysed using a data acquisition package (Anadat and Labdat, RHT Infodat, Montreal, Canada).

MEASUREMENT OF RESPIRATORY MECHANICS

Respiratory mechanics were measured during mechanical ventilation using well characterized methods.[15 16] Multi-linear regression analysis was used to calculate respiratory system compliance (Crs,dyn) and resistance (Rrs) from measurements of airway opening pressure (Pao), flow ($\dot{V}$) and volume (V) using the equation:

$$Pao = V/Crs,dyn + \dot{V}Rrs + PA,EE \qquad (1)$$

The constant term in equation (1) (PA,EE) reflects alveolar pressure.[17] Data were used only if the coefficient of determination (r^2) of this fit was > 0.98.

CORRECTION FOR GAS PHYSICAL PROPERTIES

Measurements of flow obtained from a pneumotachograph are influenced by the physical properties of the gas passing through. When using gases with different physical properties, one must correct for this effect. We used the principles applied by Johns, Pretto and Streeton[18] to determine the appropriate correction factor for the gas concentrations used in this study. Using a 100-ml syringe filled with the gas mixture used in each part of the study, 100 ml of gas were flushed through the pneumotachograph and the resulting flow integrated to produce a volume measurement. By repeating this manoeuvre 20 times with each gas mixture, the relevant correction factors were calculated and subsequently applied to the flows measured with the relevant gas mixture.

STUDY DESIGN

All measurements were completed in the anaesthetic induction room before surgical stimulation. After tracheal intubation and 5 min of steady state mechanical ventilation during infusion of propofol, a first set of three discrete 20-s epoch measurements were obtained. Infusion of propofol was then discontinued and anaesthesia was maintained with 1% halothane and 50% nitrous oxide in oxygen. An anaesthetic gas analyser (ICOR agent ANM 605) was used to determine when a steady state concentration had been reached. An expiratory halothane concentration of 0.7% (1 MAC) was achieved within 5–8 min. Measurements of respiratory mechanics were then repeated.

STATISTICAL ANALYSIS

A 20% difference in resistance (Rrs) between asthmatic and normal children, or a 20% change in Rrs with anaesthetic were considered clinically significant. Based on the intra-subject variability of Rrs, calculated using the multi-linear regression technique,[15 19] groups of 30 subjects have been shown to have 95% power to detect a 20% difference in Rrs between groups.

Comparisons between asthmatic and normal children were made using the unpaired two-tailed t test. Paired two-tailed t tests were used to compare changes in respiratory mechanics before and after administration of halothane. Statistical significance was accepted at the 5% level. Data analysis was performed using SPSS 6.1 for Windows. Data are presented as mean (SD).

Results

The two groups of patients were comparable in age, weight, sex and size of the tracheal tube (table 1). The different clinical patterns and treatment of asthma are shown in table 2. Seventeen of the asthmatic children had received a bronchodilator on the morning before admission to theatre. There was no significant difference in airway resistance between the asthmatic children who received bronchodilators

and those who did not (22.6×10^{-4} (SD 5.6×10^{-4}) *vs* 20.2×10^{-4} (5.7×10^{-4}) kPa ml^{-1} s^{-1}).

Ventilation variables were comparable between the groups. With the ventilator set to achieve an end-tidal carbon dioxide concentration of approximately 4.6 kPa, the lungs of the children were ventilated with a tidal volume of approximately 10 ml kg^{-1} and a frequency of 0.25 Hz, with an inspiratory–expiratory time ratio of 0.5 (table 3). There

Table 3 Ventilation variables measured 5 min after tracheal intubation during propofol infusion for maintenance of anaesthesia (mean (SD)). No significant difference between groups

were no significant differences between the two groups in airway pressure (peak pressure, mean pressure and end-expiratory pressure) and respiratory mechanics (dynamic compliance and resistance) (table 4).

During administration of halothane, in both groups there was a significant increase in tidal volume and a decrease in *R*rs, while *C*rs,dyn did not change (table 4). Both of these changes were small and not clinically significant. Furthermore, changes in tidal volume and respiratory mechanics were equivalent in both groups before and after administration of halothane. The decrease in airway resistance was comparable in asthmatic patients who had received bronchodilators in the morning and those who had not (7.4×10^{-4} (1.3×10^{-4}) *vs* 5.8×10^{-4} (1.2×10^{-4}) kPa ml^{-1} s^{-1}).

Discussion

We have found that respiratory mechanics were comparable in asthmatic and non-asthmatic children after induction of anaesthesia with propofol. Furthermore, changes during halothane anaesthesia were not clinically significant suggesting that propofol was not associated with any adverse effects in children with or without asthma.

This study provides information on respiratory mechanics in children with and without asthma, receiving routine induction of anaesthesia with propofol, followed by maintenance with halothane. This anaesthetic regimen mimics that which would

be used clinically in children, if propofol was shown to be safe in children with asthma. Ideally, we would have wished to obtain measurements of respiratory mechanics before and after propofol and before and after halothane. This design is impractical as propofol is given to induce anaesthesia. If anaesthesia was induced with a volatile agent, such as halothane, the presence of this agent would be likely to mask any changes caused by propofol. In addition, the design used in this study mimics the clinical situation in which these drugs are used. To circumvent our inability to measure respiratory mechanics before and after introduction of propofol, we compared results obtained in asthmatic and non-asthmatic children and after achieving a concentration of 1 MAC of halothane. If propofol produced bronchospasm in children, we would have expected to see a significant decrease in *R*rs after introduction of halothane. Similarly, if propofol had more adverse effects in asthmatic children, we would have expected to find a higher resistance in this group compared with the control, and a bronchodilator response with halothane. Neither of these patterns was seen.

Some reports have suggested that propofol causes histamine release in healthy[10] and atopic patients,[11] and may induce bronchospasm.[20 21] To our knowledge, there are no reports of respiratory mechanics after propofol anaesthesia in children. In this study, *R*rs was slightly higher in asthmatic children and this difference was found at all stages of the study but was not statistically significant. The difference in group means was small ($< 1.0 \times 10^{-4}$ kPa ml^{-1} s^{-1}) and not clinically significant. *C*rs,dyn was also slightly lower in the asthmatic group. These differences may have resulted from either differences in baseline lung function or greater propofol-induced histamine release in asthmatic children. In both cases the differences were too small to be considered important and suggest that the use of propofol is safe in children with asthma.

It has also been suggested that propofol causes greater bronchospasm when combined with another histamine-releasing substance such as atracurium,[22] which can induce histamine-release from mast cells.[23] All children in this study received propofol and atracurium at induction of anaesthesia. If histamine release was a significant clinical problem with either or both of these drugs, we might have expected a greater effect in asthmatic children as airway sensitivity to histamine is increased in asthmatics.[24] However, we did not observe any significant differences in ventilation variables or in respiratory mechanics between the two groups of children. These findings support a recent study in which it was found that atracurium 0.5 mg kg^{-1} had no clinically significant effects on the airways.[25]

Halothane produced small but consistent bronchodilatation in both groups and the decrease in *R*rs was similar in children with and without asthma. Previous studies have shown that halothane reduces airway resistance, primarily when increased by chemical agonists.[26 27] Most recently, 1 MAC of halothane has been found to dilate the airways of normal canine lungs without preconstriction.[28] These authors also showed that halothane does not exert any effect on lung tissue mechanical properties. While one must always be cautious in extrapolating data from animal studies to humans, our results are consistent with these findings as our single compartment model was sensitive enough to detect a mild but statistically significant decrease in *R*rs without any change in *C*rs,dyn. The decrease in *R*rs contributed to the mild increase in tidal volume which was not clinically significant.

While no changes in group mean lung function occurred, to ensure that no clinically important subgroup was missed, we examined the magnitude of the reductions in resistance occurring in individual children. A 10% decrease in resistance is the minimum that would be considered clinically significant and is well beyond the variability of our measurements. One non-asthmatic and four asthmatic children showed a reduction in resistance of 10% or more after introduction of halothane and no child had a change of 20%, demonstrating that the changes in resistance were not clinically significant.

In interpreting our data one must realize that we do not have measurements of absolute lung volume. If propofol caused bronchoconstriction this could be accompanied by an increase in functional residual capacity (FRC) (or less decrease in FRC than is usually produced by induction of anaesthesia). Under these circumstances the introduction of halothane would be expected to produce bronchodilatation and a reduction in FRC to the normal (anaesthetic) baseline. As airway resistance is volume-dependent, a decrease in FRC may result in an increase in resistance, masking the bronchodilator effect of halothane. We do not believe this possible scenario can explain our data for the following reason. As part of our multi-linear regression analysis of lung function, we produced a value for end-expiratory alveolar pressure (*P*A,EE in equation (1)). This measurement has been validated against direct measurements of alveolar pressure in animals.[17] End-expiratory alveolar pressure is determined by the elastic recoil of the lungs and chest wall at the absolute lung volume at which end-expiration occurs and by any externally applied positive end-expiratory pressure (provided sufficient expiratory time has been allowed for the lungs to empty to their "resting" volume). Thus *P*A,EE is dependent on absolute lung volume and can be used as a surrogate marker of end-expiratory lung volume, provided respiratory system compliance does not change. In this study, compliance did not change with the introduction of halothane and the mean change in *P*A,EE was 0.039 kPa for the non-asthmatic group and 0.017 kPa for asthmatics. These data strongly suggest that a change in lung volume did not occur with the introduction of halothane and that this potential confounder is not the reason that we did not see a significant reduction in airway resistance with halothane.

Among the different techniques used to measure dynamic respiratory mechanics that have been validated for use in children during anaesthesia, multiple linear regression techniques (MLR) are the most easily implemented.[15 16 19] During ventilation, MLR uses measurements of *Pao*, $\dot{V}$ and *V* throughout the entire respiratory cycle to calculate *Crs*,dyn and *Rrs*. We achieved consistently a good fit during mechanical ventilation ($r^2 > 0.98$). This good coefficient of determination suggests that the application of the single-compartment model for measurements of dynamic mechanics in our study is a good approximation of the mechanical properties of the respiratory system ventilated at a single frequency.

Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients

P. TIAINEN AND P. H. ROSENBERG

Summary

Subclinical disturbance in hepatocellular integrity, indicated by glutathione transferase Alpha (GSTA), has been associated with halothane, sevoflurane and propofol, but not with isoflurane anaesthesia. We anaesthetized 82 patients with isoflurane or halothane at 1 MAC for superficial surgery. GSTA concentration were measured with a sensitive time-resolved immunofluorometric assay in serum samples. GSTA concentrations increased from a baseline value of geometric mean 1.8 μg litre^{-1} (95% confidence intervals 1.4–2.2 μg litre^{-1}) to a peak of 4.3 (3.3–5.7) μg litre^{-1} in the isoflurane group and from 2.1 (1.6–2.9) μg litre^{-1} to 6.2 (4.1–9.5) μg litre^{-1} in the halothane group. The change in GSTA was significant within groups but the difference between groups was not significant. Two patients exhibited an unexpectedly large increase in GSTA (peaks 370 and 620 μg litre^{-1}) and a mild increase in alanine aminotransferase after halothane anaesthesia. We conclude that hepatocellular integrity was mildly disturbed after isoflurane and halothane anaesthesia but there was no difference between anaesthetics. Halothane anaesthesia may be associated with more advanced hepatocellular disturbance in some cases. (*Br. J. Anaesth.* 1996; **77**: 744–747)

Key words
Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane. Enzymes, glutathione transferase. Liver, function. Liver, hepatotoxicity.

Disturbance in hepatocellular integrity indicated by a sensitive marker, glutathione transferase Alpha (GSTA), has been noted after halothane,[1–3] sevoflurane[3] and propofol[4] anaesthesia, but not after isoflurane anaesthesia.[1 2] There is some disagreement between studies which used an enzyme immunoassay or a time-resolved immunofluorometric assay for GSTA measurements after sevoflurane[3 5] and propofol[4 6] anaesthesia. For example, the enzyme immunoassay kit does not appear to be sensitive enough to detect small changes in serum concentrations of GSTA.[7] In addition, because of the relatively short half-life of GSTA in serum (56 min),[8] GSTA should be assayed in samples collected at short intervals. This has not been the case in several recently published studies involving anaesthesia and GSTA where no samples were obtained for several hours after the end of anaesthesia.[2 5 6] Therefore, we have attempted to confirm the reported differential influence of isoflurane and halothane anaesthesia on hepatocellular integrity by using a new, sensitive, time-resolved immunofluorometric assay for GSTA[9] and short sampling intervals.

Patients and methods

The study was approved by the Ethics Committee of the Surgical Hospital, Helsinki University Central Hospital. Informed consent was obtained from all patients. We studied 82 patients, aged 22–64 yr, with a body mass index (BMI) <30 kg m^{-2} (weight × height^{-2}) undergoing superficial surgery during general anaesthesia lasting at least 2 h (table 1). Exclusion criteria were patients with known liver disease or a history of heavy alcohol consumption, those with hyperthyroidism or receiving thyroxine medication, those receiving medication likely to affect the liver, and those who were suspected to have had an adverse anaesthesia-related effect after a previous inhalation anaesthetic. Administration of paracetamol or corticosteroids was not allowed within 3 days before or during the study.

Patients were allocated randomly to one of two groups of 41 patients each, to receive either isoflurane or halothane anaesthesia. Premedication comprised oral diazepam, approximately 0.2 mg kg^{-1}. Glycopyrronium 0.2 mg, fentanyl 3 μg kg^{-1}, thiopentone 3–6 mg kg^{-1} and vecuronium 0.1 mg kg^{-1} were given during induction of anaesthesia. After tracheal intubation, normocapnia was maintained with mechanical ventilation using oxygen-enriched air ($F\text{I}_{O_2}$=0.35) without positive end-expiratory pressure. Anaesthesia was maintained with isoflurane at an expiratory concentration of 0.8%, which was 0.68 (SD 0.04) MAC (age-corrected mean) or 0.5% halothane, which was 0.65 (0.03) MAC, for 30 min. Thereafter, isoflurane was maintained at 1.2%

(1.02 (0.05) MAC) or 0.75% halothane (0.98 (0.04) MAC), until the end of anaesthesia. Small increments of fentanyl 0.05–0.1 mg were given if heart rate or arterial pressure increased. Nitrous oxide (FI_{N_2O}=0.65) was added if a patient expressed clinical signs of inadequate anaesthesia after fentanyl increments. If neuromuscular block was needed, it was maintained with increments of vecuronium 1 mg and antagonized with neostigmine 2 mg and glycopyrronium 0.4 mg. Inspiratory and expiratory concentrations of isoflurane and halothane were monitored continuously (Capnomac Ultima, Datex, Helsinki, Finland). Other monitoring included non-invasive arterial pressure every 5 min and continuous electrocardiography, pulse oximetry, and inspiratory and expiratory P_{O_2} and P_{CO_2} (Capnomac Ultima and Cardiocap, Datex, Helsinki, Finland). Haemodynamic state was characterized by calculating the mean of systolic arterial pressure and heart rate during anaesthesia. The threshold of hypotension was defined as systolic arterial pressure 85 mm Hg, and the degree of hypotension was calculated as the area under the curve (AUC) of hypotension. Hypotension was defined as an AUC value of >100 mm Hg min. Hypotension was managed by increasing the rate of fluid administration and if nitrous oxide was administered, it was discontinued (two patients in each group). After anaesthesia, patients were observed for 3 h in the post-anaesthesia care unit and thereafter on the ward. After operation, oxycodone 0.07 mg kg^{-1} i.v. or 0.14 mg kg^{-1} i.m. was given when a patient requested pain medication.

SAMPLES AND LABORATORY ANALYSIS

Peripheral venous blood was obtained before anaesthesia (baseline), hourly during anaesthesia, and 0, 1, 3, 6 and 24 h after the end of anaesthesia. Serum was stored at −20 °C, that is at a temperature which we have found to conserve the antigenic integrity of GSTA for an immunoassay.

GSTA concentrations were measured with a time-resolved immunofluorometric assay according to a standard assay procedure, except that the Eu^{3+} label was incubated for 3 h.[9] Samples from each patient were analysed in one assay cycle. The detection limit of the assay was 0.03 μg litre^{-1} and the measuring range was 0.3−1000 μg litre^{-1} at 10-fold serum dilution. Mean intra-assay and inter-assay coefficients of variation (CV) were 4.5–5.4% and 11.3–17.0%, respectively.[7] The reference ranges of GSTA were 0.7–6.0 μg litre^{-1} and 0.7–14 μg litre^{-1} for females and males, respectively.[9]

Baseline concentrations of alanine aminotransferase (ALT), aspartate aminotransferase (AST), glutamyl transferase and bilirubin were measured in routine hospital laboratory tests in serum samples obtained before anaesthesia. The detection limits for AST and ALT were less than 5 iu litre^{-1} and the inter-assay CV was 2.2–3.6%. ALT and AST were also measured 24 h after the end of anaesthesia.

STATISTICAL ANALYSIS

The skewed distributions of GSTA concentrations and aminotransferase activities were normalized by logarithmic transformation. Changes were compared between groups and at successive times using repeated measures analysis of variance (ANOVA). Student's *t* test was used for comparison of the peak and area under the concentration curve (AUC) values between the groups on a logarithmic scale. Systat software was used in computing.[10] For power analysis, GSTA concentration >66% above or >40% below the reference was considered as clinically significant, that is 0.22 on $\log_{10}$ scale. The SD values of GSTA concentrations were predicted to be 0.3 on $\log_{10}$ scale. Forty-one patients in both groups were required for a power of 90% at α=0.05 or 36 patients for 85%, respectively.[11]

Results

Results from 75 patients were analysed (38 in the isoflurane group and 37 in the halothane group). Six patients were excluded because the baseline GSTA concentration was higher than the upper limit of the reference range, and one patient because she underwent re-operation because of bleeding. Patients in the isoflurane and halothane groups were comparable in sex distribution, age, height, weight, BMI, type of surgery and incidence of malignancy (table 1). Peroperative bleeding was 500 ml or less, except in four patients in the isoflurane group (600–1100 ml) and in five patients in the halothane group (600–1600 ml). Duration of anaesthesia and need for fentanyl, nitrous oxide, vecuronium and neostigmine were similar in both groups (table 2). Mean values for arterial pressure were the same in both

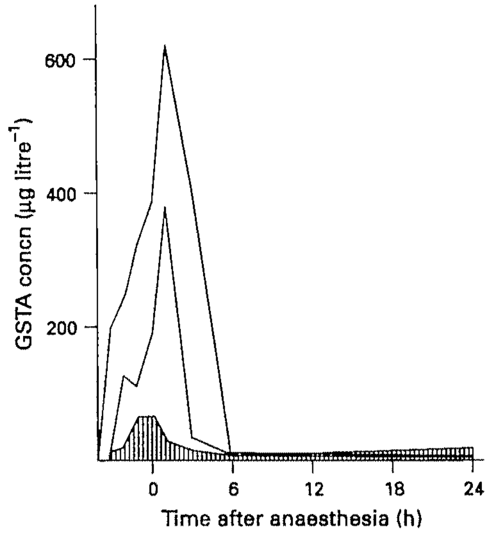

Figure 1 GSTA concentrations in serum. Lines indicate GSTA concentrations in two patients who exhibited an unexpectedly large increase in GSTA after halothane anaesthesia. Hatched area contains all GSTA concentrations in the other 73 patients, including a secondary increase in one patient 24 h after isoflurane anaesthesia.

groups, but heart rate was higher in the isoflurane group (table 2).

Seven patients in the isoflurane group and eight patients in the halothane group were hypotensive during anaesthesia. AUC values of hypotension ranged from 110 to 790 mm Hg min (median 290 mm Hg min) in the isoflurane group and from 100 to 450 mm Hg min (median 220 mm Hg min) in the halothane group.

GSTA concentrations varied in the isoflurane and halothane groups at successive times ($P<0.001$, repeated measures ANOVA). GSTA concentrations were significantly ($P<0.01$) higher than baseline from 2 h after induction to 3 h after the end of anaesthesia in both groups. In the isoflurane group, GSTA concentration was less than baseline at 6 and 24 h after the end of anaesthesia ($P<0.01$) (table 3). There were no significant differences in GSTA concentrations between the isoflurane and halothane groups during the study. Neither the peak nor AUC of GSTA differed significantly between the isoflurane and halothane groups (table 3). There were nine patients in the isoflurane group and 12 patients in the halothane group with peak GSTA values above the reference range during or immediately after anaesthesia. One patient exhibited an unexplained secondary increase in GSTA from 1.4 to 19.1 µg litre^{-1} at 24 h after isoflurane anaesthesia.

The peak concentration of GSTA (geometric mean) was 4.7 (95% confidence interval 3.4–6.6) µg litre^{-1} in hypotensive patients and 5.3 (3.9–7.2) µg litre^{-1} in normotensive patients (ns). The corresponding results for AUC were 5.3 (2.4–11.8) µg litre^{-1} h and 7.4 (4.8–11.5) µg litre^{-1} h (ns), respectively. The increase in GSTA was not associated with the addition of nitrous oxide, duration of anaesthesia (<180 min *vs* ≥180 min), type of surgery, malignancy, peroperative bleeding (<500 ml *vs* ≥500 ml), age (<40 yr *vs* ≥40 yr), sex or BMI (<23 kg m^{-2} *vs* ≥23 kg m^{-2}) when the peak and AUC values of GSTA were compared by *t* test and the successive GSTA concentrations with repeated measures ANOVA with one grouping factor (each of those mentioned above) or two grouping factors (volatile anaesthetic and each of those mentioned above).

Two patients (aged 46 and 53 yr; BMI 27.0 and 27.3 kg m^{-2}) exhibited an unexpectedly large increase in GSTA during and after halothane anaesthesia for surgery of breast cancer (fig. 1). There was a rapid decrease in GSTA to the reference range after anaesthesia in these two patients. No other signs or symptoms except for an increase in ALT (from 25 to 50 iu litre^{-1} and from 17 to 121 iu litre^{-1}) were observed and no obvious reason for the increase in GSTA was evident. Both patients recovered normally and ALT, AST, glutamyl transferase, bilirubin and GSTA concentrations were within reference ranges in control samples approximately 1 yr later.

There was a minor decrease in aminotransferase activities (table 4), but no significant difference between groups. There were no clinical signs or symptoms of hepatic disorder in any patient.

Discussion

We found a small, short-lasting increase in GSTA concentrations in serum after isoflurane and halothane anaesthesia. This indicated a mild subclinical disturbance in hepatocellular integrity.[1] The mechanisms of the hepatic effect are unclear. Hypotension, nitrous oxide, duration of anaesthesia, type of surgery, malignancy, bleeding, age, sex or BMI were not associated with the increase in GSTA. An unexplained secondary increase in GSTA without significant primary peak in the isoflurane group was similar to that described in previous studies.[1 2 4]

The lack of difference in GSTA between isoflurane and halothane contrasts with the results of earlier studies.[1 2] Compared with the study of

Murray, Rowlands and Trinick,[2] we exposed younger patients (mean age 41 *vs* 59 yr) to lower concentrations of inhalation anaesthetics (1.0 *vs* 2.0 MAC) for shorter intervals (mean duration 3.2 *vs* 10 h). In their study,[2] aspartate aminotransferase activity increased to 110 iu litre^{-1} (mean) 48 h after anaesthesia, which suggests more advanced disturbance in hepatocellular integrity than in studies without any increase in aminotransferases.[1 3] The relatively insensitive enzyme immunoassay for GSTA used by Murray, Rowlands and Trinick,[2] and infrequent sampling after anaesthesia may be the reason why there was no change in GSTA concentration after isoflurane anaesthesia.

The discrepancy between our study and that of Hussey and colleagues[1] is unclear. Patients with recent exposure to halothane (within 6 months) were not included in either study but differences in earlier exposure to halothane could be a confounding factor. We speculate that differences in the concentrations of inhalation anaesthetics and ventilation mode may explain why Hussey and colleagues[1] obtained higher GSTA concentrations after halothane than after isoflurane anaesthesia. The concentration of volatile anaesthetic was standardized (about 1.0 MAC) in our study. Ventilation was controlled mechanically and normoventilation was achieved by monitoring end-tidal $P\text{CO}_2$. In contrast, in the study of Hussey and colleagues,[1] the inspiratory concentration of volatile anaesthetic varied (1.0–3.0% isoflurane and 1.0–1.5% halothane in oxygen–nitrous oxide) and ventilation was spontaneous.

There is substantial evidence that immunological mechanisms may cause delayed hepatic injury after halothane anaesthesia (halothane hepatitis).[12] However, the time course of the changes in GSTA in our study did not indicate immunological mechanisms. Very deep anaesthesia is deleterious to the hepatic circulation.[13] This effect is more pronounced with halothane than with other anaesthetics, but the differences are small at 1 MAC concentration.[13] The direct toxicity of halothane on hepatocytes under hypoxic conditions or glutathione depletion could also cause liver injury, but in a recent well-controlled study[14] the authors rejected these mechanisms.

It would be tempting to implicate halothane as the cause of the unexpectedly large increase in GSTA in two of our patients after halothane anaesthesia. However, we found no mechanism to explain the relatively large changes in GSTA. Neither of these patients used any medication nor had any other known disease except breast cancer. They were not hypotensive during anaesthesia. Both had been anaesthetized twice, 1–22 yr before the present anaesthetic. A volatile anaesthetic (isoflurane) had been administered in one of the previous anaesthetics.

By using a sensitive immunoassay for measurement of serum concentrations of GSTA, we have previously detected small increases in GSTA after halothane,[3] sevoflurane[3] and propofol[4] anaesthesia. This study showed that hepatocellular integrity appeared to be disturbed to a similar degree during general anaesthesia with isoflurane or halothane at 1.0 MAC concentration. However, in two patients halothane anaesthesia was associated with large increases in serum concentrations of GSTA with minor increases in ALT. The significance of this is not clear.

Acknowledgements

We are grateful to associate professor Kimmo K. Karhi, PhD, Division of Biochemistry, Department of Biosciences, University of Helsinki, for GSTA assays. We thank Ms Annika Puustinen, MSci, and Mr Jouko Pettersson, MSci, for skilful technical help in GSTA assays. This work was partly supported by a grant from Abbott-Finland.

Standardization of non-invasive impedance cardiography for assessment of stroke volume: comparison with thermodilution

H. H. WOLTJER, H. J. BOGAARD, G. J. SCHEFFER, H. I. VAN DER SPOEL,
M. A. J. M. HUYBREGTS AND P. M. J. M. DE VRIES

Summary

Since its introduction by Kubicek and colleagues, impedance cardiography has been suggested as a non-invasive, simple, safe and cost-effective method of measuring stroke volume. Several controversial reports on its validity have been published. Pitfalls of this method included the nature of the electrode system and the validity of the equations. Therefore, the purpose of this study was to compare two different spot electrode arrays and the two most frequently used stroke volume equations with each other and with thermodilution. In 37 patients, 24–36 h after cardiac surgery, we performed simultaneous measurements of stroke volume with impedance cardiography (SV_{IC}) and with thermodilution (SV_{TD}). SV_{IC} was obtained using the lateral spot (LS) electrode array, according to Bernstein, and a newly proposed modified semi-circular (MSC) spot electrode array. The equations of Kubicek and Sramek–Bernstein were used to calculate SV_{IC}. The Sramek–Bernstein equation was valid only when the LS array was used; the Kubicek equation determined SV_{TD} correctly only when the MSC array was used. However, a considerably better correlation and agreement (mean difference (2 SD)) was found between SV_{IC} and SV_{TD} for the latter ($r = 0.90$, 0.5 (17.1) ml *vs* $r = 0.64$, −4.9 (31.8) ml for the Sramek–Bernstein equation). We conclude that the most valid measurement of stroke volume using impedance cardiography was obtained when the MSC array was used together with Kubicek's equation. (*Br. J. Anaesth.* 1996; **77**: 748–752)

Key words
Measurement techniques, impedance cardiograpy. Measurement techniques, thermodilution. Monitoring, stroke volume. Model, mathematical.

The technique of impedance cardiography (IC) has gained popularity as a low-cost, simple, safe and non-invasive method of monitoring cardiac function. As a measure of cardiac systolic time intervals, its validity has received strong support.[1 2] However, as a method of monitoring stroke volume (SV), for which it has attracted the most interest, IC remains a controversial method.[3–6] One of the pitfalls of this method may be the substantial degree of methodological diversity that exists in the use of IC.

Impedance cardiography was introduced into clinical practice by Kubicek and colleagues[7 8] using their proposed equation and band electrode array. However, the band electrodes are not practical for use; they are difficult to apply correctly and uncomfortable for the patient, particularly in the intensive care unit.[5] New electrode arrays were introduced using disposable spot electrodes. The spot electrode array most frequently used now is the eight spot electrode array according to Bernstein.[9] Bernstein also introduced a new equation, based on the findings of Sramek, Rose and Miyamoto[10] to calculate stroke volume from the impedance cardiogram at the same time. This resulted in several studies comparing the Kubicek and Sramek–Bernstein equations.[11 12] However, apart from incidental notes, no reports have been published in which replacement of the band electrodes by the eight spot electrodes has been evaluated. Therefore, we compared recently the band electrode array according to Kubicek and colleagues and the eight spot electrode array according to Bernstein.[9] From this study we concluded that with the latter, significantly different information was obtained. Furthermore, it was shown, in an additional study,[14] that the eight spot electrode array generated a less homogeneous electrical field, which is one of the essentials for IC. In addition, a new spot electrode array was proposed which generates a far better homogeneous electrical field and produces the same information as the original band electrode array. These studies were performed in healthy subjects.

In this study we evaluated measurement of SV with IC, using the newly proposed spot electrode array, after coronary bypass surgery. This array was compared with the standard Bernstein array and combined with both the Kubicek and the Sramek–Bernstein equations.

Patients and methods

We studied 40 patients, all 70 yr or less, undergoing coronary bypass surgery. The number of coronary bypasses during surgery varied from 1 to 6. Patients were excluded if they were haemodynamically unstable, showed cardiac arrhythmias or if there were variations in the separate thermodilution cardiac output measurements of more than 15% of the mean.

The study was approved by the institutional Human Ethics Committee and all patients gave informed consent.

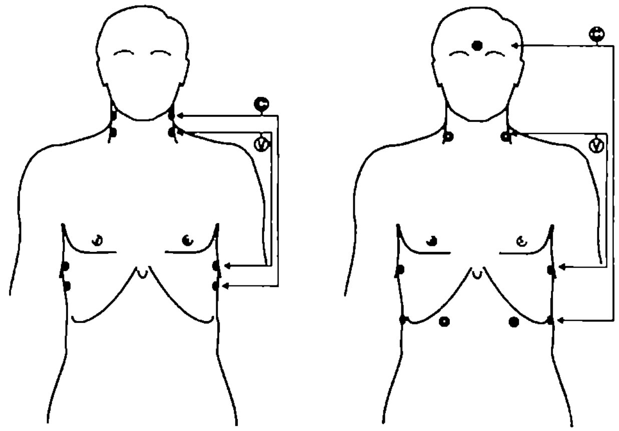
IMPEDANCE CARDIOGRAPHY

All impedance measurements were performed with the IPG-104 impedance Mini-Lab (RJL, Systems, Detroit, USA and Sanofi Sante, Maassluis, The Netherlands). The impedance cardiogram (d*Z*) and its first derivative (d*Z*/d*t*) were recorded in each patient using two different electrode configurations: an eight spot electrode configuration and a nine spot electrode configuration (fig. 1). The eight spot electrode configuration, as proposed originally by Bernstein,[9] uses four voltage detecting electrodes: two on each lateral site in the base of the neck and two on each lateral site of the thorax. Another four current ejecting electrodes are applied: two 5 cm above and two 5 cm below the voltage detecting electrodes in the neck and on the thorax, respectively. According to Sramek, Rose and Miyamots[10] the recommended distance between the voltage measuring electrodes is 17% of a person's height. In order to standardize the distance between the voltage detecting electrodes and exclude any anatomical abnormalities of the xiphisternum, this percentage was calculated and used as distance in order to place the caudal voltage electrodes on the thorax.

The nine spot electrode configuration (modified semi-circular (MSC) array) uses the same voltage detecting electrodes as the eight spot configuration. However, five current injecting electrodes are applied: one placed on the forehead of the patient and four in a semi-circular manner low on the abdomen: two in the mid-axillary lines and two in the mid-clavicular lines, all 15 cm caudal from the voltage detecting electrodes on the thorax. This array was developed recently in our laboratory. Measurements using the MSC array were comparable with those performed with the original band electrode array in a former study by our group.[14]

In each array, electrodes in one horizontal level were connected electrically and a sinusoidal current at 0.8 mA RMS and 60 kHz was passed between the cranial and caudal current injecting electrodes, and the resulting voltage was measured between the inner pairs. As current strength was known, impedance could be calculated.

Simultaneously with the impedance recordings, lead I of the ECG was recorded. All data from the impedance cardiograph and the ECG were stored digitally and averaged using our data acquisition system. From the averaged signal, left ventricular ejection time (LVET) was determined manually, as described by Lababidi and colleagues[15] and maximum impedance change (d*Z*/d*t*max) was measured from baseline (zero).



Lateral spot electrode array

Modified semi-circular electrode array

Figure 1 Spot electrode configurations, as used in this study, where C = current injecting electrodes and V = voltage measuring electrodes. The spot electrodes at one horizontal level are always electrically connected.

CALCULATIONS

For calculation of SV from the impedance cardiogram (SV_{IC}), impedance signals of 20 heart beats were averaged according to Kim, Song and Lee[16] in order to eliminate the effect of respiration.[17] In this way highly reproducible data can be obtained.[18]

SV_{IC} was calculated according to the equation of Kubicek and colleagues,[7 8]

$$SV = \rho \times (l^2/Z_0^2) \times dZ/dt\text{max} \times LVET$$

where SV = stroke volume (ml), ρ = resistivity of blood (Ω cm) calculated from the packed cell volume (PCV) according to Geddes and Sadler[19] and Hill and Thompson[20], l (cm) = inner distance between the voltage detecting electrodes (as calculated previously as 0.17 times a person's height), Z_0 = baseline thoracic impedance (Ω) read directly from a digital display on the impedance cardiograph, d*Z*/d*t*max = maximum rate of change of impedance during systole ($\Omega\ s^{-1}$) and LVET = left ventricular ejection time (s).

In addition to the equation of Kubicek and colleagues, the Sramek–Bernstein equation was also used to calculate SV_{IC}[9 10]

$$SV = \sigma \times (l^3/4.25)/Z_0 \times dZ/dt\text{max} \times LVET$$

where σ = a dimensionless weight correction factor according to Bernstein.[9] Both calculations were performed for each electrode configuration for each patient.

/

THERMODILUTION

A pulmonary artery catheter (Baxter/Edwards, Irvine, USA) was inserted in the perioperative period via the right internal jugular vein. Saline 0.9% (10 ml) with a temperature of 5 °C was injected manually with a closed injection system. The moment of injection of saline was chosen randomly. Stroke volume (SV_{TD}) was calculated automatically using a stroke volume computer (Marquette electronics Inc., Milwaukee, WI, USA). This procedure was repeated four times; the average of these four measurements was taken as SV_{TD}. All separate SV_{TD} measurements had to be within 15% of their mean, otherwise measurements were rejected and the patient was withdrawn from the study.

All measurements were performed 24–36 h after the coronary bypass operation. At the time of measurements all patients were breathing spontaneously. The sequence of the electrode configurations was chosen randomly.

STATISTICAL ANALYSIS

Linear regression analysis was performed to describe the relation between SV_{IC}, as calculated by each of the equations, and SV_{TD} for each electrode configuration. The paired Student's *t* test was used to compare data from both arrays. The level of statistical significance was set at $P < 0.05$. Bias plots according to the principles detailed by Bland and Altman[21] were also drawn.

Data were analysed for the whole group and separately for the two sexes.

Results

After exclusion of three patients because of large variations in the four SV_{TD} values obtained, SV measurements of 37 patients were evaluated; 28 men (mean weight 81.0 (SD 9.9) kg, *l* 30.0 (1.3) cm, PCV 30.5 (2.7) %, age 59.9 (range 41–72) yr) and nine women (weight 71.0 (9.4) kg, *l* 28.1 (0.8) cm, PCV 28.8 (2.9) %, age 63.3 (45–78) yr).

There were no significant differences in LVET between measurements from both electrode arrays. Using the LS array, we found a significantly higher Z_0 compared with the MSC array in both men and women (table 1). Only in men was dZ/d$t$max significantly lower with the LS array.

SV_{IC} did not differ significantly from SV_{TD} when the LS array was used together with the Sramek–Bernstein equation or when the MSC array was used in combination with the Kubicek equation to calculate SV_{IC} (table 2). Other combinations of electrode arrays and equations always led to a significant difference between the two methods. These findings were similar for both men and women.

impedance cardiography together with the MSC electrode configuration.

Discussion

In this study we obtained impedance measurements with two electrode configurations: the LS array and the MSC array. SV_{IC} was calculated using the Kubicek and Sramek–Bernstein equations and all SV_{IC} values were compared with the respective SV_{TD} measurements. As mentioned previously it has been shown in a recent study by our group[14] that measurements obtained with the MSC array are comparable with those made with the original band electrode array.

Although d*Z*/d*t*max was significantly lower with the LS array in men, the main difference between the measurements from both arrays was in the determination of Z_0. This difference was the main cause of the varying results in the calculation of SV_{IC}. Independent of the equation, SV_{IC} was always significantly lower with the LS array than with the MSC array. The difference in Z_0 between measurements from both arrays cannot be considered as a trend between both arrays; independent of the equation used to calculate SV_{IC}, the correlation coefficients between SV_{IC} and SV_{TD} were considerably lower, in general, for the LS array. This finding may be explained by the fact that the LS array generates a less homogeneous electrical field,[14] indicating that Z_0 values between patients were not comparable. The MSC array, however, generates a far better homogeneous electrical field.[14]

The Kubicek equation showed considerably better correlation coefficients and a better agreement between SV_{IC} and SV_{TD} compared with the Sramek–Bernstein equation. It is remarkable how the Sramek–Bernstein equation appeared to be valid only when the LS array was used, and the Kubicek equation calculated SV_{TD} accurately only when the MSC array was used. In our opinion, this may be caused by the different use of Z_0 and l in both equations.

The best results were found when the Kubicek equation was used together with the MSC electrode array. However, despite the good correlation coefficient between SV_{IC} and SV_{TD} ($r = 0.90$), the Bland and Altman relation revealed that the difference in stroke volume between the two techniques could approach 17 ml. This indicates an error of up to 25% for an actual stroke volume of 70 ml. However, it is important to emphasize that this is also a result of the inaccuracy of the reference method used in this study (thermodilution[22]).

Data were analysed separately for both sexes. It is known that in women, higher Z_0 values are found together with a relative increase in d*Z*/d*t*max.[23 24] However, the effect of this difference between men and women on calculation of SV_{IC} has never been evaluated in comparison with thermodilution. Although only nine women were enrolled in this study, there was no evidence that SV_{IC} was calculated inaccurately in women.

We cannot comment on the validity of IC in the determination of stroke volume changes, as each point in figure 2 relates to a single individual. Further work is needed to determine the validity of the impedance cardiographic technique in the measurement of stroke volume changes in a single patient, for example when their condition deteriorates or improves. Monitoring of stroke volume together with its course may be a useful and important application of the impedance cardiographic technique in clinical anaesthesia.

We conclude that the LS array should not be used in impedance cardiography. We recommend the MSC array together with Kubicek's equation in the use of IC, because with this combination, optimal results may be expected. In order to standardize the method of IC we propose that this combination should be used together with the averaging sample technique, according to Kim, Song and Lee,[16] in order to eliminate the effect of respiration.

Lack of specific renal haemodynamic effects of different doses of dopamine after infrarenal aortic surgery

A. R. J. GIRBES, A. G. LIEVERSE, A. J. SMIT, D. J. VAN VELDHUISEN, J. H. ZWAVELING,
S. MEIJER AND W. D. REITSMA

Summary

Dopamine is administered frequently in the operating theatre and intensive care unit patients undergoing mechanical ventilation with the aim of specifically enhancing renal blood flow. In an uncontrolled, open study, we administered sequentially different doses of dopamine (0, 2, 4, 8 and 0 μg kg^{-1} min^{-1}) during a 1-h period each. Systemic haemodynamic and renal haemodynamic variables were measured simultaneously using a pulmonary artery catheter and radiopharmaceuticals, respectively. We studied seven haemodynamically stable patients (mean age 66 yr), with a serum creatinine concentration < 160 μmol $litre^{-1}$, after elective infrarenal abdominal aortic reconstruction. All patients received extradural analgesia with bupivacaine and sufentanil, and none had a previous history of heart failure. Dopamine induced a dose-dependent increase in cardiac index which returned to baseline after cessation of the dopamine infusion. Glomerular filtration rate (GFR) increased with all doses of dopamine, whereas renal blood flow (RBF) increased significantly only with the 2- and 4-μg kg^{-1} min^{-1} doses. However, the ratio RBF/cardiac output remained unchanged with the 2- and 4-μg kg^{-1} min^{-1} doses, but decreased with 8 μg kg^{-1} min^{-1} from 14 (1.5) % to 10 (1.3) %. We conclude that dopamine increased RBF and GFR as a result of an increase in cardiac output. (*Br. J. Anaesth.* 1996; **77**: 753–757)

Key words
Pharmacology, dopamine. Kidney, function. Kidney, blood flow. Surgery, vascular. Cardiovascular system, effects.

Dopamine, a naturally occurring catecholamine, has a complicated influence on the cardiovascular and renal systems. This is because dopamine stimulates different types of adrenergic receptors: not only α- and β-adrenergic but also specific dopamine receptors.[1] Dopamine can be used for various indications depending on the given dose. In doses of 0.5–3.0 μg kg^{-1} min^{-1}, the so-called "renal dose", the predominant effect of dopamine is a marked increase in renal plasma flow, glomerular filtration rate and sodium excretion. This is caused mainly by stimulation of dopamine receptors. In doses of 3–10 μg kg^{-1} min^{-1}, dopamine exerts positive inotropic effects, primarily as a result of β_1 receptor stimulation. In doses exceeding 10 μg kg^{-1} min^{-1}, dopamine induces vasoconstriction and positive chronotropism as a result of predominant α-adrenergic and β-adrenergic effects, respectively.

Alterations in renal blood flow may contribute to the initiation of events which lead to renal failure.[2] In the intensive care unit dopamine is often used in doses of up to 4 μg kg^{-1} min^{-1} to increase or preserve renal blood flow. In clinical practice dopamine is given during mechanical ventilation, particularly during positive end-expiratory pressure (PEEP) ventilation for this purpose. Cardiac output is decreased during PEEP,[3 4] leading to decreased renal blood flow. Furthermore, PEEP decreases the release of atrial natriuretic peptide.[5] The renal vasodilating and natriuretic properties of a low-dose infusion of dopamine are therefore believed to be beneficial.

In previous studies in healthy subjects and patients with congestive heart failure (CHF) we and others have demonstrated that renal blood flow and sodium excretion are increased by administration of dopamine or its analogues.[6–10] However, there are no clinical studies on the renal haemodynamic effects of different "low-dose" dopamine infusions during mechanical ventilation with PEEP and their relation to systemic haemodynamics. As cardiac output and venous return are altered significantly during mechanical ventilation, it is reasonable to argue that renal haemodynamics and the effects of low-dose dopamine may be different from results obtained in healthy volunteers and patients with CHF.

In our department patients are admitted after major vascular surgery where sedation and

mechanical ventilation are continued until the patient is stable, and tracheal extubation is usually performed several hours after admission. Therefore, we performed a dose-finding study in these patients undergoing mechanical ventilation after operation to determine the dose of dopamine with the most pronounced renal haemodynamic effects.

Patients and methods

We studied seven consecutive postoperative patients admitted to the intensive care unit (ICU) who had undergone abdominal infrarenal aortic reconstruction, fulfilling the following inclusion criteria: stable haemodynamic state, defined as no need for inotropic drugs or rapid fluid administration and lack of active bleeding; normal hepatic function; stable ventilatory condition with a Pa_{O_2}/FI_{O_2} ratio > 25 kPa (FI_{O_2} = fractional inspiratory oxygen) with 8 cm of PEEP and normal airway pressures; and a preoperative serum creatinine concentration < 160 μmol litre^{-1}.

Patients receiving either α- or β-adrenergic agonists or antagonists, dopamine agonists or antagonists, monoamine oxidase inhibitors, angiotensin converting enzyme inhibitors or diuretics in the previous 3 months were excluded. Patients with a previous history of congestive heart failure were also excluded. All patients had a pulmonary artery catheter (Baxter Thermodilution Catheter, Edwards Laboratories, Irvine, CA, USA) inserted before operation for peroperative monitoring. The position was checked in the ICU by a standard chest roentgenogram. All patients had an extradural infusion of a combination of 0.125% bupivacaine and sufentanil 1 μg ml^{-1} at a rate of 8 ml h^{-1} for analgesia. Additional sedation comprised a continuous infusion of midazolam during the study. An infusion of 0.45%–2.5% sodium–glucose was given at a rate of 3500 ml day^{-1}. Potassium was administered according to serum potassium concentrations. Initially, supplements of crystalloids and colloids were given in the immediate postoperative phase and (mild) hypothermia was corrected. At the moment when no inotropic support and no additional rapid fluid infusion were required, the study was started. All patients gave written informed consent and the study was approved by the Medical Ethics Committee of the University Hospital of Groningen.

After haemodynamic stability was established and patients were normothermic, measurements were started after a further equilibration period of 1.5–2 h. After 1 h of baseline measurements, an infusion of dopamine was started. During the first hour the rate of infusion was 2 μg kg^{-1} min^{-1}. In the second and third hours this dose was increased to 4 and 8 μg kg^{-1} min^{-1}, respectively. During the fourth hour the dopamine infusion was decreased gradually over 10 min. At the end of this hour the study was terminated.

RENAL FUNCTION TESTS

Glomerular filtration rate (GFR) and effective renal plasma flow (ERPF) were measured simultaneously using ^{125}I-iothalamate and ^{131}I-hippurate, respectively, according to the method described by Donker and colleagues.[11] The radiopharmaceuticals were infused at a constant rate after a priming dose had been given. After the previously mentioned equilibration period of 1.5–2 h, clearances were determined every hour. Filtration fraction (FF) represents the ratio GFR/ERPF. Hourly urine samples were collected via a bladder catheter. Serum and urinary electrolyte concentrations were assayed by routine Technicon SMA-C Auto-Analyzer (Technicon, Tarrytown, NY, USA). After measurements of baseline values during the first hour, hourly measurements were performed during the subsequent 4 h.

HAEMODYNAMIC MEASUREMENTS

Using the pulmonary artery catheter, inserted via the jugular vein, cardiac output, pulmonary capillary wedge, pulmonary arterial and central venous pressures were measured every 30 min. Haemodynamic measurements and derived variables were determined as described previously.[12] Arterial pressure was measured via a radial arterial cannula. Haemodynamic data were measured together with renal function tests, thereby allowing simultaneous evaluation of the renal and systemic haemodynamic effects of dopamine.

PLASMA NEUROHUMORAL VARIABLES

Blood samples were obtained for measurement of plasma renin activity (PRA) and plasma aldosterone concentration (PAC) at the end of each hour during the study. PRA and PAC were determined by radioimmunoassay. The intra-assay coefficients of variation were 5.2% and 8% for PRA and PAC, respectively. The inter-assay coefficient of variation was 15% for PAC and 10.3% for PRA. Serum catecholamine concentrations were determined by high pressure liquid chromatography (HPLC) with electrochemical detection, after an extraction procedure.[13]

STATISTICAL ANALYSIS

All data are given as mean (SEM), unless otherwise stated. Paired statistics were performed comparing baseline values with values at specific times, which means that every patient served as his own control. Paired t tests were used for normally distributed data, whereas the Wilcoxon test was used for non-normally distributed data. The software package SPSS for Windows, version 6.0 was used on a 486 DX personal computer. For non-normally distributed data, medians and ranges are given. All values for ERPF and GFR were corrected for a body surface of 1.73 m^2. Renal blood flow (RBF) was calculated as (uncorrected ERPF)/(1 − packed cell volume). The percentage renal blood flow–cardiac output (CO) ratio was calculated as RBF/CO × 100%. Differences were considered statistically significant at the 5% level.

Table 1 Renal and systemic haemodynamics. SVR=Systemic vascular resistance; GFR = glomerular filtration rate; RBF = renal blood flow. Systemic haemodynamics were determined every 30 min, whereas renal haemodynamics were determined every 60 min. The first value in each panel for a specific time indicates the value halfway between the hour for the systemic haemodynamics. *Significant difference compared with baseline; †significant difference compared with previous value

Results

We studied six males and one female, mean age 66 (range 46–77) yr. All underwent uncomplicated infrarenal abdominal aortic reconstruction.

EFFECTS ON SYSTEMIC AND RENAL HAEMODYNAMICS (TABLE 1)

A dose-dependent increase in cardiac index was observed, from 2.77 (0.30) litre min^{-1} m^{-2} at baseline to a maximum of 4.24 (0.24) litre min^{-1} m^{-2} with dopamine 8 μg kg^{-1} min^{-1}. After cessation of administration of dopamine, cardiac index returned to values comparable with baseline: 2.93 (0.31) litre min^{-1} m^{-2}. There were no significant increases in heart rate except with a dose of 8 μg kg^{-1} min^{-1}. Filling pressures (mean PACWP and CVP approximately 12 (1.2) and 8 (0.7) mm Hg, respectively), mean arterial pressure (approximately 90 (8) mm Hg) and pulmonary pressures (approximately 25 (2) mm Hg) remained unchanged during the study. Systemic and pulmonary vascular resistance decreased during infusion of the higher doses of dopamine and returned to values similar to baseline after dopamine was stopped.

Table 2 Effects of different doses of dopamine on renal function. *Significant difference compared with corresponding baseline values

	Urine volume (ml h^{-1})	Na$^+$ excretion (mmol h^{-1})	FeNa$^+$ (%)
Baseline	115 (24)	11.9 (3.7)	0.09 (0.03)
t1 (2 μg kg^{-1}min^{-1})	164 (50)	17.6 (7.4)*	0.12 (0.06)
t2 (4 μg kg^{-1}min^{-1})	260 (54)*	27.9 (8.0)*	0.2 (0.06)*
t3 (8 μg kg^{-1}min^{-1})	336 (56)*	36.0 (7.5)*	0.24 (0.05)*
t4 (0 μg kg^{-1}min^{-1})	140 (33)†	15.7 (4.8)	0.11 (0.03)

GFR increased for all doses of dopamine, from 80 (8.8) ml^{-1} min^{-1} per 1.73 m^2 to a maximum of 101 (12.9) ml^{-1} min^{-1} per 1.73 m^2. RBF increased from a mean of 676 (116) ml^{-1} min^{-1} per 1.73 m^2 to a maximum of 809 (125) ml^{-1} min^{-1} per 1.73 m^2 with the 4-μg kg^{-1} min^{-1} dose (table 1). Filtration fraction varied non-significantly during the study from 0.19 (0.01) to 0.21 (0.01). However, there was a decrease in the contribution of cardiac output to RBF with the 8-μg kg^{-1} min^{-1} dose (from 14 (1.5) % to 10 (1.3) %).

RENAL EFFECTS (TABLE 2)

Hourly urine volume increased from 115 (24) ml h^{-1} at baseline to 336 (56) ml h^{-1} with dopamine 8 μg kg^{-1} min^{-1}. Sodium concentration and fractional sodium excretion increased in a dose-dependent manner from 11.9 (3.7) mmol h^{-1} and 0.09 (0.03) % to 36.0 (7.5) mmol h^{-1} and 0.24 (0.05) %, respectively. All returned to values comparable with baseline at the end of the study when dopamine was stopped.

NEUROHORMONES AND CATECHOLAMINES (TABLE 3)

There were no significant changes in PRA during the study. Plasma concentrations of aldosterone were reduced significantly by dopamine 8 μg kg^{-1} min^{-1}. Median plasma concentrations of noradrenaline were increased significantly by dopamine infusion. After stopping dopamine, plasma concentrations of noradrenaline returned to values comparable with

Table 3 Neurohormones during the study period. Values are mean (SD) or median (range) for non-normally distributed data. Baseline 1 values were determined immediately before start of the study and baseline 2 values were determined at the end of the baseline period. *Significant difference compared with baseline values

	PRA (nmol litre^{-1}h^{-1})	Aldosterone (nmol litre^{-1})	Noradrenaline (nmol litre^{-1})	Adrenaline (nmol litre^{-1})
Baseline 1			3.08 (0.75–8.79)	0.82 (0.010–3.58)
Baseline 2	1.26 (0.31)	0.38 (0.11)	3.48 (0.25–10.0)	0.49 (0.010–2.35)
t1 (2 μg kg^{-1}min^{-1})	1.19 (0.31)	0.27 (0.07)	4.46 (0.74–14.2)*	0.20 (0.010–7.66)
t2 (4 μg kg^{-1}min^{-1})	1.09 (0.33)	0.19 (0.04)	9.96 (1.44–29.5)*	0.40 (0.10–9.55)
t3 (8 μg kg^{-1}min^{-1})	0.90 (0.28)	0.13 (0.02)*	19.66 (2.96–51.4)*	0.33 (0.05–8.57)
t4 (0 μg kg^{-1}min^{-1})	0.93 (0.24)	0.24 (0.06)	4.95 (1.07–33.1)	0.47 (0.010–1.96)

baseline. Dopamine concentrations increased from a median baseline value of 7.5 (range 2.0–11.3) nmol litre^{-1} to 413 (28.0–1840) nmol litre^{-1}. After stopping the infusion of dopamine, plasma concentrations of dopamine decreased to 11.9 (7.6–326) nmol litre^{-1}.

Discussion

We found that although dopamine increased GFR and RBF at different doses, no specific enhancement of renal flow was present. The increase in RBF was caused mainly by an increase in cardiac output. With dopamine 8 μg kg^{-1} min^{-1}, the fraction of cardiac output directed to the kidney was even decreased. Furthermore, dopamine acted as a diuretic in a dose-dependent manner, with an increase in diuresis and (fractional) sodium excretion. The decrease in plasma concentration of aldosterone, which may also have contributed to the natriuretic effect of dopamine, was related probably to dopamine DA_2 receptor stimulation of the adrenal zona glomerulosa.[14 15]

Dopamine is frequently administered in the ICU to patients undergoing mechanical ventilation to improve GFR and RBF. An improvement in mainly RBF has been shown in many studies investigating healthy volunteers or non-mechanically ventilated patients with congestive heart failure.[6 8 16–18] However, few data exist indicating an increase in renal perfusion in patients undergoing mechanical ventilation. Mostly, only estimates of renal function, such as creatinine clearance and diuresis are measured.[19 20] Additionally, in most studies the β-agonist activity of dopamine is insufficiently regarded, as cardiac output is not measured simultaneously.

Despite the frequently used terminology "renal dose" of dopamine, indicating a dose of dopamine with preferential effects on renal haemodynamics, our study showed that such a renal-selective dose did not exist. Furthermore, different doses of dopamine have been investigated in different studies. To our knowledge this is the first study examining different doses of dopamine in patients undergoing mechanical ventilation. However, all of our patients received thoracic extradural analgesia with bupivacaine and sufentanil. The resulting sympathetic block may interfere with the distribution of flow and therefore the RBF/CO ratio. Vascular DA_1 receptor stimulation results in predominant post-glomerular vasodilatation by direct vasodilatation of the efferent arterioles.[9 18] Because of this mechanism, a preferential increase in RBF has been observed in heart failure patients and in healthy subjects.[6–9 16] The results in our patients suggest that the renal vasodilating effects were outweighed by the systemic effects and were not caused by absent or decreased sympathetic innervation of the kidney, as in kidney transplant recipients a specific renal vasodilating effect of dopamine 2 μg kg^{-1} min^{-1} is still present (assuming the absence of sympathetic innervation in transplanted kidneys).[21] However, the filtration fraction in our patients was lower than that reported in healthy volunteers and (especially) heart failure patients,[8–10] which makes a further decrease in filtration fraction as an indication of specific renal vasodilatation more difficult to achieve.

If an increase in RBF and GFR is considered the goal of treatment, our data indicate that 4 μg kg^{-1} min^{-1} is the optimal dose of those studied. However, this is no reason to give dopamine and should not be considered as the "renal dose".

Dopamine increases stroke volume and cardiac output in a dose-dependent manner, with a maximal increase with the highest dose (8 μg kg^{-1} min^{-1}). Heart rate increased only with the highest dose of dopamine (8 μg kg^{-1} min^{-1}). The positive inotropic effect of dopamine is caused not only by its direct β_1-agonist activity, but also by inhibition of uptake-1.[22] Uptake-1 inhibition of dopamine may be involved in the increase in plasma concentrations of noradrenaline. Furthermore, as dopamine is a precursor of noradrenaline, stimulation of endogenous noradrenaline formation cannot be excluded. Additionally, dopamine may enhance release of noradrenaline via β_2-receptor stimulation. We found no effects on plasma renin activity or adrenaline. Although DA_1 receptor stimulation can increase PRA,[9] evidence exists that balanced DA_1 and DA_2 receptor stimulation does not alter PRA.[10] The most important stimulus for an increase in adrenaline concentration is hypoglycaemia and some evidence suggests that stimulation of adrenal DA_2 receptors, present on chromaffin cells, induces inhibition of adrenaline release.[23] This may explain why no increase in plasma concentrations of adrenaline was observed.

The reduction in systemic and pulmonary vascular resistance was an unexpected finding in our study. Several mechanisms may be involved; first, all patients received thoracic extradural analgesia, which causes sympathetic block. The influence of dopamine on ganglionic receptors is therefore modified. Second, DA_1 receptor-mediated effects, causing vasodilatation, may be involved and override direct α_1-receptor-mediated vasoconstrictive effects, even at this dose. Rajfer and colleagues[24] observed a decrease in vascular resistance with increasing plasma dopamine concentrations, with administration of levodopa, a dopamine prodrug. Lundberg and colleagues also observed a decrease in systemic vascular resistance during infusion of dopamine.[25]

Although our study was uncontrolled, recovery of all variables to (almost) baseline values after stopping dopamine infusion indicated a drug-related and not time-related effect. Our study further emphasizes the different effects of dopaminergic drugs in different categories of patients, as we and others have shown previously.[10 26 27]

LABORATORY INVESTIGATIONS

Antinociception by intrathecal midazolam involves endogenous neurotransmitters acting at spinal cord delta opioid receptors

C. S. GOODCHILD, Z. GUO, A. MUSGREAVE AND J. P. GENT

Summary

Intrathecal midazolam causes antinociception by combining with spinal cord benzodiazepine receptors. This effect is reversible with doses of naloxone, suggesting involvement of spinal κ or δ but not μ opioid receptors. The antinociceptive effects of intrathecally administered drugs in the spinal cord were demonstrated by measurements of the electrical current threshold for avoidance behaviour in rats with chronically implanted lumbar intrathecal catheters. A comparison was made of suppression by two opioid selective antagonists (nor-binaltorphimine (κ selective) and naltrindole (δ selective)) of spinal antinociception caused by equipotent doses of opioids selective for different receptor subtypes (U-50488H (κ), DSLET and DSBULET (δ), fentanyl (μ)) and the benzodiazepine midazolam. Nor-binaltorphimine selectively suppressed the effects of U-50488H but not midazolam or fentanyl. However, the δ selective antagonist, naltrindole, caused dose-related suppression of antinociception produced by both δ opioid agonists and midazolam with the same ED$_{50}$ (0.5 nmol). We conclude that intrathecal midazolam caused spinally mediated antinociception in rats by a mechanism involving δ opioid receptor activation. (*Br. J. Anaesth.* 1996; **77**: 758–763)

Intrathecal injection of midazolam has been shown to produce analgesia in humans[1,2] and antinociceptive effects in rats.[3,4] This effect in rats is caused by an action on GABA$_A$ receptors in the spinal cord and may also be produced by the archetypal benzodiazepine, chlordiazepoxide.[5–7] It has also been shown that the antinociceptive effects of intrathecal midazolam may be suppressed by the opioid antagonist naloxone and this effect was dose-dependent.[5,8] Doses that blocked the midazolam effects were similar to those needed to suppress the effects of the κ opioid agonist ketocyclazocine and significantly greater than those needed to block the effects of the μ selective opioid agonist, fentanyl.[5,8] The results from those experiments implied that intrathecal midazolam, after combining with GABA$_A$ receptors, caused the release of endogenous opioids that acted at a κ or δ but not a μ opioid receptor.

The aim of this study was to investigate the possible role of both of these opioid receptors in the production of spinally mediated antinociception by midazolam. This was achieved by observing the effects on spinal antinociception of different receptor-selective antagonists.

Materials and methods

These experiments were carried out with the permission of the Licensing Authorities of Great Britain under Home Office Licence No. PPL/50/001310 and in all cases the authors adhered to the Guidelines for Investigation of Pain in Experimental Animals.[9]

INTRATHECAL CANNULATION

Rats (150–200 g) were anaesthetized with halothane in oxygen-enriched air ($F\text{I}_{O_2}$=0.5) and Portex catheters (id 0.28 mm, od 0.61 mm) were implanted under aseptic surgical conditions into the lumbar subarachnoid space to lie next to the most caudal segments of the spinal cord, as described previously.[10] A minimum period of 18 h elapsed between catheter implantation and nociceptive testing. One experiment was performed on each animal per day up to a permitted maximum of six experiments.

NOCICEPTIVE TESTS

The electrical current threshold for nociception (ECT) was measured in the skin of the neck and tail every 5 min, as described previously.[10] The standardized response (*r*) was calculated by dividing the three ECT readings obtained 5, 10 and 15 min after intrathecal injection by the three pre-injection readings. In some experiments the tail flick latency (TFL) test was also used. In those experiments TFL

*Present address: University Department of Anaesthesia, Monash Medical Centre, 246 Clayton Road, Clayton, Victoria, 3168, Australia. Correspondence to C. S. G.

was always measured 10–15 s before the ECT test was performed, as described previously.[10] The response to the intrathecal drugs was then calculated:

$$\%\text{MPE}=\frac{\text{mean TFL post-drug}-\text{mean TFL pre-drug}}{\text{cut-off time}-\text{mean TFL pre-drug}}\times 100$$

AGONIST DOSE–RESPONSE STUDIES

Dose–response relationships for a κ (U-50488H, Upjohn Ltd) and two δ (DSLET, RBI; DSBULET) opioid agonists were investigated. This was done in order to define doses of each agonist which produced just maximal, spinally mediated antinociceptive effects (maximum increase in the tail threshold with no increases in the neck threshold) and which were approximately equipotent with midazolam 46 nmol and fentanyl 0.74 nmol. These doses have been demonstrated previously to be equipotent and produce maximal spinally mediated antinociceptive effects.[10]

The responses (*r* values calculated as above) were combined for each dose of each agonist to calculate mean (SEM). Dose–response curves were plotted for each agonist and the dose of each agonist which produced a maximal increase in tail ECT with no change in the neck threshold was calculated.

In addition, the time course of the antinociceptive effect was examined for DSLET; electrical current thresholds in four animals who received intrathecal DSLET 9.1 nmol were measured for 40 min after intrathecal injection of drug. The nociceptive thresholds for each test were combined for each testing time between animals and plotted on a time–response curve.

EXPERIMENTS USING NOR-BINALTORPHIMINE

In this group of experiments each rat received intrathecal injection of an equipotent dose of agonist (U-50488H 210 nmol, midazolam 46 nmol or fentanyl 0.74 nmol) given alone at the beginning and again at the end of the series of experiments. Nociceptive thresholds were measured as above. These control responses obtained in the absence of any antagonist were pooled for each drug to derive a mean control agonist response to agonist alone (*R*). In addition, the pre- and post-series control responses for each agonist were compared statistically (Mann–Whitney *U* test) to test for drug tolerance or cumulative effects of antagonist. In the experiments intervening between the two control agonist responses, a range of doses of nor-binaltorphimine (0.0012–1.24 pmol), dissolved in saline, was injected, mixed with agonist, in the same intrathecal injection.

The responses to nor-binaltorphimine in suppressing the effects of all of these agonists were calculated as percentage suppression of control agonist response from the expression:

$$\%\text{suppression}=\frac{R-r}{R-1}\times 100$$

where R=mean control agonist response in the absence of antagonist and r=response to agonist in the presence of a particular dose of antagonist. The values obtained for each antagonist dose were combined to produce a mean (SEM) and plotted as antagonist dose–response curves.

EXPERIMENTS WITH NALTRINDOLE

In these experiments naltrindole 0.0011–11.1 nmol was given intrathecally dissolved in 5% glucose in a volume of 5 µl mixed with the agonists, and nociceptive thresholds were measured as above. The agonists used were fentanyl 0.74 nmol, U-50488H 210 nmol, DSLET 9.1 nmol, DSBULET 4 nmol and midazolam 46 nmol.

CONTROLS

Five rats with intrathecal catheters were given, on separate occasions, intrathecal naltrindole alone (11.1 nmol) and nor-binaltorphimine (1.24 pmol). The effects of these were assessed with both tests (ECT and TFL). These were the highest doses of antagonists used.

Baseline (pre-drug injection) values for tail nociceptive thresholds were compared with those obtained for the same animal on previous occasions in order to exclude changes induced by progressive neurological damage or residual drug effects. We did not perform control experiments for intrathecal saline alone (the vehicle for some drugs) as we have reported previously that this had no effect on nociceptive thresholds.[3] We did however perform control experiments in four animals who received 5 µl of intrathecal injections of 6% glucose solution which was the vehicle used for other drugs reported in this study.

STATISTICAL ANALYSIS

All data are shown as mean (SEM). Statistical comparisons were made using Mann–Whitney *U* tests. $P \leq 0.05$ was considered statistically significant.

Results

Evidence that the catheter was intrathecal (a positive lignocaine test) was obtained in all rats after all experiments. We compared the baseline ECT values in the tail for each animal at the beginning of each experiment and there was no change in thresholds over the course of the series which would have suggested neurological damage or residual drug effects. Also, there was no evidence of tolerance to drug effects from comparison of the responses to the same agonists obtained at the beginning and end of the series of experiments with each of the antagonists.

Table 1 Equipotent doses of U-50488H, DSLET and DSBULET derived from their dose–response relationships

Drug	Dose (nmol)	ECT (tail) (mean (SEM))	No. of experiments
U-50488H	210	1.55 (0.26)	11
DSLET	9.1	1.97 (0.23)	6
DSBULET	3.37	1.91 (0.28)	6

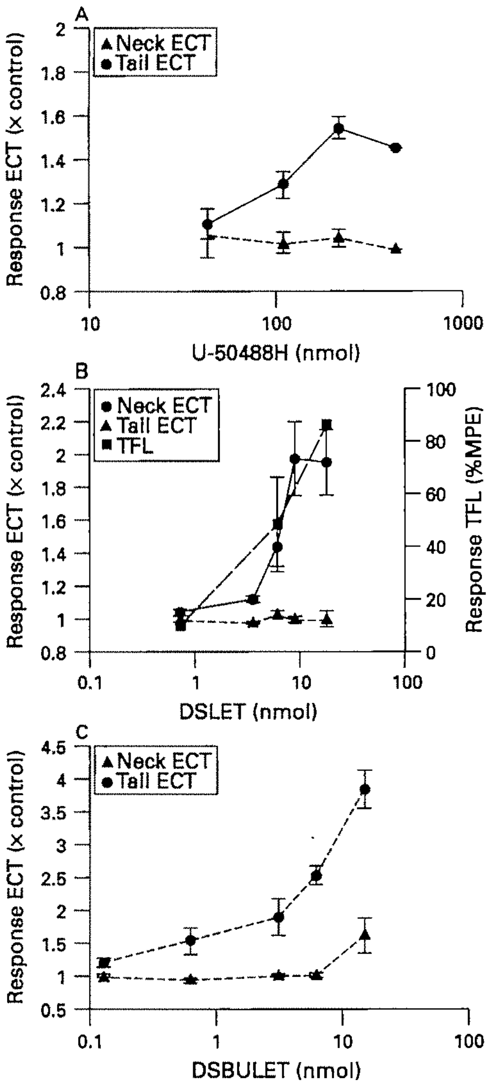

Figure 1 Dose–response curves for intrathecal U50488H (A), DSLET (B) and DSBULET (C) for neck and tail electrical current threshold (ECT) values and tail flick latency (TFL) (mean, SEM of 22 experiments in 13 rats (A), 31 experiments in six rats (B) and 30 experiments in six rats (C)).

AGONIST DOSE–RESPONSE STUDIES

All three opioids produced dose-dependent spinally mediated antinociception that was present and had a peak effect within 5 min (fig. 1). The doses of the three agonists, shown by these dose–response studies to produce just maximal segmental antinociceptive effects (increase in tail thresholds with no change in neck thresholds), are shown in table 1.

The antinociceptive effects assessed with the ECT for the δ and κ opioid agonists did not differ significantly from each other or from those obtained in the experiments with antagonists of midazolam (46 nmol; 1.81 (0.1) ECT tail) and fentanyl (0.74 nmol; 1.91 (0.07) ECT tail) (Mann–Whitney *U* test; $P > 0.1$). TFL was also measured in the experiments with DSLET. These measurements were performed only for doses of intrathecal DSLET of 0.728, 6.19 and 18.2 nmol. DSLET caused a dose-related increase in TFL.

Time–response curves were constructed from four experiments in four animals in the group that received DSLET and in six rats that received intrathecal DSBULET (fig. 2). Intrathecal DSLET 9.1 nmol produced an increase in the ECT in the tail with no change in the neck and this change occurred at 5 min and persisted for 20 min after injection and regressed towards control values during the following 20 min. Intrathecal DSBULET 3.37 nmol caused a sharp increase in the ECT in the tail with no change in the neck thresholds and this change in the tail was also stable for 15 min after injection.

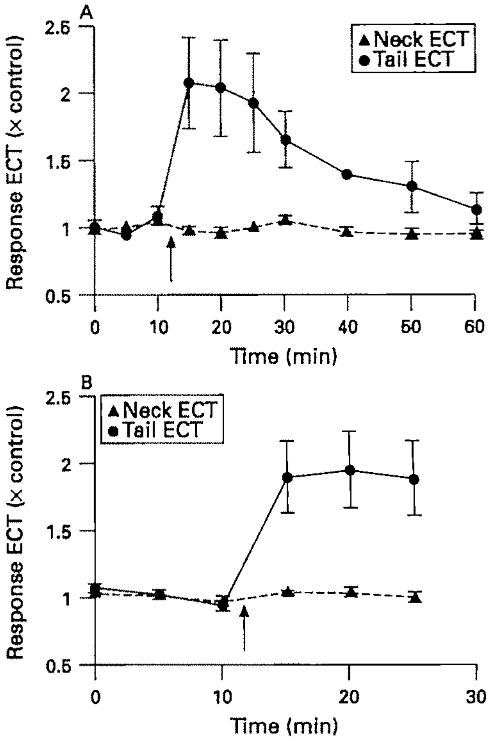

Figure 2 Time–response relationships for electrical current threshold (ECT) measurements after intrathecal DSLET 9.1 nmol ($n=4$ rats) (A) and DSBULET 3.37 nmol ($n=6$ rats) (B) (mean, SEM). Arrows indicate the time of intrathecal injection of drug.

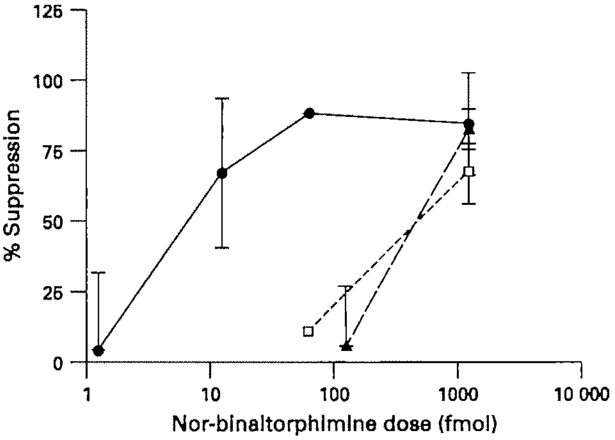

Figure 3 Nor-binaltorphimine dose–response curves for suppression of ECT antinociceptive effects of intrathecal midazolam 46 nmol (19 experiments, five rats) (▲), fentanyl 0.74 nmol (18 experiments, three rats) (□) and U-50488H 210 nmol (22 experiments, five rats) (●).

EXPERIMENTS WITH NOR-BINALTORPHIMINE

Nor-binaltorphimine dose–response curves for suppression of the antinociceptive effects of U-50488H,

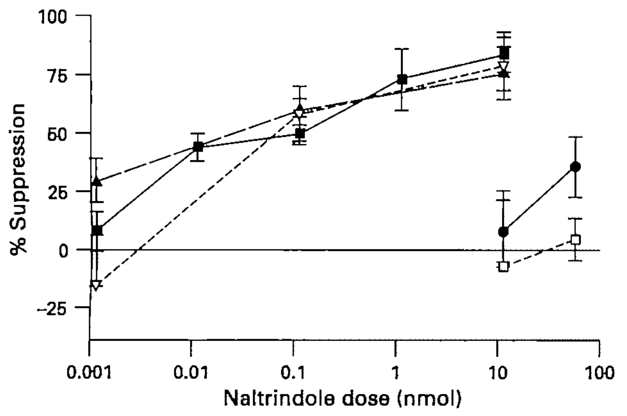

Figure 4 Naltrindole dose–response curves for suppression of ECT antinociceptive effects of intrathecal midazolam 46 nmol (16 experiments, eight rats) (▲), DSLET 9.1 nmol (24 experiments, eight rats) (■), DSBULET 4 nmol (16 experiments, four rats) (▽), fentanyl 0.74 nmol (eight experiments, eight rats) (□) and U-50488H 210 nmol (eight experiments, eight rats) (●). TFL measurements were also made in DSLET experiments but these are not shown for clarity because the naltrindole dose–response curve for suppressing this effect of DSLET is coincident with the curves for midazolam and the ECT effects of DSLET.

midazolam and fentanyl are shown in figure 3. The selective κ opioid antagonist suppressed only the antinociceptive effects of the κ opioid agonist U-50488H. There was 70% suppression of the effects of fentanyl and midazolam at the highest dose of norbinaltorphimine (i.e. 1.24 pmol); 5% of this dose (0.062 pmol) caused 100% suppression of the effects of U-50488H. Mean control responses before and after the experimental series to agonist alone were, respectively: U-50488H 1.62 and 1.57; midazolam 2.3 and 2.64; and fentanyl 2.14 and 2.08. There were no significant differences between the pre- and post-series controls for each drug (Mann–Whitney *U* test) indicating that no tolerance or cumulative drug effects had occurred.

EXPERIMENTS WITH NALTRINDOLE

Figure 4 shows naltrindole dose–response curves for suppression of the antinociceptive effects of all agonists tested. Naltrindole, a selective δ opioid antagonist, had no effect on fentanyl or U-50488H spinal antinociception at a dose of 11.1 nmol. In contrast, this dose of naltrindole produced highly significant suppression of spinally mediated antinociception caused by DSLET and DSBULET, the δ opioid agonists, and also midazolam. TFL results for DSLET are not shown in figure 4 in the interest of clarity. However, naltrindole 0.011 and 11.1 nmol caused 41.3 (19) % and 90.26 (10.6) % suppression of the TFL increases caused by intrathecal DSLET 9.1 nmol, the same dose–response relationship as that for suppression of the ECT effects of intrathecal midazolam and DSBULET. The dose–response curves for naltrindole antagonism of both δ opioid agonists and midazolam were coincident. The ED_{50} for this effect, that is the theoretical dose which would cause 50% suppression of spinally mediated antinociception, was the same for all three drugs (approximately naltrindole 0.5 nmol).

CONTROLS

ECT values in the tail were not changed in the four animals which received 5-μl injections of 6% glucose alone, indicating that this vehicle had no effect on nociceptive thresholds.

The pre and post-series control responses to agonist alone were: DSLET 1.97 (0.23) and 1.9 (0.18) ECT, 64.3 (13.3) and 74.7 (14.6) TFL; DSBULET 2.09 (0.07) and 2.09 (0.29) ECT.

Mean control responses to fentanyl and midazolam given alone were, respectively, 1.91 (0.07) and 1.8 (0.1). There were no significant differences between pre- and post-series control values for each δ opioid agonist given alone and there were no significant differences between control agonist responses, that is they were equipotent in causing spinally mediated antinociception and there was no evidence of tolerance to these agonists in this series of experiments.

Discussion

In the experiments reported here, we used two important principles to study the receptors responsible for spinally mediated antinociception caused by intrathecally administered agonists. First, in every experiment used for this analysis nociceptive thresholds in the tail increased after drug administration, with no change in neck thresholds. If drug is injected too rapidly intrathecally or at too large a volume, we have found previously that neck thresholds increase also. Second, traditionally, one analyses receptor subtypes using the technique described by Arunlakshana and Schild[11] to calculate the pA_2 value. In our experimental preparation the concentrations of agonist and antagonist are unknown and the system does not reach steady state, a requirement for pA_2 calculations.

Therefore, the technique of antagonist dose–response curve analysis was used in this as in previous studies.[3,5–7,12] This technique has since been verified by Mackay.[13,14] An antagonist dose–response curve describes the inter-relationship between the antagonist and a native receptor if this receptor causes a physiological effect by binding with exogenous drug or endogenous neurotransmitter. Thus the same antagonist dose–response curve with the same ED_{50} is obtained with a particular antagonist, suppressing the effects of two different drugs, whether they bind to the same receptor, or if one or both causes the release (directly or indirectly) of an endogenous agonist which then binds to the same receptor as the antagonist to produce the effect.

Previous experiments with naloxone indicated that intrathecal midazolam activated a spinal opioid system.[5,8] Benzodiazepine antinociception is probably not a μ opioid effect as fentanyl spinal antinociceptive effects were more sensitive to suppression by naloxone than those of either ketocyclazocine (the archetypal κ opioid agonist) or midazolam[5,8] and naloxone has been shown to display some selectivity for the μ receptor.[15] Although ketocyclazocine is the archetypal κ opioid it is not very selective. However, other studies indicated that a κ opioid ligand with higher selectivity for the κ opioid receptor than ketocyclazocine, ICI 197067, had a similar ED_{50} for naloxone suppression of its spinally mediated antinociceptive effects.[16] Although naloxone is more selective for the μ opioid receptor, the degree of selectivity is not high and it does not discriminate between δ and κ opioid sites. Clearly further experiments with more selective antagonists are needed. This study demonstrated a very high degree of selectivity for nor-binaltorphimine for antagonism of the effects of the κ opioid agonist U-50488H compared with the μ opioid agonist fentanyl. Spinal antinociception produced by midazolam was not suppressed by the doses of nor-binaltorphimine which were selective for the μ opioid receptor, although some suppression was produced by the higher, non-selective doses of nor-binaltorphimine which also suppressed fentanyl antinociceptive effects.

Naltrindole showed a high degree of selectivity for the δ opioid receptor. Suppression of spinal antinociception caused by the δ selective opioid agonists, DSLET and DSBULET, occurred over a range of doses of naltrindole which were three or four orders of magnitude less than those which caused small amounts of suppression of responses to fentanyl and U-50488H. The naltrindole dose–response curve for suppression of antinociception produced by midazolam was to the left of the curves for the κ and μ opioids and it is coincident with all the curves for suppression of the effects of the selective δ opioid agonists. It may be concluded that intrathecal midazolam produces antinociception by activating a system which involves δ opioid receptors. Furthermore, this system is confined to the spinal cord because all experiments in this study demonstrated a differential effect on tail thresholds, that is tail thresholds increased, with no change in ECT occurring in the neck and thus all drug effects and interactions between agonist and antagonist must have occurred at the spinal cord level. It is clear that the initial step in this process is combination of the drug with a typical $GABA_A$/BZ receptor complex as both bicuculline, a $GABA_A$ antagonist, and flumazenil, a benzodiazepine receptor antagonist, suppressed midazolam spinally mediated antinociception in a dose-related manner.[5 6] However, flumazenil and bicuculline did not block the spinal analgesic effect of μ, κ or δ opioid agonists.[17 18] Therefore, the results indicate that intrathecal midazolam positively modulates the effect of GABA at $GABA_A$ receptors and the effect of this is to cause the release of an endogenous opioid acting at δ opioid receptors. It is not known if these $GABA_A$/BZ receptors are pre- or postsynaptic and on what neuronal elements in the spinal cord they are located. However, the effect of positive modulation of GABA at these receptors is to increase chloride flux into the neurone, thus inhibiting its firing. Thus the effect would be to decrease neurotransmitter release from a presynaptic terminal or postsynaptic cell. We must therefore conclude that the pre- or postsynaptic effect leads to decreased release of an inhibitory neurotransmitter that normally inhibits the neuronal release of an opioid acting at δ opioid receptors.

It has been shown previously that intrathecal midazolam 46 nmol increases ECT values without affecting TFL.[10] There have been reports of TFL increases and mixed antinociceptive and hyperalgesic effects after administration of midazolam.[19] However, studies using the preparation that we used in which tail and neck ECT values were measured have consistently demonstrated increases in tail ECT with no change in TFL or neck ECT in the same experiments.[10] The possibility exists in other studies for spread of drug to the brain and that these supraspinal actions lead to mixed effects and TFL increases.

The dose of midazolam (46 nmol) used in these studies produced spinally mediated antinociception measured by the ECT test and was equipotent with doses of fentanyl and DSLET. However, the δ opioid agonist also caused an increase in TFL and increases in ECT values. This TFL effect must be mediated by a spinal cord mechanism as increases in TFL occurred after intrathecal DSLET at doses which caused increases in ECT in the tail without any change in the neck thresholds. We conclude that these two antinociceptive effects of the δ opioid are mediated by separate spinal cord mechanisms. The first (revealed by the ECT test) may be activated by intrathecal benzodiazepine causing the release of an endogenous δ opioid. The second (revealed by the TFL test) may be activated by exogenous δ opioids or endogenous opioid peptides selective for δ opioid receptors but not those released by midazolam.

These results provide further evidence that intrathecal midazolam produces antinociceptive effects by interactions with spinal systems. There may be useful potentiation of antinociceptive and analgesic effects to be gained by concurrent therapy with a μ selective opioid and midazolam. This suggestion, based on the results presented here, is supported by other studies in rats.[4] These authors reported potentiation of submaximal doses of intrathecal morphine by intrathecal injections of midazolam in the tail flick test. This additive effect is interesting because midazolam alone does not increase TFL, concurring with observations reported previously.[10] The mechanism of this interaction is unknown but the results reported here showed intervening steps involving the release of endogenous neurotransmitter substances. These may be the source of that interaction and potentiation, although more work needs to be performed to verify this suggestion.

A model of the first pass passage of drugs from i.v. injection site to the heart—parameter estimates for lignocaine in the sheep

R. N. UPTON

Summary

A general model, based on indicator dilution principles, of the initial distribution and effects of drugs in a target organ after i.v. bolus administration is presented. The model was validated from previous studies of myocardial pharmacokinetics and pharmacodynamics of lignocaine in sheep. It is proposed that i.v. drug injection produces a concentration "peak" of drug in venous blood, which is attenuated by vascular mixing, and lung and heart kinetics, as the drug is transported from the injection site to the heart where it exerts its effects. The model predicted that the first passage of this peak through the heart was the principal component of myocardial concentrations of lignocaine for 10 min after injection before recirculation became important. Injection rate, cardiac output and myocardial blood flow were important determinants of the magnitude of the first pass peak. The model provides a physiological framework for analysing the initial distribution of drugs. (*Br. J. Anaesth.* 1996; **77**: 764–772)

Key words
Pharmacokinetics, models. Liver, metabolism. Anaesthetics local, lignocaine. Sheep.

Drugs that have direct effects on the heart (such as i.v. anaesthetics, anti-arrhythmics, analgesics and sedatives) are often administered as an i.v. bolus in anaesthesia and critical care medicine. After this type of administration, the time courses of both therapeutic and adverse effects change rapidly in the first 10 min after injection.[1 2] As a generalization, clinical practice has empirically evolved dose regimens that minimize adverse effects by matching the dose and rate of injection of a drug to the pathophysiological state of the patient, but the physiological basis of the dose regimens is often poorly understood.[1] While studies of the pharmacokinetics of these drugs in systemic blood provide some insight, evidence is accumulating that the time course of many of the direct myocardial effects in the period immediately after bolus administration are related closely to the time course of their concentration in the heart.[3 4]

It has been increasingly recognized that the conventional one-, two- or three-compartment interpretation of bolus kinetics (for example, see Gibaldi and Perrier[5] and Wood[6]) is not well suited to the description of the initial kinetics of drugs administered as i.v. boluses.[7 8] Limitations include poor description of vascular mixing,[9] poor description of lung kinetics[7 10] and in the case of cardioactive drugs, poor description of the time course of myocardial drug concentrations, and their determinants, in the period immediately after a drug bolus.[1 11]

The origin of many of these limitations may be traced to the assumption that drug is added instantly to an initial distribution volume with little or no anatomical basis. Although the concept of an initial distribution volume is widespread in the literature, in reality, a bolus dose of a drug is added to a stream of flowing blood, which mixes with other blood in the venous "tree", passes through the lungs and enters the organs of the body, including the heart, where it exerts its effects. The aim of this article is to develop a physiologically realistic model of this process based on indicator dilution principles, and to examine the predicted determinants of initial myocardial drug concentrations and effects after bolus administration. The validity of each component of the model is examined by comparison with a detailed set of physiological data from previously published experiments on myocardial pharmacokinetics and pharmacodynamics of lignocaine using a chronically instrumented sheep preparation.

AN "INDICATOR DILUTION" INTERPRETATION OF BOLUS KINETICS

The conventional compartmental approach to bolus kinetics recognizes that there is an initial period of "intravascular mixing" of drug with blood after bolus injection, but this process is generally ignored. However, the mechanisms of this process are well understood and can be described by indicator dilution principles[12] developed for the measurement of blood flow. For example, a classical method for measuring cardiac output is based on injection of indocyanine green (ICG) into the stream of venous blood flowing to the heart. A hypothetical "dye curve" in the blood downstream from the injection site (e.g the aorta) is shown in figure 1. Note that the

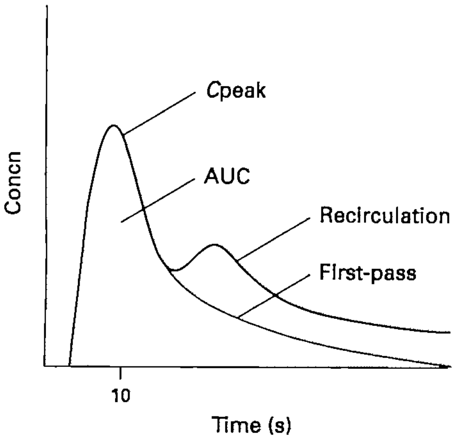

Figure 1 A hypothetical indicator dilution measurement of cardiac output. The first pass area under the curve (AUC) and peak concentration (*C*peak) are functions of cardiac output.

ICG concentration is initially zero, that there is a short lag between injection and first detection of ICG in blood, that there is a peak concentration (*C*peak), and that there is often a second peak because of recirculation of ICG. For flow measurements, various techniques are used to subtract the contribution of recirculation, leaving the first pass peak shown in figure 1, and cardiac output is determined from dose and the AUC of this peak. By rearranging the formula for cardiac output,[12] it is apparent that *C*peak is some function (f) of dose and cardiac output (Q_T).

$$C\text{peak}=f\,(\text{dose}/Q_T) \qquad (1)$$

In this article this indicator dilution analysis is expanded to examine the determinants of the shape of this peak for the first pass passage of a drug from the venous injection site to the heart. A central hypothesis is that although these indicator dilution principles are only applicable over a period of less than 30 s for an intravascular indicator such as ICG, they are applicable over a larger time scale for drugs that can leave the vascular space.

Methods

DEVELOPMENT OF THE MODEL AND PARAMETER ESTIMATION

On anatomical and theoretical grounds, the injected drug peak would be expected to pass though several sites in its passage to the target organ. These sites, together with the factors which could modify the shape of the peak at each site, are summarized in figure 2 and are examined in turn (with the sites referred to by a letter for direct comparison with fig. 2).

In common with all physiological models, this model is highly dependent on estimation of the large number of parameters comprising the model. For the purpose of illustration, these parameters were estimated for the local anaesthetic and anti-arrhythmic lignocaine, with the heart as the target organ, from previously reported studies of lignocaine using a conscious chronically instrumented sheep preparation.[2 4 13–15] Lignocaine causes significant reductions in myocardial contractility by a direct action on the myocardium,[16] probably by a direct action on Na–Ca exchange.[17]

Figure 2 An overview of the processes affecting the shape of a first pass drug peak from the venous injection site to a target organ. The panels on the left indicate the site of the various processes, while the panels on the right indicate the most important determinants of the process. The letters in brackets correspond to the appropriate sections in the text.

A. Venous injection site

General form. It was assumed that for an i.v. bolus, the dose is injected at a constant rate over a period T. The dose rate (given the variable name Doserate) is therefore as follows, where dose=total mass of drug given and t =time after the start of the dose:

$$\text{Doserate}=(\text{dose}/T) \quad \text{for } 0\leqslant t\leqslant T \qquad (2)$$

It was assumed that drug injection gives a square wave drug concentration peak in blood (*C*inj) immediately downstream of the injection site, whose shape depends on local blood flow (Qinjsite) and the dose rate:

$$C\text{inj}=(\text{Doserate}/Q\text{injsite}) \quad \text{for } 0\leqslant t\leqslant T \qquad (3)$$

This is a direct application of indicator dilution principles—the higher the flow, the lower *C*inj, and vice versa.[12]

Parameter estimates for lignocaine. A dose of 100 mg over 1 s was assumed for comparison with previously published work,[2 4 14] and the injection was assumed to be made into the caudal end of the inferior vena cava, with a flow of 1 litre min^{-1} (Upton RN, unpublished observations).

B. Vascular mixing and dilution with cardiac output

General form. After injection, this hypothetical square wave was assumed to travel from the injection site to the pulmonary artery, with two factors influencing its shape in transit. The first is progressive dilution with other venous blood until, by the pulmonary artery, the peak has been diluted with the entire cardiac output (Q_T). Assuming it is still in the form of a square wave and ignoring the time taken to travel from the injection site to the pulmonary artery, this concentration (Cunmixed) is given by the following equation, analogous to equation (3):

$$C\text{unmixed} = (\text{Doserate}/Q_T) \quad \text{for } 0 \leq t \leq T \qquad (4)$$

However, in reality, as shown in figure 1, the shape of this peak is not a square wave, but has been modified by factors such as dispersion during transit along the vessel[18] and the dynamics of the mixing process. It was assumed that these two processes occur sequentially, and that the shape of the peak after dispersion was equivalent to the passage of the square wave peak created by the first process (eqn (4)) through a small well mixed compartment through which the entire cardiac output flowed. The final concentration in the pulmonary artery (Cpa) was therefore given by the following equation, where Vmix was the volume of this hypothetical mixing compartment:

$$dC\text{pa}/dt = (Q_T/V\text{mix}) \times (C\text{unmixed} - C\text{pa}) \qquad (5)$$

Parameter estimates for lignocaine. A baseline value for cardiac output (Q_T) of 5.6 litre min^{-1} was assumed for comparison with previously published work.[2] The volume of the mixing compartment was estimated from studies of the time course of ICG concentrations in the pulmonary artery for various combinations of injection duration and cardiac output[19] using hybrid physiological modelling (appendix).

C. Passage through the lungs

General form. The kinetics of the passage of the peak through the lungs was represented as a single flow-limited compartment through which cardiac output flowed. An extraction term (Elung) was included to account for any metabolism or prolonged retention of drug in the lung. The resultant drug concentrations in arterial blood emerging from the lungs (Ca) were therefore given by the following equations, where Vlung=apparent volume of the lung and Ca′=a temporary variable:

$$dC\text{pa}/dt = (Q_T/V\text{lung}) \times (C\text{pa} - C\text{a}')$$
$$C\text{a} = C\text{a}'(1 - E\text{lung}) \qquad (6 \text{ and } 7)$$

Parameter estimates for lignocaine. Vlung and Elung were determined by hybrid physiological modelling (appendix) from studies using chronically instrumented sheep in which arterial blood was sampled rapidly together with measures of cardiac output.[14] Arterial drug concentrations in the first minute after injection were assumed to be a result of the first pass passage of the drug, and pulmonary artery concentrations were determined by application of the vascular mixing algorithm (eqns (2–5)).

D. Distribution to organs

Emerging from the lungs in arterial blood, the peak is distributed to all organs of the body (except the lung and those supplied by portal systems) in line with the fraction of cardiac output they receive. As outlined previously, this model addresses only the relevant target organ, as the fate of the drug in other organs does not influence the first pass peak in this organ.

F. Target organ kinetics

General form. The kinetics of the passage of the peak through the target organ was represented as a two-compartment model with membrane limited transfer from the first (nominally capillary) to the second (nominally parenchymal) compartment, where the transfer between the compartments was described by a permeability term (PS) in keeping with standard capillary permeability nomenclature.[20] If Qorgan is the blood flow of the target organ, and Vcap and Vpar are the apparent volumes of the nominal capillary and parenchymal compartments (concentrations Ccap and Cpar, respectively), the equations describing this system were as follows:

$$V\text{cap}\,(dC\text{cap}/dt) = Q\text{organ}\,(C\text{a} - C\text{cap}) + \text{PS}\,(C\text{par} - C\text{cap})$$
$$V\text{par}\,(dC\text{par}/dt) = \text{PS}\,(C\text{cap} - C\text{par}) \qquad (8 \text{ and } 9)$$

The advantage of this model is that a single-compartment, flow-limited model is a subset of its solution if PS is greatly exceeds Qorgan.

Parameter estimates for lignocaine. These were determined by hybrid physiological modelling (appendix) of studies with chronically instrumented sheep in which arterial (afferent for the heart) and coronary sinus (efferent) blood were sampled rapidly, in conjunction with measures of myocardial blood flow using an ultrasonic Doppler flow probe on the left mainstem coronary artery.[2] Initial trials showed a single flow-limited compartment model was preferred statistically, but was modified by the addition of a small first-order loss from the compartment (rate constant=k_{out}), which further improved the fit. Equation 8 was therefore modified as follows:

$$V\text{m}\,(dC\text{m}/dt) = Q\text{m}\,(C\text{a} - C\text{m}) - k_{\text{out}} \times C\text{m} \qquad (10)$$

where Vm and Cm =apparent volume of, and concentration in, the heart, respectively. Note that the heart concentrations of this equation are equivalent to those in the coronary sinus, that is there is venous equilibrium).

G. Target organ dynamics

General form. The relationship between the target organ drug concentration and a drug effect in that organ (Eorgan) was represented by a sigmoidal Emax relationship,[21] where Emax=maximum drug effect and EC_{50}=drug concentration at which 50% of Emax was achieved, n="Hill factor" controlling the steepness of the sigmoidal curve and "baseline" is the predrug magnitude of the effect:

$$E\text{organ} = ((E\text{max} \times C\text{organ}^n)/(\text{EC}_{50}{}^n + C\text{organ}^n)) + \text{baseline} \qquad (11)$$

This equation can describe several concentration effect relationships, as it includes linear and Emax models as approximate subsets of its solutions, and the organ concentration can be for either the capillary or parenchymal compartments.

Parameter estimates for lignocaine. These were determined using hybrid physiological modelling (appendix) of studies in which myocardial contractility and coronary sinus blood concentrations of lignocaine were determined after bolus injection of lignocaine in sheep.[4 14] Contractility was determined from the maximum rate of rise of left ventricular pressure (LV (dP/dt)max), which was measured using a left ventricular micromanometer catheter, and was expressed as the percentage reduction from baseline values. Initial trials showed that the sigmoid *E*max model had redundant parameters for this data set, and it was replaced with a linear effect model modified for a drug which caused reductions in the effect from a baseline value:

$$Em = \text{baseline}_{\text{eff}} - \text{slope}_{\text{eff}} \times Cm \qquad (12)$$

where *E*m=percentage reduction in myocardial contractility.

Equation solving

The model, as implied by equations (2–7), (10) and (12) was implemented as a set of differential equations in the "Scientist" modelling package (Scientist for Windows, Version 2, Micromath, Salt Lake City, UT, USA), although any differential equation solver would be suitable. In general terms, the model could be used to predict the shape of the peak at each of the sites shown in figure 2, and the resultant time course of a drug effect. Equation (3) is optional, and can be included if venous injection site concentrations are of interest.

Predictions of the model. The model was used to predict the peak first pass concentrations of lignocaine, and the times of these peaks, in venous, pulmonary artery and arterial blood and the heart after an injection of 100 mg over 30 s.

To examine to what extent the first pass peak contributed to initial distribution *in vivo*, the predictions of the model were compared with the experimental data reported previously for lignocaine pharmacokinetics and pharmacodynamics in the heart.[4 14] The former accounted only for the first pass passage of the drug peak, while the latter *in vivo* measurements by definition included the first pass peak and the contribution of recirculation.

The sensitivity of the model to changes in various parameters was also analysed. Of the parameters shown in figure 2, it was thought that injection rate, cardiac output and target organ blood flow were the parameters that were most likely to vary in a "clinical" setting. The effect of changing these was summarized concisely by their effect on the coronary sinus concentrations alone as the simple linear nature of the pharmacodynamic model (eqn (12)) implies that the effect follows the same time course as the coronary sinus concentrations, and the kinetic model for the heart (eqn (10)) implies that the heart concentrations were proportional to the coronary sinus concentrations. To examine the effect of blood flow, cardiac output was increased or decreased by 50% (from 5.6 to 8.4 and 2.8 litre min^{-1}, respectively). In a separate set of simulations, myocardial blood flow was increased or decreased by 50% (from 0.122 to 0.183 and 0.061 litre min^{-1}, respectively). In a final set of simulations, cardiac output and myocardial blood flow were increased together by 50%, and then decreased together by 50%. To examine the effect of injection rate, simulations were performed with the duration of injection set at values of 1, 10, 30, 60, 120 or 240 s.

Results

PARAMETER ESTIMATES FOR LIGNOCAINE

The values of the parameters of the model are summarized in table 1; all estimated parameters were determined with a high degree of confidence. Although the vascular mixing component of the model was entirely empirical, there was good agreement between the model and the published data,[19] as shown in figure 3. The parameters for lung kinetics gave a good description of the observed arterial concentrations emerging from the lung (fig. 4), but the fit was improved by removing a small (0.08 min) lag from the measured concentrations consistent with previous observations of injection site to lung transit time.[19] The membrane-limited model of the target organ collapsed to a single-compartment, flow-limited model on fitting. This latter model was able to describe coronary sinus concentrations within the confidence limits of the measured data; a better fit was obtained by adding a small first-order loss from the compartment (fig. 5). This may have a physiological basis, as loss of lignocaine from the surface of the heart into fluid (and presumably tissues) surrounding the heart has been documented.[22] The linear pharmacodynamic model gave an adequate description of the relationship between the measured coronary sinus concentration and effect data (fig. 6).

Table 1 Parameters of the model for lignocaine in the heart

Parameter	Description	Value used (SD)	Source
Dose	Total dose	100 mg	Assumed
T	Duration of injection	1 s	Assumed
$\dot{Q}$inj	Local blood flow at the injection site	1 litre min^{-1}	Assumed
$\dot{Q}$T	Cardiac output	5.6 litre min^{-1}	Measured directly
*V*mix	Volume of the hypothetical venous mixing compartment	0.255 litre	Hybrid modelling
*V*lung	Apparent volume of the lung	1.06 (0.021) litre	Hybrid modelling
*E*lung	Apparent first pass extraction by the lung	0.32 (0.03)	Hybrid modelling
$\dot{Q}$m	Blood flow through heart	0.122 (0.021) litre min^{-1}	Measured directly
*V*m	Apparent volume of the heart	0.450 (0.03) litre	Hybrid modelling
*k*out	First order loss rate constant from the heart	0.062 (0.04) litre min^{-1}	Hybrid modelling
$\text{Slope}_{\text{eff}}$	Slope of linear pharmacodynamic model	11.08 (0.56)	Hybrid modelling
$\text{Baseline}_{\text{eff}}$	Baseline of linear pharmacodynamic model	3.16 (1.17)	Hybrid modelling

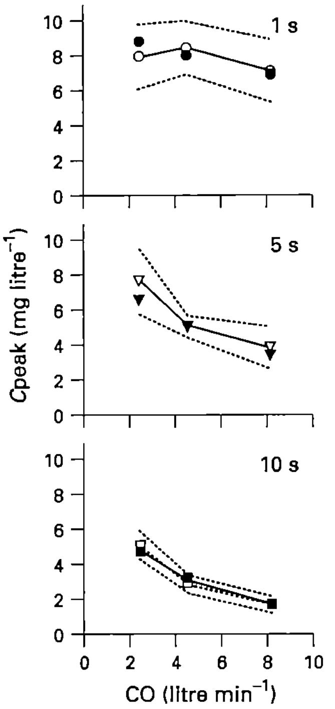

Figure 3 Predictions of the venous mixing component of the model (eqns (2–5)) using a value of *V*mix of 255 ml compared with the observations of Upton and Huang[19] on the initial mixing of indocyanine green with venous blood. The panels show the relationship between peak concentration (*C*peak) and cardiac output (CO) for injections rates of 1 s (top), 5 s (middle) and 10 s (bottom). Similar results were also found for the area under curve of the peak. In each case, the open symbols indicate the observed values, the dashed lines their 95% confidence limits and the filled symbols, predicted values.

PREDICTIONS OF THE MODEL

The major prediction of this model was that bolus drug injection produces a large concentration peak in venous blood which is progressively attenuated by various kinetic processes in transit to the target organ (table 2). It was also shown that the predicted first pass peak contributed a large component to the experimentally determined coronary sinus lignocaine concentrations (and therefore myocardial effect) in the first 10 min after the dose (fig. 7). Of the parameters examined, changes in cardiac output alone produced the largest changes in peak coronary sinus concentrations (fig. 8), with the highest cardiac output associated with the lowest concentration. Conversely, changes in myocardial blood flow alone also produced large changes in peak coronary sinus concentrations (fig. 8), but with the highest flow associated with the highest concentration. When cardiac output and myocardial blood flow were increased or decreased simultaneously, the opposing factors were cancelled such that there was a less dramatic change in coronary sinus concentrations (fig. 8). However, the lower flow state was associated with a longer duration of action and a slight delay in the time of the maximum concentration. Altering injection rate from 1 to 240 s produced large changes in coronary sinus concentrations (fig. 9), but for injection rates in the range 1–30 s, the changes were only minor.

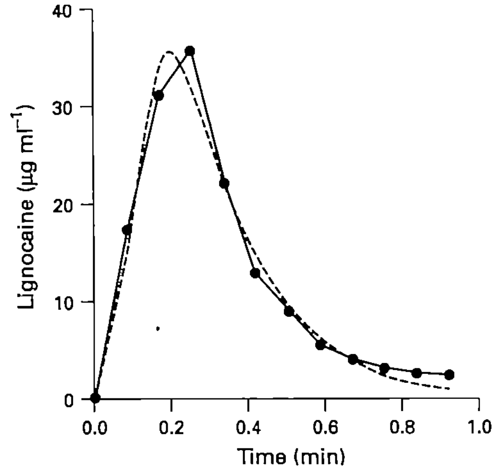

Figure 4 Predicted (—) first pass arterial concentrations of lignocaine (based on eqns (2–7)) emerging from the lungs in the first minute compared with those measured *in vivo* by Huang and colleagues (●).[14]

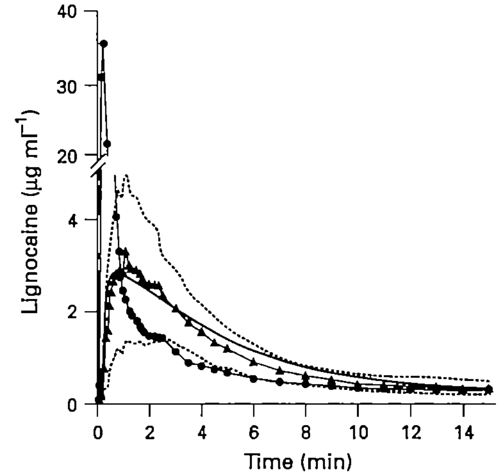

Figure 5 Predicted (–) coronary sinus concentrations of lignocaine based on equation (10) compared with those measured by Huang and colleagues[14] (▲) shown with their 95% confidence limits (dotted lines). Measured arterial concentrations (●) are shown for comparison.

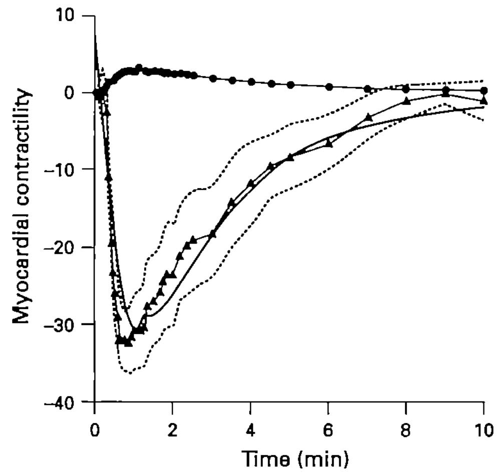

Figure 6 Predicted (–) effect of lignocaine on myocardial contractility (reduction from baseline) based on equation (12) compared with that measured by Huang and colleagues[4] (▲) shown with their 95% confidence limits (dotted lines). Measured coronary sinus concentrations (●) are shown for comparison. The units of the vertical axis are arbitrary.

Table 2 Peak first pass concentrations of lignocaine at various sites after injection of 100 mg over 30 s

Site	Peak concentration (mg litre^{-1})	Time of peak (min)
Venous injection site	35.7	0–0.5
Pulmonary artery	35.7	0.5
Aorta	22.1	0.5
Heart	2.6	0.9

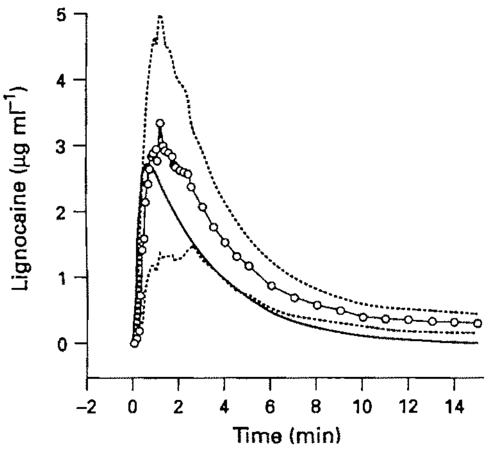

Figure 7 Predicted (–) first pass peak of lignocaine in coronary sinus blood after i.v. injection of 100 mg over 1 s compared with measured concentrations (○) and 95% confidence limits (dotted lines), which by nature includes the contribution caused by recirculation. The first pass peak makes a large contribution to the heart concentrations of lignocaine in the first 10 min after injection.

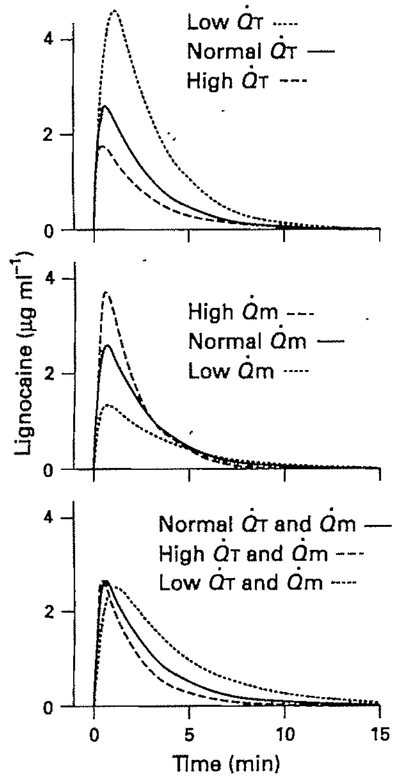

Figure 8 Effect of cardiac output (Q_T) and myocardial blood flow (Q_m) on the first pass peak of lignocaine in the heart, as given by coronary sinus blood concentrations. The upper panel shows Q_m held constant, with 50% increases or decreases in Q_T. The middle panel shows Q_T held constant, with 50% increases or decreases in Q_m. The lower panel shows Q_T and Q_m varying in unison.

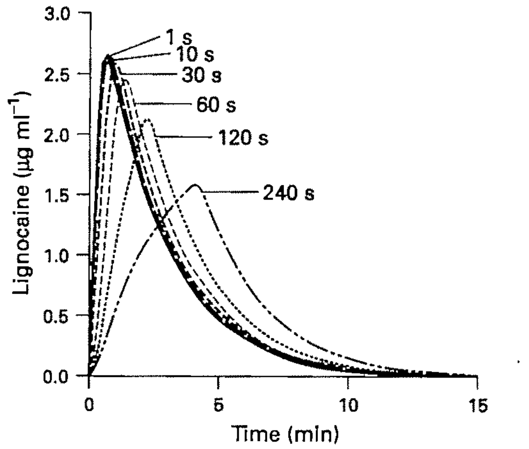

Figure 9 Effect of altering duration of injection of the same dose of lignocaine on its first pass peak in the heart, as given by coronary sinus blood concentrations.

Discussion

It was shown that initial drug kinetics after an i.v. bolus injection were consistent with the concept of the formation of a concentration "peak" of drug in the flow of venous blood, which is attenuated by vascular mixing, and lung and target organ kinetics as the drug is transported from the injection site to the target organ. The first passage of the peak through the heart was the principal component of the myocardial concentrations of lignocaine for 10 min after injection. Injection rate, cardiac output and myocardial blood flow were important determinants of the first pass peak. While there are deficiencies in the model, it is clear that it provides a useful framework for studying initial distribution processes and their physiological determinants.

OTHER APPROACHES TO INITIAL DRUG DISTRIBUTION

The limitations in the interpretation of the initial distribution volume and half-life terms of conventional compartmental models have been raised by previous workers. Chiou[7 8] showed the initial volume of distribution depended on the time that the first blood sample was obtained (i.e. the time allowed for "initial mixing"), and that there was considerable variation in the literature of the reported initial volume of distribution for the same drug. Indeed, the initial volume was related linearly to the time of the first blood sample. The role of the lung in first pass kinetics was also considered by this author.

There have been three general approaches to addressing these limitations, which will be discussed in turn. First, some workers have developed revised compartment models. Niazi[23] advanced the concept of volume of distribution as a variable that changes with time. However, the fundamental compartmental description of a drug added to a volume rather than a flow remains. By rapid sampling of arterial blood from 1 min after injection of thiopentone and an intravascular marker, Henthorn, Avram and Krejcie[24] were able to show that thiopentone and the marker had a common central volume in humans.

Subsequent work in dogs with continuous sampling showed that this common volume was the first pass peak emerging from the lungs, and led to the construction of a physiological model of the process.[9 25] The vascular mixing component of this model is essentially the same as that proposed in the current model. They differ in that their model incorporates a two-compartment model of the remainder of the body, and was validated against arterial concentrations rather than target organ drug concentrations and effects. The model of early alfentanil disposition proposed by Wada and Ward[26] also shares similar features with the present model, and was validated by hybrid modelling of literature data.

Second, to avoid a compartmental description of the initial distribution process, stochastic recirculatory models of the process have been proposed.[27–30] This approach greatly improves the ability of these methods to describe early blood drug concentrations compared with compartmental models and includes the role of cardiac output in initial distribution. Some disadvantages include lack of a physiological description for the "transport function", validation against limited data sets, and neglecting the significant effect of cardiac output on the whole body transport function.

Third, there have been occasional theoretical and experimental reports of an indicator dilution approach to initial drug distribution in which the drug is considered to be added to a flow rather than a volume. The most significant theoretical contribution is that of Crawford.[31] It was proposed that rapid i.v. injection of a drug resulted in a "slug" of drug in blood which travelled for two or three circulations of the blood before being dispersed. In his analysis, Crawford essentially analysed the fate of the slug at each of the sites shown in figure 2, although many of his calculations were by necessity crude. Experimental studies reflecting indicator dilution principles include that of Crankshaw, Rosler and Ware,[32] who studied the relationship between peak arterial concentrations of thiopentone and duration of bolus injection.

ASSUMPTIONS AND LIMITATIONS OF THE MODEL

The present model is essentially a refinement of the approach of Crawford,[31] with the important addition of a detailed set of experimental data with which to validate the model. As the construction of any model requires making simple assumptions, these assumptions are examined. The most significant of these concerns the nature of the vascular mixing process (i.e. the relationship between drug injection and peak entering the lungs). Although the nature of this process has been described previously,[33] this type of analysis is relatively complex.[18] The approach used in the present model was essentially empirical and ignored intravascular transit time from the inferior vena cava to the pulmonary artery, which in the sheep was 4–9 s.[19] Fortunately, despite this, the predicted results closely matched those observed for a variety of injection rates and cardiac outputs. Note that the volume of the vascular mixing compartment is independent of the physicochemical properties of a drug, and that the injection site blood flow (Qinj) is not a determinant of the final concentration in the pulmonary artery.

The assumption of single-compartment, flow-limited kinetics in the lungs is also a simplification, as the lung probably behaves in a similar manner to a chromatographic column.[34] Again, any lag introduced by the passage of the peak from injection site to the lung was ignored in the final model (although accounted for in the curve-fitting process). The contribution of intravascular transit time of blood through the lung is likely to be small. The concept of an apparent first pass "retention" by the lung, whether a result of metabolism or an apparent extraction caused by "deep" distribution, is well supported by the literature,[10] particularly for basic drugs where the retention can be greater than 90%.

While more sophisticated models, such as dispersion models,[35] may be a more physiological description of myocardial drug kinetics, it seems likely that the essentially flow-limited nature of myocardial uptake of lignocaine[36] is retained in the present model.

The assumption that the target organ drug concentration is the sole determinant of the magnitude of target organ drug effects should also be made with caution, as this relationship does not hold if there is "tight" homeostatic control over the process affected by the drug (e.g. arterial pressure) or acute tolerance caused by receptor down regulation. For the lignocaine data, there is some suggestion of homeostatic control of myocardial contractility affecting the myocardial concentration–effect relationship as evidenced by the slight discrepancy between the model and data after 8 min in figure 6.

In general terms however, comparison of the model with these data (figs 3–6) suggests that addressing these assumptions would help "fine tune" the model, but that the assumptions are not sufficient to compromise the relevance of its quantitative and qualitative predictions.

IMPLICATIONS OF THE MODEL

While i.v. bolus administration of lignocaine is not common clinically, this drug was chosen because of the extensive published data set suitable for validating the model. However, it was felt that the general principles applicable to this drug and the heart would apply to any relatively lipophilic drug that acted in a well-perfused target organ.

CONTRIBUTION OF FIRST PASS DISTRIBUTION

Recirculation is often thought of as a rapid phenomenon, which is probably based on a knowledge of the behaviour of intravascular indicators. This study showed that recirculation of drugs takes considerably longer, and that the first passage through the heart can account for a large component of the myocardial concentrations and effects of lignocaine for the first 10 min after injection (the remainder is a result of recirculated drug entering the heart). This is consistent with the report of van Rossum and colleagues[37] that the mean transit time of many drugs in the body is of the order of 10 min. Note that the heart, which has a high relative perfusion, is often thought of as an organ in which recirculation occurs rapidly. It seems likely that the dominance of the first pass peak in initial organ concentrations is not a function of a failure of drug to recirculate, but rather indicates that the recirculated concentrations are much less than the first pass concentrations in this period.

SENSITIVITY ANALYSIS

While it has been noted previously that some pharmacokinetic parameters are related to cardiac output,[38] our work reinforces the fact that cardiac output is fundamental to the kinetics of bolus administration.[27,29] Indeed, it is more appropriate to consider bolus injection of a drug as an "indicator dilution" experiment "in reverse" rather than the traditional addition of a drug to a hypothetical volume. The concepts of the latter approach are difficult to reconcile with the actual physiological events. The role of myocardial blood flow was also highlighted by the model. This information provides greater insight into the effects of pathophysiological changes in blood flow distribution on dose requirements.

The model also provides insight into the effect of injection rate on initial drug concentrations and effects. An interesting feature of figure 9 is that the damping action of the lung and vascular mixing result in little difference in the time course of initial heart concentrations for injection rates between 1 and 60 s. If applicable to other drugs, this may indicate why in clinical practice the rate of bolus drug injection preferred by different clinicians is variable within this range. The model can also be used to test the relative merits of injection rate profiles other than a "square wave". We are currently pursuing this in our laboratory.

Appendix

HYBRID PHYSIOLOGICAL MODELLING FOR PARAMETER ESTIMATION

This refers to the process whereby the parts of the system of interest are represented as a structural model, while the remainder is represented as empirical functions.[26,39] The complete model is validated by independently validating each of its component submodels in turn. Each submodel is treated as a hybrid of the complete model for which only its inputs and outputs are of interest. For example, for modelling myocardial kinetics the submodel was based on a modified single flow-limited compartment. The input functions were arterial concentrations and myocardial blood flow. These were fitted to empirical equations (a sum of exponentials for the blood concentrations and a fifth-order polynomial for the blood flow data). The structure and origin of the input function is irrelevant provided it provides an excellent fit for the input data. The output (coronary sinus concentrations) of the structural submodel was then curve-fitted to optimize its parameters by a least squares method based on the maximization the "model selection criteria (MSC)", which is essentially the Akaike information criterion scaled to normalize for data sets (Y) of different magnitudes (Micromath Scientific Software, Salt Lake City, UT, USA):

$$\mathrm{MSC}=\ln\left(\frac{\sum_{i=1}^{n} W_i(Y_{\mathrm{obs}_i}-\overline{Y_{\mathrm{obs}}})^2}{\sum_{i=1}^{n} W_i(Y_{\mathrm{obs}_i}-Y_{\mathrm{cal}_i})^2}\right)-\frac{2p}{n}$$

where w_i=a weighting term and p=number of parameters.

The input and output functions of each of the hybrid submodels discussed in the text are summarized in table 1a.

Table 1a Input and output functions of each of the hybrid submodels discussed in the text

Submodel	Input function(s)	Output function
Vascular mixing (eqns (2–5))	Dose rate	Pulmonary artery ICG concentrations
Lung kinetics (eqns (2–7))	Dose rate and pulmonary artery concentrations	Arterial concentrations
Myocardial kinetics (eqn (10))	Arterial concentrations myocardial blood flow	Coronary sinus concentrations
Myocardial dynamics (eqn (12))	Coronary sinus concentrations	Reductions in myocardial contractility

Measurement of cardiac output by transoesophageal Doppler echocardiography in anaesthetized horses: comparison with thermodilution

L. E. YOUNG, K. J. BLISSITT, D. H. BARTRAM, R. E. CLUTTON, V. MOLONY AND R. S. JONES

Summary

In order to determine if transoesophageal Doppler echocardiography could be used to estimate cardiac output in anaesthetized horses, we have compared the technique with estimations of cardiac output by thermodilution in eight healthy adult thoroughbreds. Measurements of aortic blood flow velocity were made by high pulse repetition frequency (HPRF) and continuous wave (CW) Doppler echocardiography from a 3.5-MHz transoesophageal probe. Cardiac output was increased during the study by administration of dobutamine, providing a range of cardiac output measurements by thermodilution from 15.0 to 64.4 litre min^{-1}. Estimations derived from CW Doppler overestimated cardiac output compared with thermodilution (bias=4.0 litre min^{-1}). Estimations from HPRF Doppler echocardiography more closely reflected measurements obtained by thermodilution (bias=0.7 litre min^{-1}). Limits of agreement between the techniques were similar for both modes of insonation (HPRF=−7.7 to 9.1 litre min^{-1}, CW=−4.9 to 12.8 litre min^{-1}). There were significant differences in bias between both Doppler techniques and thermodilution for individual horses. As a result, for any individual horse, limits of agreement between the techniques were closer (HPRF=±6.4 litre min^{-1}, CW=±7.6 litre min^{-1}). We conclude that transoesophageal echocardiography provided an alternative, effective and non-invasive method for measurement of cardiac output in anaesthetized horses. (*Br. J. Anaesth.* 1996; **77**: 773–780)

Key words

Measurement techniques, cardiac output. Measurement techniques, thermodilution. Measurement techniques, transoesophageal echocardiography. Horse.

Halothane anaesthesia in horses produces cardiac depression and systemic hypotension.[1 2] These adverse cardiovascular effects have been implicated in the higher incidence of intraoperative morbidity[3 4] and mortality[5] in horses compared with other species. Cardiovascular monitoring during equine anaesthesia is restricted generally to recording heart rate, rhythm and arterial pressure.[6 7] Information on the mechanisms of cardiovascular dysfunction which occur during general anaesthesia in this species has been limited by the invasive nature of the monitoring techniques that were available previously. The availability of echocardiography has removed many of these limitations; the shift in frequency which occurs when ultrasound is reflected from a moving object can be used to calculate blood flow velocity. Doppler echocardiography measures blood velocity in targeted areas of the heart and great vessels. Integration of the resultant velocity–time curve gives a value which represents the summated distance travelled by the blood with each cardiac cycle. If this value is multiplied by the cross-sectional area of the vessel and heart rate, an estimate of cardiac output is obtained.[8]

Cardiac output in horses is measured most frequently by thermodilution or dye dilution techniques,[9–12] although the need for cardiac catheterization and the associated risks tend to limit the procedure to research applications. Recent studies have shown that transoesophageal echocardiography is feasible in anaesthetized horses and that the technique provides parallel alignment between ultrasound beam and aortic blood flow,[13] a necessary criterion for accurate estimations of velocity by Doppler echocardiography. In this study we aimed to assess correlation and agreement between transoesophageal Doppler assessment of aortic flow and cardiac output determined by thermodilution in horses during halothane anaesthesia. Aortic flow velocity–time curves were obtained by both pulsed and continuous

wave methods of insonation and limits of agreement of both techniques were compared.

Materials and methods

EXPERIMENTAL PREPARATION

The study conformed to the UK Animals Act (Scientific Procedures, 1986, Home Office licence No. PPL 60/1674). We studied eight thoroughbred horses (four mares and four geldings), aged 3–6 yr and weighing 490–600 kg (mean 545 kg). The horses were clinically normal, housed indoors and kept in moderate work. Food, but not water, was withheld from the horses from 20:00 on the day preceding the study. On the morning of the procedure, the skin overlying the left jugular vein was anaesthetized by surface application of EMLA cream (Astra, Kings Langley, UK) followed 40 min later by subcutaneous administration of 2% lignocaine. A 13-gauge over-the-needle catheter (Intaflon, Vygon, Cirencester, UK) was placed in the jugular vein through the desensitized skin.

In a padded induction area, the α_2 adrenoreceptor agonist, romifidine 100 μg kg^{-1} (Sedivet, Boehringer Ingelheim, Bracknell, UK) was administered i.v. via the jugular catheter. Anaesthesia was induced 5 min later with ketamine 2.2 mg kg^{-1} i.v. The trachea was intubated with a 25- or 30-mm cuffed tracheal tube which was adapted to allow collection of gas from its distal end.[14] Initially the horses breathed spontaneously from a large animal circle system supplied with halothane in 100% oxygen. When an adequate depth of anaesthesia was obtained the horse was transferred to a padded operating table and ventilation was controlled using intermittent positive pressure (Large Animal Anaesthesia Control Centre, North American Drager, Telford, PA, USA). Initially, ventilatory frequency and tidal volume were set to 10 bpm and 7 litre, respectively. A commercial blood-gas analyser was used to monitor arterial Pa_{CO_2} from arterial blood samples obtained from the great metatarsal artery. Minor adjustments of the ventilator controls were used to maintain Pa_{CO_2} at 4.6–6.0 kPa. End-tidal halothane concentration was measured from end-expired gas sampled from the end of the tracheal tube using a calibrated anaesthetic gas monitor (Servo Gas monitor 120, Siemens PLC, Cumbernauld, UK). The vaporizer was adjusted throughout the study to maintain an end-tidal concentration of 0.9%.

INSTRUMENTATION

Echocardiography

Immediately after induction of anaesthesia a 3.5-MHZ transoesophageal echocardiographic probe (Vingmed Sound, Horten Norway) was inserted into the oesophagus via the ventral nasal meatus. The probe was purpose-made for equine use and was constructed from a 160-cm human colonoscope.[13] The probe was used in conjunction with a Vingmed CFM 700 echocardiograph. The maximum depth for 2-dimensional (2-D) and M-mode imaging was 24 cm. The frame update rate was 19–55 frames per second, depending on the sector angle selected and the imaging depth. The maximum depth for colour flow mapping and spectral Doppler studies was 20 cm. Doppler studies were conducted using the transducer in high pulse repetition frequency (HPRF) and continuous wave (CW) mode, with ultrasound emitted at a frequency of 2.5 MHz.

The probe was advanced into the oesophagus through the external nares until a long axis view of the left ventricular outflow tract and aorta were obtained by 2-D echocardiography.[13] The HPRF Doppler sample volume was then guided to the centre of the vessel above the aortic valve in the area where colour flow Doppler echocardiography demonstrated the fastest flowing blood.[15] Continuous wave ultrasound was directed in the same axial position down the whole length of the aorta and left ventricular outflow tract. When the sample volume had been positioned the transducer was dedicated to acquisition of Doppler data. Adequate alignment with aortic blood flow was assumed from the clarity of the audible signal and when a complete velocity envelope was obtained.[16]

Thermodilution

After the horses had been positioned in left lateral recumbency on a padded operating table, two 8-F percutaneous catheter introducer sets (Haemaquet-Steri Lock, Bard Ltd, Crawley, UK) were inserted into the right jugular vein, using a percutaneous Seldinger technique. A 150-cm long thermodilution catheter (od=2.31 mm) (Columbus Instruments, Columbus, OH, USA) was inserted via one introducer until pressure recordings from its distal port indicated that it was situated in the pulmonary artery.

The thermodilution catheter had a proximal port, but high internal resistance to injectate flow precluded its use for thermal indicator administration during thermodilution studies. A separate catheter was made from a 200-cm length of polyethylene tubing (800/200/225 (od=1.6 mm), Portex Arterial Medical, South Gate, London, UK) for delivery of the thermal indicator. The atrial end of the catheter was sealed closed by heat from a Bunsen burner. Five holes (diameter=0.5 mm) were pierced along the final 4 cm of catheter body, using a hot 14-gauge i.v. needle. The open end of the tubing was then placed over the body of a 14-gauge i.v. needle, the hub of which was connected to a pressure injector. The pressure injector was driven by compressed air at an operating pressure of 30 pounds per square inch (psi) which ensured that the charge of 45 ml of injectate was delivered within 3 s, as recommended by Ganz and Swan.[17] A test injection of 45 ml of 0.9% saline solution was then made via the catheter using the pressure injector to ensure that flow occurred evenly through the side holes and that injection was completed within 3 s. The catheter was sterilized using ethylene oxide.

The sterile catheter was pre-filled with heparinized saline (5 u. ml^{-1}) and introduced into the right atrium by advancing it down the second percutaneous introducer set. To position the catheter it was connected to a pressure transducer, and advanced down the introducer until a characteristic right ventricular pressure waveform was obtained. It was then withdrawn until the pressure trace indicated it had just re-entered the right atrium. With the catheter in position a test injection with 45 ml of 0.9% saline was carried out while observing a 2-D image of the right atrium obtained by transthoracic echocardiography. Correct catheter placement was confirmed by the sudden short-lived appearance of multiple echogenic speckles in the right atrium, coinciding with injection.

A Cardiomax II model 85 cardiac output computer (Columbus Instruments, Columbus, OH, USA) was used to measure cardiac output by thermodilution. Previous work had demonstrated that satisfactory dilution curves could be obtained from standing horses when 45 ml of saline at room temperature were injected using a pressure injector through the separate catheter in the right atrium.[18] Normal saline stored at room temperature was used as the thermal indicator for all horses. During these studies, ambient temperature varied between 14.4 and 19.2 °C. The dilution curves from each estimation were displayed on a chart recorder allowing visual inspection of each curve. Only measurements from dilution curves with a characteristic fast attack slope and a slower return to baseline were acceptable.

DATA COLLECTION

Data from HPRF and CW transoesophageal echocardiographic studies were measured by a single observer from video-taped images of aortic blood flow velocity spectra. Cardiac output was calculated from aortic velocity spectra using the equation:

$$\text{cardiac output} = \text{VTI} \times \text{aortic cross-sectional area} \times \text{heart rate}$$

where VTI=area under the velocity spectra (velocity time integral).

Area under individual velocity envelopes (VTI) was measured using software within the echocardiograph. The modal velocity delineated by the brightest line in the velocity envelope was used to delineate the area beneath spectra derived from HPRF studies, while maximum velocity was used for CW envelopes. Doppler signals from five consecutive cardiac cycles were measured for each cardiac output estimation and mean VTI and heart rate for the group of five cycles were calculated. Heart rate was calculated from the five corresponding RR intervals from the electrocardiogram of the ultrasonograph.

The cross-sectional area of the aorta was calculated from the aortic diameter measured from a 2-D long axis image of the aorta at the level of the sino-tubular junction.[14] In this view, the anatomical boundaries of the vessel are parallel to the ultrasound beam, resulting in considerable lateral broadening of the vessel walls.[19] According to the recommendations of Hatle and Angelsen[16] vessel diameter was measured perpendicular to the long axis of the aorta by a line joining the middle of the band of echoes corresponding to the vessel walls. To obtain each diameter, three measurements were made during systole from three consecutive cardiac cycles and an average value obtained. The 2-D images needed for measurements were recorded on video tape immediately before each set of cardiac output measurements.

Mechanical ventilation was discontinued before each cardiac output measurement, and the ventilator was switched off in the expiratory pause just after an inspiratory cycle was complete. Injection of thermal contrast was initiated by pressing the pressure injector foot pedal, to coincide with the second "p" wave of the ECG after the ventilator was stopped. The record facility of the VHS video recorder on the Vingmed CFM 700 was also activated.

Each estimate of cardiac output by Doppler echocardiography was compared with a mean of three closely successive thermodilution estimates. In accordance with the manufacturer's instructions, at least 60 s were allowed to elapse between consecutive thermodilution measurements. The first of the three injections coincided with video recording of aortic velocity waveforms by HPRF Doppler echocardiography. The insonation mode of the Doppler echocardiograph was then changed from HPRF to CW between the first and second thermodilution estimations. Doppler spectra were not recorded coincident with the final thermodilution measurement in the sequence.

EXPERIMENTAL PROCEDURE

A group of five sets of three thermodilution measurements with associated Doppler recordings constituted a set of data for each horse at each cardiac output level. After the first group of five measurements were made, dobutamine 2 μg kg^{-1} min^{-1} was infused via the jugular catheter. After 15 min cardiac output estimations were repeated. The infusion rate was then increased to 4 μg kg^{-1} min^{-1}, and after another 15 min, the final set of cardiac output data were collected. At the start of each data acquisition period, 2-D images were recorded for measurement of aortic diameter. If the dobutamine infusion produced any disturbance to cardiac rhythm that was considered to be a risk to the horse, the infusion was discontinued and the procedure was terminated.

STATISTICAL ANALYSIS

Agreement between the two techniques was assessed using the methods of Altman and Bland.[20] The mean difference between cardiac output estimations made by Doppler techniques and thermodilution (defined as bias) was determined for all pairs of measurements (ΔCO_p). The SD of these differences ($\text{SD}\Delta CO_p$) was then used to determine limits of agreement for the pooled data (defined as bias $\pm 2\text{SD}\Delta CO_p$). The analysis of Altman and Bland[20] is designed for single pairs of measurements originating from independent subjects. As in many previous studies, in this study multiple measurements of cardiac output were made in a small number of individuals. To further distinguish within-subject and between-subject variation in bias and limits of agreement, the following additional analysis was performed: differences in bias between horses were assessed using one-way analysis of variance. The mean difference between techniques and the variance of the differences were determined for each horse. A within-subject SD of the difference was determined from the mean of the variances from individual horses (SDΔCO_w). The limits of agreement between techniques for an individual were then determined ($\pm$2SDΔCO_w). Measurements of aortic diameter before and during dobutamine infusion were compared by paired Student's *t* test. Although it is recognized that calculation of product moment correlation coefficient (*r*) is not an appropriate method to assess agreement between measurement techniques,[21] the linear relationships between the HPRF and CW derived cardiac output estimates and those from thermodilution were determined. The analysis was performed to allow comparison of our data with similar studies in other species in which calculation of *r* was the sole method of data analysis.

Results

A total of 95 comparisons of cardiac output estimations from Doppler and thermodilution techniques were made for both insonation modes. Only five estimates were obtained from one horse, as supraventricular tachycardia (heart rate 186 beat min^{-1}) commenced 10 min after infusion of dobutamine 2 $\mu g\ kg^{-1}\ min^{-1}$. Supraventricular tachycardia (heart rate >150 beat min^{-1}) occurred in three more horses during infusion of dobutamine 4 $\mu g\ kg^{-1}\ min^{-1}$ before cardiac output estimations had been made.

The range of cardiac output values measured by thermodilution during the study was 14.1–65.4 litre min^{-1} with a mean value of 26.7 litre min^{-1}. When agreement between the two methods was assessed for the pooled data, estimates by CW Doppler echocardiography tended to overestimate those by thermodilution on average (bias) by 4.0 litre min^{-1} (fig. 1). Estimates derived from HPRF spectra agreed more closely with the invasive method, showing a positive bias of only 0.7 litre min^{-1} (fig. 2). The SD of the differences between Doppler-derived estimates and thermodilution (SDΔCO_p) was slightly less for HPRF estimates (4.2 litre min^{-1}) than for those derived from CW (4.4 litre min^{-1}). As a result the limits of agreement (bias$\pm$2SDΔCO_p) were slightly narrower for HPRF derived estimates (−7.7 to 9.1 litre min^{-1}) than for CW estimates (−4.9 to 12.8 litre min^{-1}). These limits of agreement represented −34% to 28% of mean cardiac output

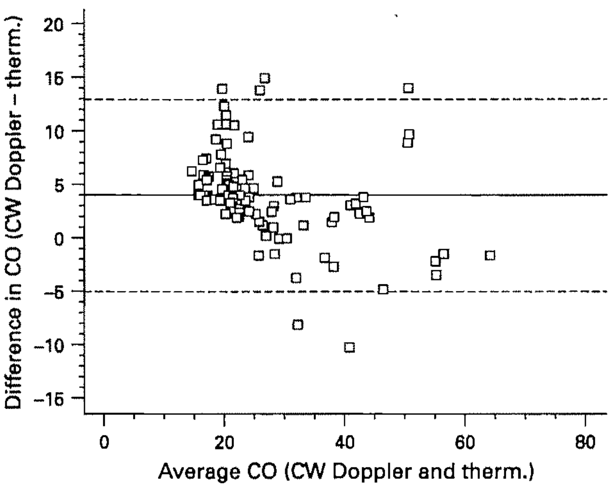

Figure 1 Differences in cardiac output (CO) measured by CW Doppler echocardiography and the mean of three consecutive thermodilution (therm.) measurements *vs* the average of the two techniques. CO is measured in litre min^{-1}.The bias, 4.0 litre min^{-1}, is indicated by the solid line and the upper and lower limits of agreement, −4.9 to 12.8 litre min^{-1}, by the broken lines.

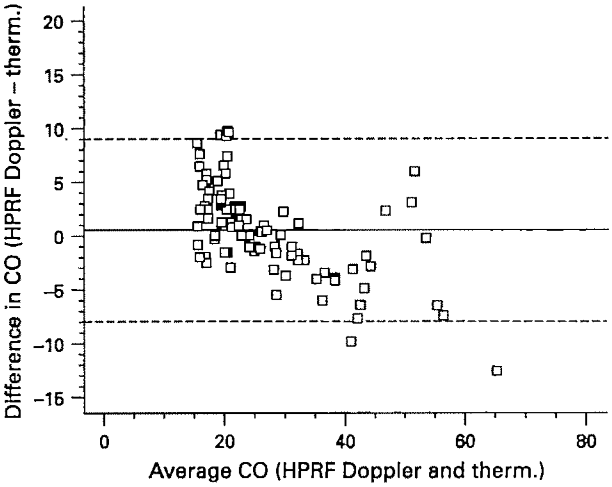

Figure 2 Differences in cardiac output (CO) measured by HPRF Doppler echocardiography and the average of three consecutive thermodilution (therm.) measurements *vs* mean of the two techniques. CO is measured in litre min^{-1}. The bias, 0.7 litre min^{-1}, is indicated by the solid line and the upper and lower limits of agreement, −7.7 to 9.1 litre min^{-1}, by the broken lines.

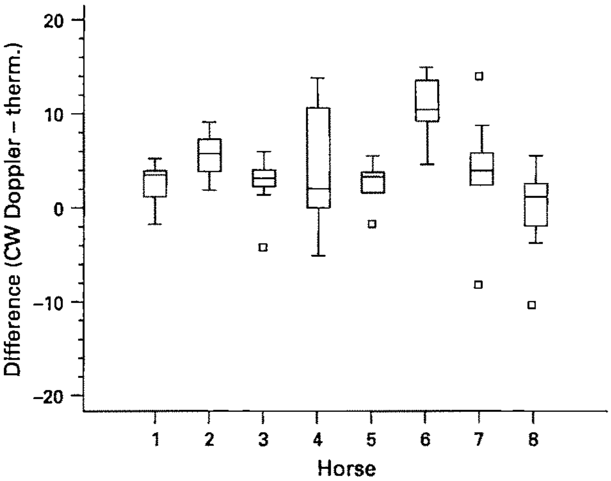

Figure 3 Box and whisker plot of differences in cardiac output (CO) measured by CW Doppler echocardiography and the average of three consecutive thermodilution (therm.) measurements in each of eight anaesthetized horses. Differences in CO are measured in litre min^{-1}. The horizontal dividing line in each box is the median value, the upper and lower border of each box are the upper and lower quartiles. Maximum and minimum values within one interquartile range are depicted by the vertical whiskers. Outlying data are shown by points. Number of measurements per horse: horse 1=15; horse 2=15; horse 3=15; horse 4=10; horse 5=10; horse 6=5; horse 7=10; horse 8=15.

Table 1 Median (range) values for aortic diameter, measured from 2-D echocardiography. Paired Student's *t* test revealed no significant difference in vessel diameters during the infusion periods (P=0.95). Mean difference from control=difference between diameters at each infusion rate of dobutamine and control value

	Control 0.9% halothane	Dobutamine 2 $\mu g\ kg^{-1}$	Dobutamine 4 $\mu g\ kg^{-1}\ min^{-1}$
No. of horses	8	7	5
Aortic diameter (cm)	7.10 (6.53–7.58)	7.07 (6.48–7.50)	7.16 (6.48–7.65)
Difference from control (cm)		−0.01 (−0.14 to 0.12)	0.07 (−0.30 to 0.4)

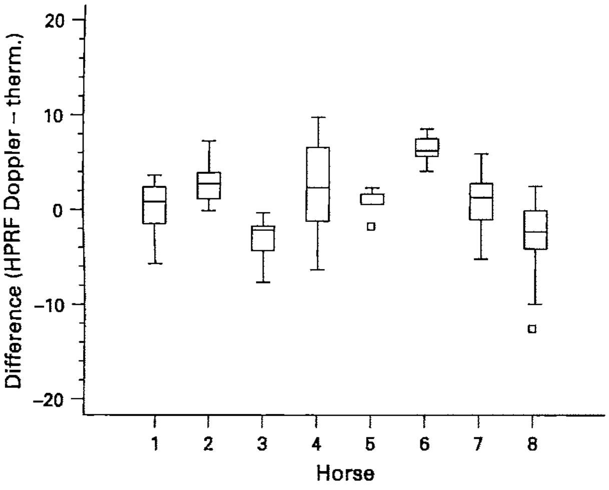

Figure 4 Box and whisker plot of differences in cardiac output (CO) measured by HPRF Doppler echocardiography and the average of three consecutive thermodilution (therm.) measurements in each of eight anaesthetized horses. Differences in CO are measured in litre min^{-1}. The horizontal dividing line in each box is the median value, the upper and lower border of each box are the upper and lower quartiles. Maximum and minimum values within one interquartile rangs are depicted by the vertical whiskers. Outlying data are shown by points. for HPRF estimates and −18% to 48% for CW estimates. The product moment correlation coefficients for the two methods of insonation were 0.92 (CW) and 0.93 (HPRF).

The calculated bias between estimates from both insonation modes and thermodilution differed significantly between horses (P<0.0001) (figs 3, 4). When mean bias was calculated as the average of values calculated for each individual horse, bias for CW estimates was 4.4 litre min^{-1} and that for HPRF, 1.3 litre min^{-1}. The SD of bias between horses were 3.0 litre min^{-1} (HPRF) and 3.1 litre min^{-1} (CW). The limits of agreement between techniques for an individual horse were ±6.4 litre min^{-1} (HPRF) and ±7.6 litre min^{-1} (CW), representing ±23% and ±28% of mean cardiac output, respectively.

There were no significant changes of clinical importance in aortic diameter with any infusion rate of dobutamine(table 1).

Discussion

Estimations of cardiac output by transoesophageal Doppler echocardiography showed a close linear relationship with measurements obtained by thermodilution. In addition, the limits of agreement between the two techniques, expressed as a percentage of mean cardiac output, were narrower in this study than those determined for humans. In human studies, blood flow across the mitral and pulmonary valves, not the aortic valves, was used most commonly to obtain velocity spectra for measurement of VTI.[22-26] Mitral and pulmonary blood flows were chosen because of superior alignment with the ultrasound beam from an oesophageal transducer in humans. The poor correlations (0.65–0.80) and wider limits of agreement obtained in these studies probably reflect difficulties in measurement of mitral and pulmonary valve areas.[27] In biped species the descending aorta runs parallel to the oesophagus, therefore it is difficult to align aortic blood flow and ultrasound from an oesophageal transducer. One group of workers compared cardiac output calculations from human aortic blood flow profiles obtained by transoesophageal echocardiography with measurements by thermodilution.[28] Because of the wide angle of incidence between the beam and the descending aorta, the device was calibrated by calculating a constant from a second transcutaneous Doppler transducer placed in the suprasternal notch. Using this technique these workers obtained a correlation of 0.91 between the two techniques and limits of agreement within 26% of mean cardiac output. Recently, a similar study failed to reproduce these results, obtaining limits of agreement between the two techniques of −44% to +36% of mean cardiac output by thermodilution.[29] Because of poor agreement between methods, the authors concluded that the technique could not replace estimation of cardiac output by the thermodilution method. Difficulty in aligning with aortic blood flow and poor results when pulmonary or mitral blood flow is used have ensured that transoesophageal Doppler echocardiography is not used widely for monitoring cardiac output in anaesthetized humans.

In horses and other quadrupeds, the anatomical relationship of aorta and oesophagus differs from humans, and a transducer within the oesophagus can be aligned with blood flow in the ascending aorta. This probably explains why the agreement and linear relationships obtained by transoesophageal techniques in horses are better than those reported in human studies. The correlations obtained in the equine transoesophageal studies were similar to those obtained in many human studies using transthoracic echocardiography.[30-33] Cardiac output estimations using transthoracic Doppler echocardiography are now used widely in human medicine,[8] and it is generally accepted that estimates derived from Doppler echocardiography agree as well with the standard methods (Fick principle, thermal and dye dilution) as the standard methods agree with each other.[34]

Similar studies have been performed in standing horses when cardiac output estimations from aortic velocity spectra derived by transthoracic echocardiography were compared with measurements made by thermodilution.[18] Overall the linear relationship and limits of agreement of the two techniques were consistently worse from the transthoracic studies in standing horses than was found in our transoesophageal study in anaesthetized horses. Poor alignment with aortic blood flow would consistently underestimate volumetric flow, but have little effect on the limits of agreement. In previous transthoracic studies in standing horses the narrowest limits of agreement were -12.9 to 11.8 litre min^{-1},[35] compared with -7.7 to 9.1 litre min^{-1} in this study. As the technique of vessel area measurement was similar in both methods, the narrower limits of agreement in the transoesophageal study must reflect more consistent alignment with blood flow in individual horses. The reference long axis 2-D image obtained from transoesophageal echocardiography that was used to guide placement of the Doppler sample volume was repeatable in every horse and the image did not appear to vary between individuals.[13] Marked inter-subject variation in correlation between transthoracic Doppler measurements of cardiac output and those from the thermodilution and Fick methods has been reported previously in humans.[36] Analysis of inter-subject variation in this study revealed significant differences in bias and limits of agreement in individual horses. This variability of bias could result from altered alignment between ultrasound beam and aortic flow, or from inaccurate vessel area measurement in individual subjects. In a study in humans,[36] this inter-subject variability remained after flow area was removed from the calculation of cardiac output, corroborating the findings of other workers that there was marked variation in alignment between ultrasound beam and aorta in individual patients during transthoracic echocardiography.[37 38] The within-subject variation caused by the requirement to realign the ultrasound transducer with blood flow for each repeated measurement in an individual during transthoracic echocardiography should also be minimized in transoesophageal echocardiography, as once in position, the transducer remains fixed in the oesophagus. Unfortunately other workers have not analysed within-subject variation in bias and limits of agreement in previous comparison studies, and therefore it is not possible to compare the equine data with other species. However, data from this study indicated the important effects of patient variation on bias and agreement between techniques, a situation which is likely to occur in humans in addition to horses.

It is generally accepted that inaccuracy in the determination of flow area is the major source of error in the Doppler technique.[31 39] Because of difficulties in its accurate measurement, it has been suggested by some workers that velocity time integral (VTI) alone can be used to reflect changes in stroke volume,[39] as a strong relationship has been demonstrated between the two variables.[33 38] The product of VTI and heart rate (minute distance) has also been proposed as an accurate and repeatable indicator of cardiac output.[40 41] McLennan and coworkers[41] showed that *in vitro* the method detected changes in flow rate of 33% with 95% certainty, a sensitivity which is similar to that of the thermodilution technique *in vitro* under conditions of pulsatile flow. In our studies, no significant measurable differences in aortic diameter were found at different cardiac output levels so that omission of vessel area from flow calculations in anaesthetized horses may be worthy of consideration. It is possible that failure to detect changes in diameter may reflect the poor sensitivity of the 2-D ultrasound measurement method, rather than indicating that aortic area is unaffected by stroke volume. Omission of vessel area measurement would also remove another source of inter-subject variation. Use of standard area measurements similar to the normograms used for aortic diameter derivation in human studies[42] may have further narrowed the limits of agreement determined for the pooled data in this study.

Continuous wave Doppler echocardiography has been used for computation of aortic flow in humans, using both transthoracic[32 33] and transoesophageal techniques.[23 28] Most of the early studies reported in the medical literature were performed using CW insonation as accuracy of range gated (HPRF) Doppler was poor until the advent of fast Fourier transform analysis.[32] In humans, the size of the HPRF ultrasound transducer limited access to the suprasternal window, the echocardiographic view providing most consistent and accurate alignment with aortic blood flow. This practical difficulty also encouraged use of the CW method. In the CW technique, maximum velocity is used to delineate the bounds of the flow velocity envelope for calculation of the velocity time integral. The spectra produced from CW studies are complex as they are formed from velocity information from along the depth of the beam. It is therefore possible that maximum velocity comes from a site other than in the aorta. Theoretically, maximum velocity should occur at the narrowest point in the circulation, which for the aorta and left ventricular outflow tract should be the aortic valve annulus. It has been shown that maximum velocity is less sensitive to poor angulation than the modal velocity, used in the HPRF studies,[43] and this may explain why some authors found better agreement between Doppler and thermodilution when CW rather than HPRF insonation was used.[44] In this study the magnitude of the bias was increased when spectra were derived using CW Doppler echocardiography. As maximum, rather than median, velocity is used to obtain VTI this is not surprising. However, the limits of agreement between Doppler and thermodilution measurements were also slightly wider when the CW mode of insonation was used. The reason for this is unclear, as use of the maximum velocity should produce a positive bias, but have no effect on the agreement between the two techniques. As the transoesophageal echocardiography probe was not moved between recording alternate HPRF and CW velocity spectra, the wider limits of agreement cannot be attributed to altered alignment. It is possible that in some individuals the CW technique detected a maximum velocity that came from the left ventricular outflow tract or from accelerated flow around the aortic arch providing a further source of between-subject variation.

In conclusion, we have demonstrated that transoesophageal Doppler echocardiography provided a useful alternative to thermodilution for measurement of cardiac output in anaesthetized horses. This infers that transoesophageal echocardiography may provide an alternative method of cardiac output estimation in other smaller quadruped species in whom cardiac catheterization and instrumentation is difficult or inappropriate.

Effect of halothane, isoflurane and desflurane on lower oesophageal sphincter tone

D. CHASSARD, J. P. TOURNADRE, K. R. BERRADA, B. BRYSSINE AND P. BOULETREAU

Summary

We have studied the effects of volatile anaesthetics on lower oesophageal sphincter (LOS) tone in three groups of eight pigs allocated randomly to receive end-tidal concentrations of 0.5, 1.0 and 1.5 MAC of desflurane, isoflurane or halothane for 15 min. LOS and oesophageal barrier pressures (BrP = LOSP − gastric pressure) were measured using a manometric method. The decrease in BrP paralleled the decrease in LOS pressure and was significant at 0.5 MAC for isoflurane and at 1.0 MAC for halothane. At 1.5 MAC, BrP values were approximately 62% of baseline values for halothane, 37% for isoflurane and 83% for desflurane. Inter-group comparisons showed that BrP did not differ at baseline and at 0.5 MAC. At 1.0 MAC the effect of isoflurane on BrP was significantly different from desflurane ($P < 0.001$) and halothane ($P < 0.02$) whereas the effect of desflurane on BrP was not significantly different from halothane. At 1.5 MAC the effect of isoflurane on BrP was significantly different from desflurane ($P < 0.01$) and halothane ($P < 0.05$) whereas the effect of desflurane on BrP was not significantly different from halothane. We conclude that desflurane maintained BrP and this may be clinically important in patients at high risk of regurgitation. (*Br. J. Anaesth.* 1996; **77**: 781–783)

Key words
Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane. Anaesthetics volatile, desflurane. Gastrointestinal tract, lower oesophageal sphincter. Pig.

Induction and maintenance of anaesthesia can be achieved in patients breathing spontaneously by administration of volatile anaesthetic agents. Halothane is used widely in children for induction of anaesthesia via a face mask[1] (a situation with a high risk of pulmonary aspiration[2]). Halothane, isoflurane and desflurane are used for maintenance of anaesthesia.[3] The lower oesophageal sphincter (LOS) can be altered by anaesthetics. It has been reported previously that thiopentone,[4] opioids, neuromuscular blocking agents and benzodiazepines[5] affect the competency of the LOS. During anaesthesia it is important to be aware of these effects because a decrease in LOS tone is associated with an increased risk of regurgitation.[6 7] Therefore, it is clinically relevant to evaluate the effects of these anaesthetics on LOS tone. Anaesthetics which decrease lower oesophageal pressure (LOSP) decrease the efficacy of the oesophageal barrier pressure (BrP = LOSP − gastric pressure) leading to regurgitation of gastric contents during the perioperative period.[4] Therefore, this study was designed to compare the effects of halothane, isoflurane and desflurane on LOS tone in pigs using a manometric method.

Materials and methods

After obtaining approval from our institutional animal care committee, we studied 24 pigs (weight 22–25 kg). Ketamine 8 mg kg^{-1} was given i.m. as premedication and propofol 2 mg kg^{-1} i.v. for tracheal intubation. Neuromuscular blocking agents were not given during the study. The lungs of the pigs were ventilated mechanically by an Ohmeda ventilator incorporated into a Modulus CD integrated anaesthetic machine (Madison, WI, USA) with a tidal volume of 15 ml kg^{-1} at a ventilatory frequency of 12–15 bpm. Ventilation was adjusted to obtain normocapnia at baseline (end-tidal carbon dioxide partial pressure of 4.6–5.6 kPa), the fractional inspired concentration of oxygen was set at 0.60 and pulse oximetry (Sp_{O_2}) was monitored continuously using the Ohmeda oximeter attached to the tail of the pig. After measurement of baseline values for LOS pressures, pigs were allocated randomly to one of three groups: halothane ($n = 8$), isoflurane ($n = 8$) or desflurane ($n = 8$). The inhaled anaesthetic was introduced and end-tidal concentrations were maintained at 0.5, 1 and 1.5 MAC for 15 min. End-tidal concentrations of each volatile agent were fixed according to previous studies in pigs. End-tidal concentrations of 0.5, 1.0 and 1.5 MAC were 0.60%, 1.20% and 1.80% for halothane,[8] 1.05%, 2.10% and 3.10% for isoflurane[9] and 5%, 10% and 15% for desflurane.[10] Halothane, isoflurane and desflurane were vaporized using Ohmeda vaporizers (Fluotec 5, Isotec 5 and Tec 6; Steeton, WY, USA). End-tidal anaesthetic concentrations were measured using a calibrated respiratory gas analyser (Ohmeda, Madison, WI, USA).

LOS PRESSURE MEASUREMENT

LOS and gastric pressures were measured with the pig supine using perfused polyethylene catheters connected to pressure transducers. Transducers were zeroed to the mid-chest position and calibrated using a water column before each measurement. Pressures were recorded using a multiple channel recording system. The first readings for LOSP were obtained 8–10 min after induction of anaesthesia. The method for LOS pressure measurements has been described previously[11]: catheters were perfused constantly with water by a low-compliance infusion pump at 1 ml min^{-1} (compliance 200 mm Hg min^{-1}). The high-pressure zone was detected with a pull-through technique.

DATA ANALYSIS

Results were expressed as mean (SD). Statistical significance was determined by one-way analysis of variance for repeated measures for intra-group comparisons and by two-way analysis of variance for repeated measures for inter-group comparisons (CSS statistica; Statsoft, Tulsa, OK, USA). When significance was found, a *post hoc* test (Newman–Keuls test) was used to determine where the differences lay. $P < 0.05$ was considered statistically significant.

Results

The effects of halothane, isoflurane and desflurane on lower oesophageal pressures and barrier pressures are shown in figure 1 and table 1.

Despite the fact that the mean values of LOSP in the isoflurane group were 24% and 22% greater than the mean values in the desflurane and halothane groups, respectively, there was no significant difference in LOSP at baseline between the three groups (halothane 19.4 (5.6) mm Hg; isoflurane 24.1 (6.4) mm Hg; desflurane 19.7 (3.8) mm Hg). Both halothane and isoflurane produced a dose-related decrease in LOSP whereas desflurane had no effect. This decrease was apparent at 1 MAC for halothane and isoflurane whereas none of the three anaesthetics decreased LOSP significantly at 0.5 MAC. At 1.5 MAC, LOSP values were approximately 72% of baseline values for halothane, 56% for isoflurane and 86% for desflurane.

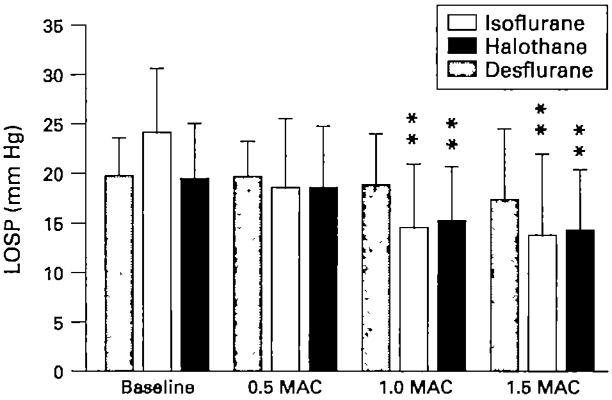

Figure 1 Effects of isoflurane, halothane and desflurane on lower oesophageal sphincter pressure (LOSP) at equipotent concentrations (mean, SD). $**P < 0.01$ compared with baseline.

Table 1 Effects of isoflurane, halothane and desflurane at 0.5, 1 and 1.5 MAC on oesophageal barrier pressure (mm Hg = lower oesophageal sphincter pressure – gastric pressure) (mean (SD)). $*P < 0.05$, $**P < 0.01$ compared with baseline; $†P < 0.05$ compared with desflurane and halothane (see text for P values < 0.05)

	Baseline	0.5 MAC	1.0 MAC	1.5 MAC
Isoflurane	15.4	10.2	5.6	5.8
	(5.0)	(5.2)*	(3.8)**†	(5.4)**†
Halothane	13.1	12.4	9.4	8.3
	(5.5)	(6.2)	(5.0)*	(5.2)**
Desflurane	12.0	11.4	11.1	10
	(5.8)	(4.9)	(5.8)	(6.0)

BrP decreased in parallel with the decrease in LOSP and this was significant at 0.5 MAC for isoflurane and 1.0 MAC for halothane. At 1.5 MAC, BrP values were approximately 62% of the baseline values for halothane, 37% for isoflurane and 83% for desflurane. Inter-group comparisons showed that BrP was not different at baseline and at 0.5 MAC. At 1.0 MAC the effect of isoflurane on BrP was significant different from desflurane ($P < 0.001$) and halothane ($P < 0.02$) whereas the effect of desflurane on BrP was not significantly different from halothane. At 1.5 MAC the effect of isoflurane on BrP was significantly different from desflurane ($P < 0.01$) and halothane ($P < 0.05$) whereas the effect of desflurane on BrP was not significantly different from halothane.

Discussion

We have demonstrated that a marked reduction in BrP occurred at 1 and 1.5 MAC of isoflurane and halothane whereas no changes were seen during administration of desflurane at equipotent MAC values.

Volatile anaesthetics have variable effects on LOSP and BrP. One study in humans reported that halothane and enflurane in combination with nitrous oxide decreased LOSP.[12] However, nitrous oxide was introduced before halogenated agents and it induced a more significant decrease in LOS pressure than after the introduction of halogenated agents. In addition, both agents were given at an inspiratory concentration of 2% without monitoring end-tidal anaesthetic concentrations. Giving the same inspiratory concentration of enflurane and halothane leads to different end-tidal concentrations (1.0 MAC is 0.29% for halothane in 50% nitrous oxide in oxygen and 0.57% for enflurane in 50% nitrous oxide in oxygen for humans). In contrast, one study performed in dogs showed that 1 h of exposure to 0.5–1% enflurane had no effect on LOSP.[13] However, this study was inconclusive because the MAC of the halogenated agent was not corrected for species (1.0 MAC of enflurane in dogs is 2.10%).

MAC values greater than 1.5 were impossible to obtain because of the design of the desflurane vaporizer. The Tec 6 vaporizer is manufactured for use in humans. MAC 2.0 is 12–14% in humans whereas it is approximately 20% in swine. The Tec 6 vaporizer does not allow inspiratory concentrations greater than 18%. Despite this, desflurane did not cause a significant decrease in BrP pressure at 1.5 MAC whereas isoflurane and halothane decreased BrP pressure at 1.0 MAC. There is no previous study on the effect of desflurane on BrP pressure to compare with our data. Failure of desflurane to affect BrP cannot be attributed to the difference in blood–muscle gas equilibration because BrP was measured after end-tidal concentrations of anaesthetic had been stable for 15 min. In humans, the blood–muscle partition coefficient of desflurane (2.02) is lower than those of halothane (3.4) and isoflurane (2.92).[14 15] Therefore, difference in equilibration between LOS muscle and end-tidal gas concentrations cannot explain the difference found. The absence of an effect of desflurane on LOS could be because of sympathetic nervous system activation which is known to occur when desflurane is administered alone.[16] In clinical practice, we usually use nitrous oxide to maintain anaesthesia. Because this agent decreases LOSP, its use may have attenuated the LOS responses observed during desflurane anaesthesia. Confirmation of this hypothesis requires a different study design.

The choice of anaesthetic technique and animal are probably important factors in the study of the effects of inhaled anaesthetics on LOS. Thus potential criticisms of our study design include the use of ketamine and propofol before administration of inhalation anaesthesia. However, ketamine is assumed not to influence LOSP.[11] In pigs, we showed recently that ketamine i.m. followed by propofol at a higher dose than that used in this study (5 mg kg^{-1} instead of 2 mg kg^{-1}) had no effect on LOS.[17] In addition, all animals received the same induction dose. As in humans, the musculature of the porcine LOS consists of smooth muscle fibres.[18] Moreover, it has been shown that the porcine LOS exhibits responses to various stimuli similar to that in humans.[19] Therefore, these results obtained in pigs could be applied to humans.

The lungs of all animals were ventilated mechanically before measurement of baseline LOS pressure and before introduction of the halogenated agents. This allowed us to obtain constant tidal volumes throughout the study. This is important because the pressure at the oesophago–gastric junction is created not only by contraction of the smooth muscles of the LOS but also by the striated muscle of the crural diaphragm.[20] All changes in pulmonary volumes could influence LOS recording. However, LOS pressures were measured at the end of expiration, a technique which minimizes the influence of respiration on LOS pressure recording.[4] Therefore, to compare LOS pressure from baseline to 1.5 MAC, the lungs of pigs were ventilated mechanically during baseline measurements.

In summary, in this animal study we have shown that in contrast with desflurane, both halothane and isoflurane decreased oesophageal barrier pressure. This finding may be clinically important in patients with a high risk of regurgitation.

Distinguishing cerebrospinal fluid from saline used to identify the extradural space

B. A. Z. EL-BEHESY, D. JAMES, K. F. KOH, N. HIRSCH AND S. M. YENTIS

Summary

Because of the potential seriousness of unrecognized dural puncture during the performance of extradural analgesia and the widespread use of normal saline for the "loss of resistance" technique, it is important to differentiate between cerebrospinal fluid (CSF) and saline dripping from the extradural needle. During insertion of lumbar drains in 10 neurosurgical patients, we first identified the extradural space using saline for loss of resistance. Temperature (using the back of the gloved hand), pH, glucose and protein (using urine testing sticks) were tested by a blinded observer for ability to distinguish saline aspirated from the extradural space from CSF aspirated on establishing the dural puncture. Temperature, glucose and protein were independently 100% accurate in distinguishing saline from CSF. One saline sample had a pH value greater than 7 compared with nine CSF samples. We conclude that simple bedside testing for temperature, glucose, protein and pH accurately distinguished between CSF and saline used to identify the extradural space. (*Br. J. Anaesth.* 1996; **77**: 784–785)

Key words
Anaesthetic techniques, extradural. Cerebrospinal fluid. Spinal cord, extradural space.

Accidental dural puncture is a recognized complication of extradural anaesthesia.[1] It is important to recognize this immediately, as subsequent injection of local anaesthetic intended for the extradural space may produce unexpectedly extensive blocks.[2] Although dural puncture is indicated usually by free flow of cerebrospinal fluid (CSF) through the extradural needle, this may not always be the case, and CSF may drip only slowly from the needle hub.[3] If saline is used to identify the extradural space, using a "loss of resistance" technique, the anaesthetist may be uncertain if any clear fluid dripping from the needle is saline or CSF. Properties of CSF which have been used to identify it include temperature, glucose and protein content, pH and the absence of turbidity on mixing with thiopentone; however, these tests have been compared in relation to distinguishing CSF from local anaesthetic, for example after extradural anaesthesia.[4] In addition, the effect of injecting saline into the extradural space on the properties mentioned above has not been determined. As most dural punctures occur during placement of the extradural needle,[1] and saline is used more widely for loss of resistance than local anaesthetic solutions,[1] it would be more relevant clinically to compare these methods of distinguishing CSF from saline aspirated from the extradural space through the needle.

Methods and results

After obtaining medical Ethics Committee approval and informed consent, we studied patients undergoing neurosurgery that required insertion of a lumbar drain as part of the procedure (or as the actual procedure). General anaesthesia was induced according to the individual anaesthetist's preference (except in two patients who had insertion of lumbar drains only during local anaesthesia). The patient was then turned to the left lateral position and the extradural space identified with a 14-gauge lumbar drain needle using loss of resistance to saline. On identifying the extradural space, 10 ml of saline were injected in the space and 0.2–1.0 ml was aspirated into a 2-ml syringe. If none of the saline could be aspirated, another 5 ml of saline were injected and if still none could be aspirated the patient was excluded from the study. After aspirating saline, the needle was advanced through the dura and a similar volume of CSF was aspirated in another 2-ml syringe. Passage of the subarachnoid drain and further management continued as standard practice. The syringes were labelled as A or B according to randomly assigned instructions, and handed to a second investigator who was unaware of the allocation. The blinded investigator then immediately tested the temperature of a drop of the contents of each syringe on the back of his gloved hand to decide if it felt "warm" or "cold". Both fluids then were tested for glucose,

protein and pH using urinary testing sticks. Data were analysed using Fisher's exact test.

Eighteen patients were recruited into the study. Eight were excluded because it was impossible to aspirate sufficient saline after an additional 5 ml of saline. The remaining 10 comprised six females and four males, mean age 45 (range 25–63) yr. The neurosurgical procedures carried out included five trans-sphenoidal hypophysectomies, two lumbar drain insertions, one transoral odontoidectomy, one transoral C1 biopsy and one excision of cervical neurofibroma.

The results of temperature and stick testing are shown in table 1. None of the saline samples tested positive for glucose or protein or was warm to the touch, compared with all 10 of the CSF samples ($P=0.0001$, two-tailed Fisher's exact test). One saline sample had a pH value >7, compared with nine CSF samples ($P=0.0001$, two-tailed Fisher's exact test). There were no incidences of bloody tap.

Comment

Anaesthetists have used different techniques for distinguishing saline from CSF during identification of the extradural space using saline for the loss of resistance test. Observation of free flow of CSF alone has been shown to be unreliable.[3] In this study, despite its small size, we have demonstrated that subjective testing for temperature of the fluid and simple bedside objective testing using urinary testing sticks can reliably distinguish CSF from saline, even when obtained from the extradural space. Although dural puncture in our study was produced with a 14-gauge needle, there is no reason to suppose the results would be different if a 16-gauge needle had been used.

Although saline normally does not contain glucose or protein, a positive test may theoretically result from blood contamination or CSF diffusion to the extradural space.[5] Our study showed that even on injection of saline into the extradural space it still tested negative for both. Earlier studies that tested for glucose to differentiate CSF from local anaesthetic injected previously into the extradural space showed that positive testing for glucose did not necessarily imply that the tested fluid was CSF.[4,5] The consistent result of glucose testing in our study may represent different properties of local anaesthetic solutions and saline, or because saline was aspirated immediately after injection, thus not providing sufficient time for contamination with glucose from the extradural space or vessels. Alternatively, injection of 10 ml of saline into the extradural space may have diluted any contamination with glucose or protein. However, of interest is the fact that even after injection of this volume and an additional 5 ml, eight patients had to be excluded because insufficient volume of saline could be aspirated. We have no explanation for the variation in saline pH values obtained; the same manufacturers' products (both saline and testing strips) were used in all cases. It is possible that for estimation of pH using testing strips, subjective judgement as to which of the manufacturer's supplied colour bands best matches the sample's indicator colour is less reliable than with the other tests.

Finally, it is important to emphasize that this study showed that testing for only temperature, glucose, protein and pH were useful at the time of identifying the extradural space with the needle. The use of aspiration testing and the test dose of local anaesthetic after insertion of the catheter are still mandatory.

Use of a pneumatic tourniquet induces changes in central temperature†

J.-P. ESTEBE, A. LE NAOURES, Y. MALLEDANT AND C. ECOFFEY

Summary

Twenty-six patients requiring orthopaedic surgery were anaesthetized and oesophageal and rectal temperature were monitored continuously. Twenty patients requiring a pneumatic tourniquet were allocated prospectively to one of two groups: passive group (Pg) with reflective insulation on all available skin surface ($n=10$) and forced group (Fg), with active warming by a forced air system ($n=10$). Six patients without a tourniquet were used as a reference group (Rg). The pneumatic tourniquet time was similar in the tourniquet groups. During tourniquet inflation, oesophageal temperature increased with time. The difference was significant compared with the reference group at approximately 20 min. At about 30 min, oesophageal temperature in group Fg was significantly higher than that in group Pg. After tourniquet deflation, temperature decreased transiently. Changes in rectal temperature were similar but delayed significantly. A mechanism to explain the increase in core temperature during pneumatic tourniquet use remains unclear. A redistribution mechanism by cooling of the blood in a cold and vasodilated limb could explain the decrease of temperature after tourniquet deflation. (*Br. J. Anaesth.* 1996; **77**: 786–788)

Key words
Surgery, orthopaedic. Equipment, tourniquets. Temperature, monitoring.

The use of a pneumatic tourniquet for "bloodless-field" surgery is common in orthopaedic practice. However, its use is known to cause many adverse effects[1]: it has been noted that central temperature increases progressively in paediatric patients while the limb tourniquet is inflated,[2 3] but not in adults. On the other hand, a significant decrease in core temperature occurs abruptly after tourniquet release.[4]

In order to clarify temperature changes during tourniquet use, we have compared oesophageal and rectal temperatures during and after a prolonged period of tourniquet inflation in adults.

Methods and results

We studied 26 male adult patients (range 18–45 yr), ASA PS I–II, undergoing orthopaedic surgery. The study was approved by the local Ethics Committee and informed written consent was obtained from each patient. Patients were healthy and none was taking medication. They had no evidence of infection and were not given blood or blood products.

Twenty of 26 patients were scheduled prospectively for fixation of a single lower extremity fracture using the pneumatic tourniquet for a prolonged period (>60 min). Patients with multiple trauma or short periods of tourniquet inflation were excluded. After induction of general anaesthesia, an 8-cm tourniquet cuff was applied around the upper thigh of the operative limb. For exsanguination, the leg was elevated for 5 min at 45° before tourniquet inflation. Arterial flow was occluded with a pressure of 350 mm Hg. For ethical reasons, the reference group (Rg) was studied without randomization and served only as a standard reference. Successively, six patients were included in group Rg: three patients undergoing the same surgery but with tourniquet contraindications (skin lesion or excessive oedema) and three patients where a tourniquet was not indicated (intramedullary nailing of shaft fractures of the tibia).

Premedication was not given and anaesthesia was induced with thiopentone 4–6 mg kg^{-1} i.v. and fentanyl 3 $\mu g\ kg^{-1}$ i.v. No neuromuscular blocking agents were used. After tracheal intubation, the lungs were ventilated mechanically with 60% nitrous oxide in oxygen in a semi-closed system without any volatile anaesthetic. Additional doses of fentanyl (5–10 $\mu g\ kg^{-1}\ h^{-1}$) or thiopentone (1.3–2.5 mg $kg^{-1}\ h^{-1}$) were given as needed. A minimal infusion of lactated Ringer's solution at room temperature was given. Ambient temperature was controlled at 20 °C. For all patients, routine monitoring included electrocardiography, pulse oximetry, end-tidal carbon dioxide and arterial pressure measurements.

Twenty patients were allocated randomly to one of two groups using a sealed envelope technique. In

†Presented in part at the European Society of Anaesthesiologists, London, June 1996.

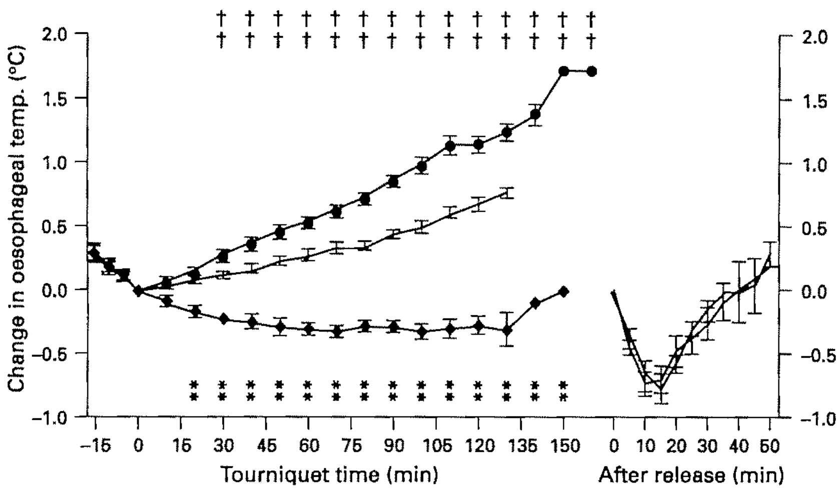

Figure 1 Change in oesophageal temperature (mean, SEM) in patients with a tourniquet undergoing active warming (group Fg) (●) or passive insulation (group Pg) (–) and in patients without a tourniquet (group Rg) (◆). Time zero for temperature reference was tourniquet inflation time whereas core temperature was measured continuously as soon as possible after induction (for the control group time zero was surgical incision). After tourniquet release a new time zero for temperature reference was the time of release of the tourniquet. $^{**}P<0.01$ group Rg *vs* group Pg; $^{\dagger\dagger}P<0.01$ group Pg *vs* group Fg.

the passive group (group Pg, $n=10$) the available skin surface was covered with passive reflective insulation material. In the forced group (group Fg, $n=10$) patients were covered by an active warming system (forced air system: Bair Hugger 500E Augustin medical SA at 38 °C with full body 300 blanket). Group Rg was treated with the same active warming procedure. As soon as possible after induction, core temperature was measured simultaneously in the lower third of the oesophagus and rectally with thermistor probes (Hewlett Packard 21075 A probe). Both temperatures were monitored (Hewlett Packard 78364 C monitor) continuously until the end of surgery. There was no intervention which could have changed the temperature.

Data are expressed as mean (SEM) and analysed using ANOVA with repeated measures. Regression analysis and the Mann–Whitney *U* test, and the Kruskal-Wallis test for non-parametric data, as appropriate, were used to determine significance ($P<0.05$).

Patient characteristics were comparable for all three groups. Tourniquet times were similar (106 (7) min and 115 (7) min for groups Pg and Fg, respectively). Initial temperatures after induction of anaesthesia were comparable. All patients had an initial rectal temperature (37.1 (0.1) °C) significantly higher ($P<0.01$) than the oesophageal temperature (36.6 (0.2) °C).

Changes in oesophageal temperature before, during and after tourniquet inflation are shown in figure 1. Before tourniquet inflation, temperature decreased similarly. Exsanguination had no significant effect. Patients in group Rg remained nearly normothermic throughout surgery. In contrast, core temperature increased significantly in both tourniquet groups and exceeded reference values at all times after 20 min had elapsed. Increases in group Fg were significantly greater than those in group Pg at all times after 30 min had elapsed. This central temperature increase correlated ($P<0.001$) with tourniquet time ($r=0.98$ and $r=0.99$ for groups Pg and Fg, respectively). Immediately after tourniquet deflation, core temperature decreased similarly in both tourniquet groups. The maximum mean decrease, 10–15 min after tourniquet deflation, was 0.7 (0.1) °C. This decrease did not correlate significant with tourniquet duration and was transient.

Changes in rectal temperature were similar but with a significant delay compared with oesophageal changes. In the tourniquet groups, pelvic temperature increased and was significantly higher than that in group Rg at all times after 50 min had elapsed. Increases in group Fg were significantly higher than those in group Pg at all times after 70 min had elapsed. This increase correlated with time ($r=0.93$ and $r=0.96$ for groups Pg and Fg, respectively; $P<0.001$). After tourniquet deflation, rectal temperature did not change.

Progressively, in both tourniquet groups, arterial pressures increased significantly (systolic arterial pressure before tourniquet 111 (18) mm Hg and before release 150 (18) mm Hg, diastolic arterial pressure before tourniquet 59 (13) mm Hg and before release 89 (12) mm Hg; $P<0.01$). After release, pressures decreased significantly to a minimal level obtained 3–10 min after tourniquet release ($P<0.01$). There was a significant difference in end-tidal carbon dioxide concentration between the level just before tourniquet release (4.3 (0.3) kPa) and the peak 3–8 min after tourniquet release (5.9 (0.4) kPa; $P<0.01$). There was no difference between tourniquet groups and no correlation with tourniquet time. All of these variations returned to normal 20 min after tourniquet release.

Comment

In this study the duration of tourniquet inflation appeared to be the main precipitating factor for the increase in core temperature. This increase correlated with duration of tourniquet inflation. It was similar to that reported in previous paediatric studies where there was no significant difference between smaller and larger children,[2 3] but it has not been described previously in adults. We have found similar changes in adults, with the greatest changes in patients who were actively warmed.

Oesophageal temperature is monitored commonly in patients receiving general anaesthesia. It is considered a true measure of core temperature and it responds rapidly to changes in body temperature. Conversely, rectal temperature correlates poorly with core temperature and has a significantly delayed response because of cooling by the legs. In our study, in all patients, initial rectal temperature was significantly higher than oesophageal temperature because of two possible mechanisms: delay in perioperative hypothermia developing and warming by blood as it returned from the traumatized leg. There was a delay when comparing changes in rectal temperature with oesophageal temperature but hyperthermia was not greater with rectal measurements.

We postulate that the increase in core temperature during tourniquet inflation was caused by slow release of ischaemic metabolites from the extremity into the systemic circulation, using vascular bone as a tourniquet bypass.[3] However, when heat loss to the environment decreases because of reduced surface area while the level of heat production remains stable, core temperature may increase. But, as observed in children, hyperthermia was greater than predicted from the reduction in effective surface area.[2] In fact, if the surface area of each leg constitutes approximately 18% of the total body surface area, the estimated mass of the leg was approximately 16% in adults.[5] It has been suggested that tourniquet ischaemia may initiate a reaction similar to that of malignant hyperthermia.[6]

After tourniquet release, core temperature decreased rapidly but transiently. This significant decline has been described previously in adults[4] and was explained by redistribution with cooling of blood in a cold and vasodilated limb. Further studies may confirm that postoperative hyperthermia could be explained, in part, by tourniquet use. We also observed other adverse effects such as an increase in arterial pressure during tourniquet use and an increase in end-tidal carbon dioxide at tourniquet deflation.

CASE REPORTS

A modification of sub-mental intubation

J. D. GREEN AND U. J. MOORE

Summary

In patients who have sustained base of skull fractures, the mode of intubation is controversial, with many anaesthetists arguing against nasal intubation. In several maxillofacial procedures temporary intermaxillary fixation (IMF) in the intra-operative period may be essential to achieve optimal results in fixation. For patients with combined facial and base of skull injury, tracheotomy may have to be performed. The submental approach to intubation allows IMF to be used without resort to nasal intubation or tracheotomy. We describe a modification of the original technique which is applicable to any reinforced tracheal tube and which does not compromise the airway. (*Br. J. Anaesth.* 1996; **77**: 789–791)

Key words
Intubation tracheal, technique. Complications, maxillofacial injuries.

Nasal tracheal intubation after severe craniomaxillofacial trauma can result in the passage of the tracheal tube into the cranium, with consequent brain damage.[1 2] To avoid this complication, oral intubation may be preferred but this may severely compromise maxillofacial repair because of interference with the placement of intermaxillary fixation (IMF), which is used to establish the patient's occlusion in the intraoperative period. In many facial fractures, particularly those involving the maxilla, this is an essential guide to optimal fracture reduction and fixation. To enable IMF to be placed, tracheotomy may be indicated but this carries significant morbidity.[3 4] The use of the submental route for tracheal intubation has been described[5 6] and provides a useful alternative route in the severely traumatized patient in whom establishment of intra-operative IMF is preferred. The technique, as described originally, involves insertion of an oral tube, the free end of which is then exteriorized through a submental incision and reconnected. This involved the use of a reinforced tracheal tube in which the universal connector was removed easily for passage through the submental tissues. These tubes are not always available in the operating room and a technique is described below to allow the use of this technique with tubes in which the universal connector is non-removable. A case report illustrates the clinical use of this technique.

MODIFIED TECHNIQUE FOR SUBMENTAL INTUBATION

The trachea is intubated via the oral route and a 2-cm submental skin incision is made close to the lower border of the mandible. Blunt dissection is carried out as close as possible to the inner aspect of the mandible into the floor of the mouth. An incision is then made in the floor of the mouth sufficient to allow the passage of a suitable tracheal tube. During dissection care should be taken to ensure no damage occurs to the facial nerve, lingual nerve or submandibular duct. Artery forceps may now be passed from the floor of the mouth out through the extra-oral incision to grasp a suitable tracheal tube which may then be drawn through the wound into the mouth. The original oral tube may now be withdrawn and the second tube substituted. When the cuff is inflated and a throat pack inserted, temporary sutures are placed to stabilize the tube. At the end of the procedure the process may be reversed to re-establish the oral route, and closure of the extra-oral wound may be achieved. However, the tube may be left *in situ* and removed subsequently, as described originally.[5]

Case report

A 26-yr old security officer was admitted to the accident and emergency department of the Newcastle General Hospital after being found unconscious at the bottom of a ladder. He had sustained head and facial injuries. On admission he was conscious with a Glasgow coma score of 10 (motor 5, eyes 1, verbal 4). He was amnesic of the event. On examination there was severe facial swelling and bruising, with a large supraorbital haematoma, left-sided rhinorrhoea and epistaxis. Both pupils responded to light; the left eye however showed a pulsatile exophthalmos with the globe displaced inferolaterally. The maxilla was freely mobile with the left zygoma displaced, and there appeared to be a comminuted fracture of the naso–ethmoid complex.

Radiographic examination confirmed extensive facial fractures. Because of the pulsation in the left

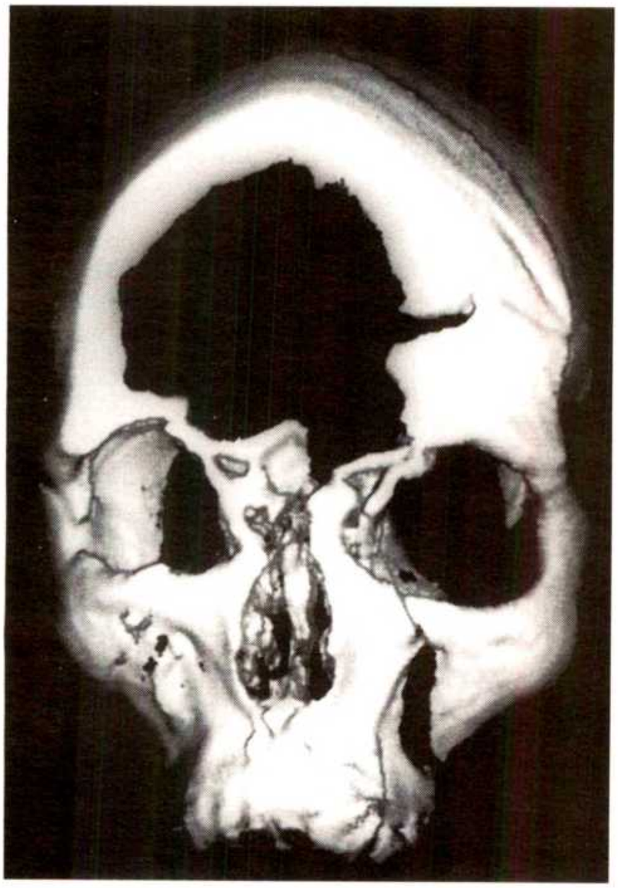

Figure 1 CAT scan: three-dimensional reconstruction showing the extensive nature of the facial injuries. The naso–ethmoidal fracture can be seen in continuity with the cranial base.

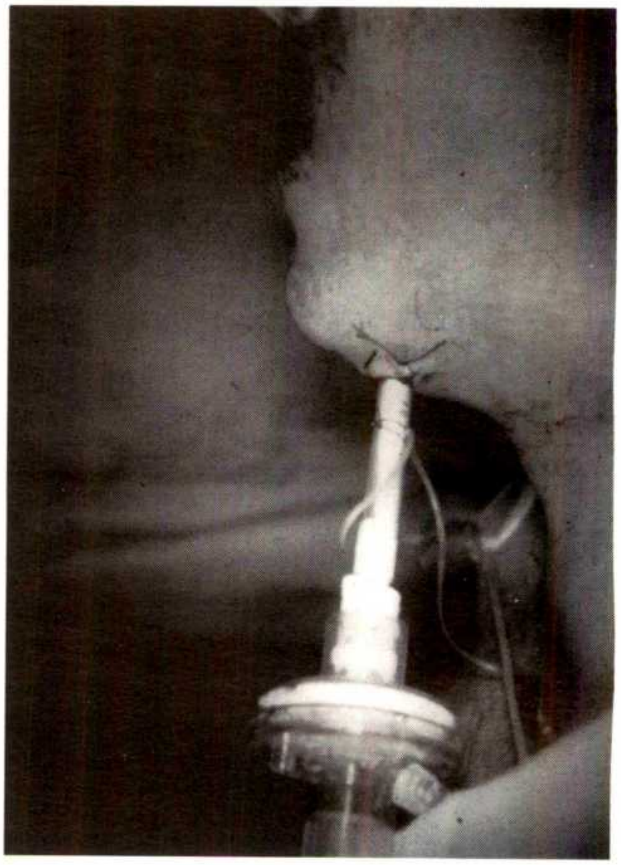

Figure 2 Photograph showing submental intubation with the tracheal tube sutured in position.

orbit a carotid angiogram was performed. This was normal with no evidence of a carotid–cavernous sinus.

Computer axial tomography (fig. 1) showed a fractured frontal bone in continuity with the left orbital roof, anterior comminution of the naso–ethmoidal complex and displacement of the left zygoma. There were also maxillary fractures with a Le Fort II fracture on the right and a Le Fort III fracture on the left. These injuries can be seen in the three-dimensional reconstruction from the CAT scan (fig. 1).

The patient was observed for 3 days while his level of consciousness improved, however the rhinorrhoea persisted and repair of the dural tear and the maxillofacial injuries were scheduled in a combined procedure. In order to achieve optimal surgical repair, application of IMF was preferred but the presence of basal skull fractures rendered nasal intubation potentially complicated. In order to avoid tracheotomy we elected to perform a modified submental intubation.

The patient's lungs were preoxygenated for 4 min after which anaesthesia was induced with fentanyl 200 μg and thiopentone 350 mg. Airway security was confirmed and, having shown that hand ventilation of the lungs was possible, vecuronium 10 mg were administered. Oral intubation was produced by passing a 9-mm id cuffed tracheal tube.

A 2-cm incision was made in the left submental region parallel to the lower border of the mandible which was extended intraorally. A 7-mm id reinforced tracheal tube was then passed through the incision from the exterior and manoeuvred with McGill forceps so that it was positioned in the oropharynx. The oral tracheal tube was then removed and the patient's trachea intubated with the submental tube. This was sutured in position extra-orally and the mouth packed (fig. 2).

Craniotomy and dural repair were performed, the orbital roof was explored and then the maxillary fractures reduced, arch bars having been wired around the upper and lower teeth, and the occlusion established. At the end of the procedure the tracheal tube was replaced with a conventionally positioned oral tube so that the incision could be sutured and closed. Neuromuscular block was antagonized with glycopyrronium 500 μg and neostigmine 2.5 mg. The patient was allowed to regain consciousness and, after confirmation of airway security, the trachea was extubated. Postoperative recovery was unremarkable, and the operative result was satisfactory. The submental scar at 6 weeks was minimal.

Discussion

Altermir[5] first described the submental route for tracheal intubation in 1986. The technique allows a patient's trachea to be intubated for maxillo-mandibular fixation and avoids nasal intubation and tracheotomy. More recently, Gordon and Tolstunov[6] have described the technique in the management of two patients. We have described how the technique was modified in the management of a patient with severe head and facial trauma. With the Mallinkrodt tracheal tube used in the US, the universal connector can be removed easily from the tube.

In past descriptions of the submental approach, the authors have performed oral intubation, removed the connector and passed the tracheal tube through the incision from interior to exterior, while the tracheal tube has been in the larynx. In this case a second tube was used, having first secured the airway with a conventionally placed oral tracheal tube. The reasons for this were two-fold. First, there was less risk of compromising the patient's airway if difficulties were encountered re-attaching the connector or passing the tube through the incision. Second, with the tube used, a Mallinkrodt Medical Safety-Flex, the manufacturer's design specifically prevents the removal of the universal connector, as does the Flexicare Medical, Reinforced Murphy tracheal tube. The procedure proved straightforward and was not associated with any marked bleeding from the incision or compromise of the patient's airway.

The modification described provides a safe alternative technique when oral intubation interferes with the surgical approach in the treatment of severe craniomaxillofacial injury.

Hepatic rupture complicating eclampsia in pregnancy

S. KARADIA, C. WALFORD, M. MCSWINEY AND M. S. NIELSEN

Summary

We describe hepatic rupture in a 37-yr-old woman admitted to the intensive care unit after an eclamptic convulsion. The intensive care and surgical management are discussed. (*Br. J. Anaesth.* 1996; **77**: 792–794)

Key words
Complications, hepatic. Complications, disseminated intravascular coagulation. Complications, eclampsia. Liver, transplantation. Intensive care.

Hepatic rupture is a rare complication of pre-eclampsia or eclampsia. It may present with lower chest or upper abdominal pain. Hepatic rupture may be associated with disseminated intravascular coagulation (DIC) and subsequent haemorrhage. In unremitting hepatic failure, transplantation may have to be considered if other treatments fail to control haemorrhage.

Case report

A healthy 37-yr-old primigravida was admitted to hospital 12 days post-term for induction of labour after a previously uncomplicated pregnancy. Arterial pressure was 120/72 mm Hg, haemoglobin concentration 126 g litre^{-1} and platelet count 236×10^{9} litre^{-1}. Multistix urinalysis was negative for protein. Labour was induced using dinoprostone pessaries and proceeded uneventfully for 4 h during which time the patient satisfactorily self-administered Entonox and used TENS for analgesia. No further requests for additional analgesia were made. Two hours before delivery she complained of severe lower chest pain. The patient was not cyanosed and arterial pressure and heart rate were normal. Clinical examination and electrocardiography were unremarkable. The pain stabilized after administration of pethidine 75 mg i.m. One hour later the patient suffered a grand mal convulsion. The convulsion was controlled with diazepam 7.5 mg i.v.

Vaginal examination revealed a fully dilated cervix with the fetal head 2 cm below the ischial spines. Neville Barnes forceps were applied and a healthy male infant was delivered. Manual removal of an incompletely separated placenta resulted in loss of 500 ml of blood. An episiotomy wound was repaired. After delivery the patient's arterial pressure was 180/105 mm Hg and urine was found to contain 2+ of protein on Multistix urinalysis (equivalent to 1 g litre^{-1}).

Eclampsia was diagnosed and i.v. magnesium sulphate was commenced in a dose of 5 g followed by an infusion of 1 g h^{-1}. Haemoglobin concentration was 135 g litre^{-1}, white cell count 22.5 g litre^{-1} and platelet count 101×10^{9} litre^{-1}. Invasive monitoring of arterial and central venous pressures was commenced in addition to pulse oximetry and urine output. Before transfer to the intensive care unit (ICU) the patient suffered a post-partum haemorrhage of 1500 ml requiring an emergency examination under anaesthesia. After anaesthesia, gynaecological examination revealed generalized oozing of blood from the external genitalia with an atonic uterus filled with blood clot. The blood clot was removed and bimanual pressure exerted to achieve uterine contraction. A vaginal pack was inserted to help tamponade the haemorrhage. Blood loss with this procedure was approximately 1000 ml. A continuous infusion of Syntocinon at a rate of 10 u. h^{-1} was commenced to maintain uterine contraction. A full blood count at this stage revealed a haemoglobin concentration of 96 g litre^{-1} and a platelet count of 62×10^{9} litre^{-1} with an international normalized ratio (INR) of 4. The patient received 6 u. of blood and 6 u. of platelets. A dopamine infusion of 3 μg kg^{-1} min^{-1} was commenced and urine output remained at 1 ml kg^{-1} h^{-1}.

The patient was transferred, with her trachea still intubated and her lungs ventilated, to the ICU for further monitoring of haematological and vital signs. She was sedated with an infusion of midazolam 50 μg kg^{-1} h^{-1} and morphine 30 μg kg^{-1} h^{-1}. No further convulsions occurred.

Repeated infusion of FFP, platelets, cryoprecipitate and colloid were administered to maintain normovolaemia and coagulation function. An infusion of aprotinin 200 000 u. h^{-1} was commenced after a loading dose of 1 000 000 u. Six hours after admission to the ICU the patient became hypotensive and developed a distended abdomen. An ultrasound scan showed intraperitoneal fluid and mixed reflectivity in the region of the liver capsule, suggesting haemorrhage. After further prompt fluid resuscitation, laparotomy was performed. At operation a sheared rupture of the right lobe of the liver was

S. KARADIA, FRCA, C. WALFORD, DA, M. MCSWINEY*, FRCA, M. S. NIELSEN, FRCA, Shackleton Department of Anaesthesia, Southampton General Hospital, Tremona Road, Southampton SO16 6YD. Accepted for publication: July 29, 1996.

*Present address: Cheltenham General Hospital, Cheltenham.

found. The liver substance showed generalized fatty infiltration and petechiae. Only limited haemostasis was achieved and the peritoneal cavity was packed and the abdomen closed. After operation she was transferred back to the ICU where she continued to show cardiovascular and haematological signs of haemorrhage. Systolic arterial pressure was now persistently low at 90 mm Hg with a tachycardia of 110 beat min^{-1} and a decreasing urine output. Haemoglobin concentration was 96 g dl^{-1} despite 22 u. of blood, platelet count 46×10^9 litre^{-1} despite 20 u. of platelets and INR was 2.4. A further laparotomy revealed a right subcapsular haematoma of the liver. A right hemihepatectomy was performed as the only means of achieving haemostasis; subsequent histology showed diffuse necrosis of the architecture of the liver.

After operation a pulmonary artery catheter was inserted. Cardiac index was 2.1 litre min^{-1} m^{-2} with a pulmonary artery wedge pressure of 11 mm Hg. Dobutamine was commenced at a rate of 5 μg kg^{-1} min^{-1} which produced a cardiac index of 4.5 litre min^{-1} m^{-2}. Further volume replacement was necessary to maintain cardiac filling pressure.

Despite an eventual blood transfusion of more than 120 u., an infusion of 20 u. of cryoprecipitate, 42 u. of platelets and 48 u. of FFP, haemostasis was not achieved and the INR remained greater than 1.5. Two further laparotomies were performed to evacuate the intraperitoneal blood clot, replace intra-abdominal packs and attempt haemostasis. A subcapsular haematoma of the remaining left lobe of the liver had developed which was treated conservatively.

As all conventional means of controlling haemorrhage had failed, the patient was referred to a supra-regional liver unit for consideration of transplantation as a means of controlling bleeding. She was accepted and transferred using the intensive care transport system. The patient remained stable throughout the journey, requiring only 3 u. of blood. On arrival the patient remained stable for 24 h when a further laparotomy was performed to remove the intra-abdominal packs, evacuate the haematoma and to administer argon diathermy to the raw surface of the left lobe of the liver. At this time the vaginal packs were removed and the uterus and external genitalia examined; there was no further oozing of blood from these sites. After operation she was haemodynamically stable, her INR remained in the range 1.2–1.5 and renal function was satisfactory, with a urine output of 1 ml kg^{-1} h^{-2}. Under these circumstances liver transplant was considered unnecessary.

Over the subsequent 5 weeks the patient continued to improve despite requiring treatment for intermittent sepsis and mild ARDS. The patient returned to her original hospital where she was reunited with her baby.

Discussion

Our patient developed eclampsia without any preceding features of pre-eclampsia. Douglas and Redman reported recently that 38% of eclamptic cases were unheralded by hypertension and proteinuria.[1] They stated that convulsions are one of a range of clinical features caused by endothelial cell damage secondary to placental ischaemia. The manifestations of the syndrome depend on the site and extent of endothelial cell damage and are not the result of a predetermined hierarchy. Convulsions may precede hypertension or proteinuria, as demonstrated in this case.

The aetiology of the pre-eclampsia complex of hypertension, proteinuria and convulsions is unknown. DIC may occur and its severity is thought to be proportional to the degree of pre-eclampsia. DIC is a result of unregulated release of free thrombin into the circulation.[2] Tissue factor is released locally at the site of tissue damage and this complexes with factor VII which results in a cascade of enzymic reactions required for thrombin generation. Damaged placental endothelium is unable to concentrate antithrombin on its surface which normally would prevent build up of thrombin. This results in widespread microvascular thromboses leading to organ damage. To maintain vascular patency, excess plasmin is generated causing fibinolysis and fibrinogenolysis. Generation of free thrombin and plasmin results in thrombotic and haemorrhagic manifestations, respectively, of DIC.

Additionally, free thrombin results in a change in platelets such that their surfaces bind and concentrate all the components of the haemostatic system. Platelet survival and numbers are reduced. Haemorrhage is the commonest manifestation of DIC because of generation of free plasmin and depletion of coagulation factors and platelets.

Eclamptic patients are prone to spontaneous haemorrhages and frequently show fibrin deposition on the basement membrane of hepatic sinusoids and arterioles. It has been postulated that sensitization of the reticuloendothelial system of the liver by previous subclinical pre-eclampsia may render it unable to clear fibrin thrombi from the circulation. As a result, infarction with vascular disruption may occur leading to intrahepatic haemorrhage and parenchymal destruction. Rarely the periportal necroses that result coalesce and form subcapsular haematoma and ultimately rupture of Glisson's capsule with intraperitoneal haemorrhage.[3] This may be exacerbated by diaphragmatic and abdominal muscular contractions but the underlying hepatic parenchyma is abnormal and a history of significant trauma can rarely be elicited.

Concerning the early diagnosis of spontaneous hepatic rupture, Howard and Jones claimed that the most important presenting complaint is right upper quadrant pain and that ultrasound scan is the quickest means of diagnosis, although computerized tomography is more sensitive.[4] Our patient complained of lower central chest pain and an ultrasound scan demonstrated the presence of intraperitoneal fluid with mixed reflectivity around the hepatic area. Howard and Jones also stated that in such cases termination of pregnancy is the first step in the treatment and that surgery may not be required. They also stated that although elevated transaminase concentrations, decreased platelets and DIC occur acutely, they resolve rapidly.[5] This was not found to be the case with our patient who, despite aggressive medical and surgical treatment, continued to show signs of bleeding and DIC.

Loevinger, Lee and Anderson reported a patient in whom transcatheter gelfoam embolization of the hepatic artery was successful in arresting intrahepatic haemorrhage after hepatic rupture.[6] They claimed that this is an alternative to surgery if the patient is clinically stable. We believe that our patient would not have been.

In a review of four cases between 1973 and 1976, Nelson, Archibald and Albo[7] found that all four continued to require significant blood replacement of 4–25 u. after laparotomy for hepatic rupture. Erhard and colleagues reported the case of a 30-yr-old primigravida who developed hepatic rupture as a complication of the HELLP syndrome (haemolysis, elevated hepatic enzymes, low platelets) who successfully underwent urgent hepatic transplantation after a hepatectomy for bleeding and hepatic necrosis.[8] Nelson, Archibald and Albo claimed that the lesion most often described is subcapsular haematoma of the right hepatic lobe with free rupture into the peritoneal cavity and resultant exsanguinating haemorrhage.[7]

Hepatic rupture, although a rare complication of eclampsia, carries a high mortality rate. In some review series this was between 60 and 70%.[9] Hence when the triad of pre-eclampsia, right upper quadrant pain and sudden hypotension is present in pregnancy or shortly afterwards, prompt recognition is essential. Ultrasound scan should be performed to aid diagnosis, and transplantation should be considered if medical and surgical intervention fails to control bleeding. Any woman who develops DIC during or after labour must be admitted to an intensive care unit or a high dependency unit for monitoring.[10]

Tolerance of laparoscopy for resection of phaeochromocytoma

C. MANN, B. MILLAT, G. BOCCARA, J. ATGER AND P. COLSON

Summary

We describe two patients who underwent resection of phaeochromocytoma by a laparoscopic approach. Although outcome from surgery was successful, there was marked variability in hormonal and haemodynamic changes. In one patient, despite an infusion of nicardipine, peritoneal insufflation produced a marked increase in catecholamine concentrations associated with transient but intense vasoconstriction, but there was no change in the second patient. In both patients, exsufflation caused no significant haemodynamic changes in spite of the high doses of nicardipine given throughout the procedures. (*Br. J. Anaesth.* 1996; **77**: 795–797)

Key words
Surgery, laparoscopy. Complications, phaeochromocytoma. Carbon dioxide, pneumoperitoneum.

Surgical removal of phaeochromocytoma is a risky procedure because of preoperative cardiovascular changes, particularly during surgical manoeuvres. Preoperative preparation, completed during operation by administration of antihypertensive agents, enables the anaesthetist to largely control the haemodynamic instability.[1–3] However, acute complications may still occur.[2 4] The laparoscopic approach described recently seems to be of great interest as it may decrease postoperative morbidity and it allows viewing of the whole of the abdominal cavity in order to reveal possible multiple tumour sites.[5 6] Nevertheless, as the pneumoperitoneum may induce haemodynamic disturbances,[7] the safety of this technique remains questionable. We report two cases in which we measured the haemodynamic changes induced by pneumoperitoneum during removal of phaeochromocytoma by a laparoscopic approach.

Case reports

PATIENT NO. 1

A 32-yr-old woman (50 kg, 158 cm) was referred with a phaeochromocytoma of the right adrenal gland, manifest clinically as hypertension, sweating and severe headache. Urinary catecholamine concentrations were 34 300 nmol/24 h (normal values 150–1600 nmol). Echocardiography revealed left ventricular hypertrophy with a wall thickness of 17 mm. Systolic arterial pressure (SAP), recorded continuously, averaged 165 mm Hg with peaks of 240 mm Hg. Continuous ECG showed several episodes of supraventricular arrhythmia. Treatment with nicardipine 150 mg day^{-1} and labetalol 200 mg day^{-1} for 10 days did not provide satisfactory haemodynamic control.

One hour before surgery and after oral premedication with hydroxyzine 100 mg and alprazolam 0.5 mg, SAP was 202 mm Hg and heart rate 109 beat min^{-1}. Anaesthesia was induced with fentanyl 0.5 mg, midazolam 15 mg and vecuronium 6 mg, and maintained with an infusion of fentanyl 1 mg h^{-1}, midazolam 10 mg h^{-1} and additional bolus doses of vecuronium. No inhalation agents were used and patient's lungs were ventilated mechanically with 60% nitrogen in oxygen at a rate of 15 bpm with a tidal volume of 8–10 ml kg^{-1}, maintaining end-expired carbon dioxide concentration at 3.5–4%. After a bolus of 2 mg, an infusion of nicardipine 4 mg h^{-1} was given to maintain SAP at 140–150 mm Hg.

A pulmonary artery catheter was inserted for continuous measurement of cardiac output (Intellicath 8F-Catheter and Vigilance Monitor, Baxter, USA); additional monitoring included invasive measurement of arterial pressure, pulse oximetry, capnography and ECG. Blood sampling was hourly, performed to measure blood-gas tensions. Plasma concentrations of catecholamines were measured using high-pressure liquid chromatography (table 1). Normovolaemic haemodilution of 600 ml was undertaken using hydroxyethyl starch and 2000 ml were given to produce a pulmonary capillary wedge pressure of 18 mm Hg. After this 90-min preparation phase, the patient was placed in a left lateral decubitus position of 30°. A carbon dioxide pneumoperitoneum with a pressure of 10 mm Hg was produced for 10 min and then suddenly, a hypertensive peak (244/131 mm Hg) with a reduction in heart rate was observed, but without any variation in cardiac output (fig. 1). This episode was controlled rapidly with nicardipine 5 mg i.v. followed by an infusion of 6 mg h^{-1}.

The various vascular tumour pedicles were isolated successively using four trocars. Despite continuous administration of nicardipine, vascular

clamping near the tumour caused marked haemodynamic changes. Supplementary bolus doses of nicardipine and bolus doses of esmolol were given when tachycardia or an increase in cardiac output, or both, were observed. After total vascular detachment of the tumour (fig. 1: double arrow), nicardipine was stopped. The tumour (6 cm in diameter) was then extracted via a MacBurney incision. The total preoperative doses of nicardipine and esmolol were 96 and 170 mg, respectively. At the end of the procedure, core body temperature was 36.2 °C. Throughout the operation, Pa_{CO_2} had been maintained at 4.1–4.9 kPa. The postoperative course was uneventful and antihypertensive treatment was not required. Analgesia comprised non-steroidal anti-inflammatory analgesics only. The patient's trachea was extubated 6 h later in the recovery room and she was transferred to the surgical unit. Oral feeding was resumed at 24 h and the patient was discharged on the third day after operation.

PATIENT NO. 2

A 64-yr-old woman (54 kg, 147 cm) was referred with a phaeochromocytoma of the left adrenal gland. The clinical picture comprised arterial hypertension, sweating, palpitations and Raynaud's phenomenon. Urinary concentrations of catecholamines were 13200 nmol/24 h (normal values 150–1600 nmol). Echocardiography revealed left ventricular hypertrophy with a wall thickness of 19 mm with moderate aortic stenosis. Treatment with nicardipine 100 mg day^{-1} for 20 days stabilized arterial pressure.

One hour before surgery and after oral premedication with hydroxyzine 100 mg and alprazolam 0.5 mg, SAP was 141 mm Hg and heart rate 88 beat min^{-1}. Anaesthesia was induced with fentanyl 0.4 mg, midazolam 10 mg and vecuronium 6 mg, and maintained by continuous infusion of fentanyl 0.4 mg h^{-1}, midazolam 4 mg h^{-1} and additional doses of vecuronium. SAP was then stabilized at 90–100 mm Hg without administration of nicardipine. No inhalation agents were used and haemodynamic and ventilatory management, and blood-gas tensions were measured, as described for patient No. 1. Normovolaemic haemodilution of 500 ml was undertaken and 1750 ml were given to produce a pulmonary capillary wedge pressure of 15 mm Hg. The patient was then placed in a right lateral decubitus position of 30°. A bolus of nicardipine 1.5 mg was administered, followed by an infusion of 6 mg h^{-1}. Haemodynamic disturbances caused by tumour manipulation were treated in the same way as those described for patient No. 1. The total peroperative doses of nicardipine and esmolol were 36 and 150 mg, respectively. At the end of the procedure, core body temperature was 35.9 °C. Throughout the operation, Pa_{CO_2} had been maintained at 3.9–4.4 kPa. The postoperative course was uneventful and antihypertensive treatment was not required. Analgesia comprised non-steroidal anti-inflammatory analgesics only. The patient's trachea was extubated 4 h later in the recovery room and she was transferred to the surgical unit. Oral feeding was resumed at 24 h and the patient was discharged on day 4 after operation.

Discussion

The cardiovascular changes induced by phaeochromocytoma are usually aggravated by the stress of surgery. Classically, arterial hypertension occurs, caused by intense vasoconstriction, often associated with myocardial hyperexcitability and arrhythmias.[24] Adrenalectomy using a laparoscopic approach has been proposed with the aim of diminishing the stress of laparotomy and avoiding direct manipulation of the gland.[5,6] However, creation of a pneumoperitoneum by carbon dioxide insufflation carries problems as it causes an increase in intra-abdominal pressure and leads to absorption of carbon dioxide.[7,8] The increase in intra-abdominal pressure causes a decrease in cardiac index by reduction of venous return and an increase in peripheral vascular resistance.[8,9] Excessive absorption of carbon dioxide may lead to sympathetic stimulation with, in extreme cases, arrhythmias induced by hypercapnia.[10] Therefore, the use of laparoscopy for phaeochromocytoma is only justifiable if it is possible to rigorously control preload, afterload and arterial $P\mathrm{CO}_2$. Our experience in the anaesthetic management of laparoscopy has led us to use calcium-channel blockers to control vasoconstriction associated with pneumoperitoneum. Moreover, with hyperventilation, hypercapnia is generally avoided. The anaesthetic technique used here did not differ from that used for conventional phaeochromocytoma surgery. The use of a potent analgesic at a high dose and a benzodiazepine proved to be sufficient to control surgical stress.[11] Calcium-channel blockers, such as nicardipine, are currently the antihypertensive agent of choice during phaechromocytoma resection.[1,11]

Meurisse and colleagues[6] observed good haemodynamic stability during laparoscopic removal of phaeochromocytoma. However, these authors admitted that insufflation of the pneumoperitoneum was a critical time. In this study, although the conditions for pneumoperitoneum were exactly the same, the responses observed in the two patients were not comparable. In our first patient, after insufflation, noradrenaline concentrations increased to three times pre-insufflation concentrations, which was probably an indication of intense mechanical stimulation of the tumour by intra-abdominal pressure. Despite preliminary infusion of nicardipine, the immediate consequence was intense vasoconstriction with a marked increase in arterial pressure. This hypertensive bout was nevertheless controlled rapidly by an additional bolus of nicardipine. In spite of the lower doses of nicardipine in our second patient, there was no vasopressor response to the pneumoperitoneum and no variation in catecholamine concentrations was recorded. In contrast, in both patients, insufflation of the pneumoperitoneum had no effect on cardiac output, whereas a 15–20% reduction in cardiac index is usually observed during conventional laparoscopic surgery.[8] The explanation for the stability was probably the preload optimization by monitoring of pulmonary capillary wedge pressure.[11,12] Recently, Giebler and colleagues performed phaeochromocytoma resection using a capnoretroperitoneoscopic technique.[13] Although they were not reported in detail, the haemodynamic changes seem to have been well tolerated.

Tumour manipulation causes marked increases in arterial pressure, heart rate and cardiac output. Administration of nicardipine or esmolol, or both, makes it possible to maintain satisfactory haemodynamic stability. However, considerable release of noradrenaline was observed in patient No. 1. In common with insufflation, successive laparoscopic manipulation may lead to significant tumour stimulation. Total tumour removal leads to a rapid decrease in catecholamine concentrations with a parallel decrease in cardiac output and vascular resistances. However, in both patients, exsufflation caused no significant haemodynamic changes in spite of the large doses of nicardipine.

COMMENTARIES

Randomization is important in studies with pain outcomes: systematic review of transcutaneous electrical nerve stimulation in acute postoperative pain

D. CARROLL, M. TRAMÈR, H. MCQUAY, B. NYE AND A. MOORE

Summary

We set out to examine the evidence for the importance of randomization of transcutaneous electrical nerve stimulation (TENS) in acute postoperative pain. Controlled studies were sought; randomization and analgesic and adverse effect outcomes were summarized. Forty-six reports were identified by searching strategies. Seventeen reports with 786 patients could be regarded unequivocally as randomized controlled trials (RCT) in acute postoperative pain. No meta-analysis was possible. In 15 of 17 RCT, we judged there to be no benefit of TENS compared with placebo. Of the 29 excluded trials, 19 had pain outcomes but were not RCT; in 17 of these 19 TENS studies, the authors concluded that TENS had a positive analgesic effect. No adverse effects were reported. Non-randomized studies overestimated treatment effects. (*Br. J. Anaesth.* 1996; **77**: 798–803)

Key words

Anaesthesia, audit. Pain, postoperative. Nerve, stimulation.

Transcutaneous electrical nerve stimulation (TENS) was developed originally as a means of controlling pain through the "gate" theory.[1] There is conflicting professional opinion on the use of TENS in acute postoperative pain. The recommendations of the Agency for Health Care Policy and Research (AHCPR)[2] for acute pain management state that TENS is "effective in reducing pain and improving physical function" while the earlier report of the UK College of Anaesthetists' working party on pain after surgery[3] states that "TENS is not effective as the sole treatment of moderate or severe pain after surgery". For postoperative pain some textbooks recommend or strongly recommend TENS,[4–8] although one at least is uncertain.[9] TENS is of doubtful benefit in labour pain,[10] but we could find no systematic review of its use in chronic pain.

The quality of methods used in clinical studies has been shown to be a key determinant of the eventual results. Schulz and colleagues[11] demonstrated that studies that were not randomized or which were inadequately randomized exaggerated the estimate of treatment effect by up to 40%. Studies which are not fully blinded can exaggerate the estimate of treatment effect by up to 17%. We sought evidence of the effect of randomization in trials with pain as an outcome, in studies of TENS in acute postoperative pain.

Methods

Several different search strategies were used to identify controlled studies for TENS in acute postoperative pain in both MEDLINE (1966–1995: Knowledge Server version 3.25: January 1996) and the Oxford Pain Relief Database (1950–1992).[12] The words "TENS" and "transcutaneous electrical nerve stimulation" were used in searching, including combinations of these words. Additional reports were identified from the reference lists of retrieved reports, review articles and textbooks.

Inclusion criteria were full journal publication, TENS and postoperative pain with pain outcomes. Reports of TENS for the relief of other acute pain conditions, such as labour pain, acute infections and procedures, or those where the number of patients per treatment group was fewer than 10 were excluded. Abstracts and review articles were not considered. Unpublished reports were not sought. Neither authors of reports nor manufacturers of TENS equipment were contacted.

Two types of control predominated—open studies compared TENS with conventional postoperative analgesia (i.m. opioid) or with disabled TENS instruments (sham TENS). Some studies used blinded observers. While there was no prior hypothesis that TENS could not be blinded adequately, it was determined that, despite the considerable efforts documented in some reports, adequate blinding was impossible in practice.

Each report which could possibly meet the inclusion criteria was read by each author independently and scored for inclusion and quality using a three-item scale.[13] Included reports received one point for randomization, a further point if this had been done correctly and a third if the number and

Correspondence to R. A. M.

reasons for withdrawals were given. Authors met to agree that studies were randomized or if the description of the method of randomization was adequate.[11]

Information on surgery, number of patients, study design and duration of treatment was extracted from randomized reports. The type of TENS equipment, its settings and the method and frequency of its use, and placement of electrodes were also extracted. Control group design and the use of TENS in these controls were similarly noted. Pain outcomes, overall findings and conclusions were noted for each report, together with adverse effect information.

A judgement was then made by us as to whether the overall conclusion of the randomized reports was positive or negative for the analgesic effectiveness of TENS. *Post hoc* subgroup analysis in the original reports was not considered in our judgement of overall effectiveness. Reports which had pain measures but which were not randomized or were inadequately randomized were examined for positive or negative analgesic effectiveness of TENS using the judgement of their authors.

Results

Forty-six reports were considered; three did not have pain outcomes, three had fewer than 10 patients per group, three had methodological problems and one reported on pain during rather than after a procedure. These were not considered further.

Nineteen reports were either not RCT or the method of randomization was inappropriate (table 1). Seventeen of the 19 reports with pain measures excluded because they were either not randomized or inadequately randomized, were judged by their authors to have positive analgesic results for TENS in acute postoperative pain.

Seventeen randomized studies with pain outcomes were found. Of these, 15 were judged by us to show no analgesic benefit of TENS in acute postoperative pain.

RANDOMIZED STUDIES

The randomized studies contained information on 786 patients (table 2). TENS was used after various operative procedures, including cardiothoracic, major orthopaedic and gastrointestinal surgery. Ten different TENS machines were used with different control settings and durations of treatment; individual titration of settings took place in six reports. Fourteen reports compared TENS with sham TENS without batteries, with batteries reversed or with sub-threshold stimulation; the other three compared TENS and i.m. opioid with i.m. opioid alone. Quality scores were generally 1 or 2 out of a maximum of 3. The most common outcome measures reported were analgesic consumption and a variety of pain score measurements. Information was not presented in formats which allowed extraction for meta-analysis (table 2).

TENS vs *sham TENS*

Fourteen of the 17 included RCT compared TENS with sham TENS; no differences were found. One of the 14[48] reported no significant difference between TENS and sham TENS for analgesic consumption, but did report a statistically significant difference for pain intensity in favour of the active TENS; the published results, however, used a one-tailed statistical test which we judged inappropriate.

TENS vs *opioid control*

Seven of the 17 included RCT compared opioid plus TENS with opioid alone, four of which also included sham TENS. Of the seven studies, five failed to detect any differences in analgesic consumption or pain measurements between TENS and non-TENS controls. Two reports were judged by their authors and by us to be positive.[42 46]

Pike[42] studied 40 patients after total hip replacement. The study had as its main outcome measure the number of pethidine injections in the first 2 days

Table 1 Non-randomized reports

Reference	Pain condition or operation type	Description	Authors' judgement about analgesic effectiveness
14	Upper abdominal	Not RCT	Positive
15	Cholecystectomy, hernia repair	Retrospective, not RCT	Positive
16	Upper abdominal	Inadequate randomization	Positive
17	Foot	Not RCT — matched case control	Positive
18	Caesarean section	Not RCT	Positive
19	General	Not RCT	Positive
20	Spinal fusion	Not RCT	Positive
21	Foot	Retrospective, not RCT	Positive
22	Urological	Not RCT	Positive
23	Urological	Not RCT	Positive
24	Urological	Not RCT	Positive
25	Abdominal, thoracic	Not RCT	Positive
26	Cholecystectomy	Not RCT	Negative
27	Thoracotomy	Inadequate randomization method	Positive
28	Laparotomy	Retrospective, not RCT	Positive
29	Low back	Not RCT	Positive
30	Lumbar, hip, gynaecological	Retrospective, not RCT	Positive
31	Knee and hip joint	Not RCT	Positive
32	Gastric bypass	Not RCT	Negative

Table 2 Randomized reports

Reference	Operation type	Study design and duration of treatment periods	No. of patients	TENS details	TENS control setting	TENS control	Pain outcomes	Results for pain outcomes	Judgement	Score
33	Appendicectomy	Parallel group TENS (15) Sham TENS (13) Standard postop. analgesia (14) 48 h	42	Dow Corning Wright, single channel, electrodes (either side of wound)	Fixed rate (tingling sensation preop.)	Sham TENS (not turned on)	VASPI @ 48 h, analgesic consumption (24 and 48 h)	No significant difference sham and active TENS for pain and drug consumption; significant difference for pain intensity control *vs* TENS and sham TENS ($P<0.01$)	Negative	1
34	Abdominal	Parallel group Sham TENS (53) TENS (53) 72 h	106	Codman, dual channel, 2 electrodes (either side of wound)	Fixed rate (tingling sensation preop.), rectangular wave form, pulse width (170 ms), pulse rate 80 s^{-1}, output 15 mA	Sham TENS (batteries reversed)	VASPI —average pain twice daily, Pmorphine consumption	No significant differences between TENS and sham TENS	Negative	2
35	Caesarean section	Parallel group (female) GA+TENS (10) Extradural+TENS (11) GA+Sham TENS (8) Extradural+sham TENS (6) 24 h	35	Stim-tec EPC Mini, Model 6011, dual channel (1 channel only used), 2 electrodes (either end of wound)	Amplitude individually titrated, wave fixed (during surgery)	Sham TENS (no batteries)	VASPI—hourly, time to first analgesic, analgesic consumption	No overall difference in analgesic consumption or pain	Negative	2
36	Coronary artery bypass	Parallel group (males) TENS (15) Sham TENS (15) Postop. analgesia (15) 72 h	45	Nuwave, Staodyn. 1 pair electrodes (T1-T5), 1 pair (either side of wound)	Individually titrated (tingling sensation)	Sham TENS (no current)	Pain (0-10) on cough and rest, opioid consumption	No significant differences TENS *vs* sham TENS	Negative	2
37	Cholecystectomy	Parallel group TENS (14) Remote TENS (12) Postop. analgesia (14) 48 h	40	3M Tenzcare, dual channel, site of electrodes not described	Individually titrated	Sham TENS (remote non-segmental)	VASPI, CATPI (4-point) @ 24 and 48 h, analgesic consumption	No significant difference TENS *vs* sham TENS for pain or analgesic consumption. Pain but not analgesic consumption significantly worse in control group ($P<0.05$) immediately after surgery	Negative	1
38	Herniorrhaphy	Parallel group (males) TENS (20) Sham TENS (20) 72 h	40	Dow Corning, Wright Care, dual channel, 2 electrodes (either side of wound)	Individually titrated—pulse duration 180 μs, frequency 70 Hz, amplitude 7.5	Sham TENS (no current)	VASPI twice daily, analgesic consumption	No significant differences TENS *vs* sham TENS	Negative	1
39	Abdominal	Parallel group TENS (15) Sham TENS (15) 48 h	34	Neuromed 3722, 2 electrodes (either side of wound)	Individually titrated (tingling sensation)	Sham TENS (batteries reversed)	VASPI (2, 4, 6, 24, 48 h), analgesic consumption	No significant differences TENS *vs* sham TENS	Negative	2
40	Laminectomy	Parallel group TENS (10) Sham TENS (10) 24 h	20	Dow Corning, Wright Care, dual channel, 4 electrodes (at each end and on either side of wound)	Individually titrated, 180 μs pulsed width, frequency 70 Hz	Sham TENS (no current)	PCA morphine consumption 24 h	No significant differences TENS *vs* sham TENS	Negative	2
41	Cardiac	Parallel group TENS (14) Sham TENS (17) 72 h	31	3M Tenz care Model 6240, dual channel, 2 pairs electrodes (either side of the wound and mid-thoracic region)	Individually titrated—pulse rate 5, width control 3, amplitude	Sham TENS (no batteries)	5 point categorical pain intensity, analgesic consumption	No significant differences TENS and sham TENS	Negative	2
42	Total hip replacement	Parallel group TENS (20) Opioid control (20) 24 h	40	EPC TimeTech clinical stimulator, dual channel, 2 pairs electrodes (1 pr paravertebrally (L2-S2), between trochanter and coccyx, 1 pr above iliac crest, head of fibula)	Individually titrated, continual stimulation		Global assessment, analgesic consumption	Significantly less pethidine consumed in TENS group on day 1 ($P<0.001$)	Positive	1

contd over

26	Cholecystectomy	Parallel group TENS (30) Opioid control (34)	64	EPC, electrodes placed within 2 cm of the wound	Pulse rate 50 s^{-1}, pulsed width 170 ms, amplitude 0–50 A		Daily dose of pethidine for 3 postoperative days	No significant difference	Negative	1
43	Inguinal hernia repair	Parellel group (males) TENS (34) Sham TENS (28) 48 h	62	3M Tenzcare dual channel, 2 pairs of electrodes (over first lumbar vertebra and on either side of wound)	Individually titrated (tingling sensation), 70 Hz rectangular pulse, amplitude	Sham TENS (controls turned off)	VASPI 6, 12, 24, 36, 48 h, opioid consumption	No significant differences TENS *vs* sham TENS	Negative	2
44	Thoracotomy	Parallel group TENS+Omnopon i.m. (20) Omnopon i.m. (20) 48 h	40	Dow Corning, Wright Care 2 channel, 2 electrodes (either side of incision)	Individually titrated, fixed pulse rate 70 s^{-1}, rectangular waveform, pulse width 180 µs		5 point pain intensity 6, 24, 48 h, analgesic consumption, time to oral analgesics, length of hospital stay	No significant differences TENS *vs* sham TENS	Negative	1
45	Abdominal	Parallel group TENS (30) Sham TENS (22) Opioids i.m. (25) 72 h	77	MedGen, electrode placement not described	Fixed—pulse width 80 ms, frequency 40 Hz, amplitude individually titrated	Sham TENS (no current)	Daily 10-point pain intensity	No significant differences TENS *vs* sham TENS, or control	Negative	1
46	Abdominal and thoracic	Parallal group TENS (61) Sham TENS (39) 24 h post surgery until discharge, TDS×20 min	100	Neuromed Model 3700, Meditronic, electrode site individually chosen	Frequency 100–150 s^{-1}, output 20–35, pulse duration 250–400 ms	Sham TENS (no batteries)	Pain, analgesic consumption, duration of relief	Significant difference reported. 2/39 partial relief or complete relief sham TENS *vs* 34/61 with active TENS. Analgesic consumption not reported	Positive	1
47	Total knee replacement	Phase 2—parallel group TENS (18) Sham TENS (18) Postop. analgesia (12) 72 h	48	Strodynamics, continuous. No other information given; electrode placement not described	Amplitude setting individually titrated, pulse duration 100 µs at 70 s^{-1}	Sham TENS (subthreshold stimulation)	Analgesic consumption, hospital stay	No significant differences TENS *vs* sham TENS or control	Negative	1
48	Thoracotomy	Parallel group TENS (12) Sham TENS (12) 48 h	24	3M Tenzcare 6240, 2 electrodes placed on either side of incision	Continuous stimulation, amplitude 7, pulse rate 3, pulse width 5	Sham TENS (no current)	Pain intensity 0–10, analgesic consumption	No significant differences TENS *vs* sham TENS. Positive result reported was with one-tailed test of statistical significance	Negative	2

after operation and a retrospective global rating. Patients with active TENS had significantly fewer pethidine injections on the first day after operation and higher scores on global rating of treatment. VanderArk and McGrath[46] recruited 100 patients undergoing abdominal and thoracic surgery in 2 months, and although there was more success with active TENS used for 20 min three times a day, maximal relief was "almost invariably associated with the first stimulation". Generally there were no obvious differences between the use of TENS in these two positive studies and the 15 which showed no benefit.

Adverse events

No report described systematic recording of adverse events, nor were any reported.

Discussion

The "gold standard" in clinical trials is adequate randomization.[11] Non-randomized studies have been shown for nearly 20 yr to yield larger estimates of treatment effects than studies using random allocation.[49] The degree of exaggeration of treatment effect when randomization is inappropriate can be as much as 40%.[11] These findings underpin the inclusion criteria chosen in systematic reviews.

For TENS in acute postoperative pain, 17 of 19 reports with pain outcomes which were either not randomized or inappropriately randomized claimed TENS to be effective, compared with two of 17 randomized controlled trials.

The possibility of bias exists. The method of randomization was described in only two reports.[16 27] The method described was inadequate in both, one using a nurse to randomize patients[16] and the other using alternate allocation.[27] Reports which said only that they were randomized may have used an inadequate method.

That these data represent the lowest common denominator of information, essentially vote counting rather than a more sophisticated analysis, reflects the nature of the analgesic scoring methods that predominated in the original reports. Pain scoring using analogue or categorical scales was reported as means (an unreliable statistic[50]) or mean analgesic consumption, or time to first analgesic was used. None of these allowed data extraction for further statistical analysis or comparison between reports. While more rigorous pain scoring might have been used, there is no evidence that all of the reports suffered a systematic failure in analgesic measurement.

Inadequacy of blinding in clinical trials of analgesic interventions continues to be of concern,[51] although this may be less of an issue with pharmacological interventions.[50] Blinding of procedures is much more difficult than blinding of drug studies. Most of the TENS studies made attempts at blinding, for example by removing batteries from the TENS apparatus (sham TENS) or by using staff with no knowledge of the study or allocation to conduct the patient assessments. Lack of blinding has been estimated to exaggerate the estimate of treatment effect of studies by some 17%.[11] Adequate blinding of TENS for both carers and patients is particularly difficult.[52] None of the reports was judged to have been blinded and this lowered the quality scores given to the 17 randomized studies. The fact that only two of the reports showed any positive effect of TENS in acute postoperative pain is all the more striking because of this potential overestimation of treatment effect caused by lack of blinding.

The clear message of the reports considered in this systematic review is that adequate randomization is an important quality standard in studies with pain outcomes. Including non-randomized studies in reviews may give the wrong answer. The AHCPR guidelines on acute pain management included non-randomized reports, and this may explain their more positive attitude towards TENS.[2]

Guest Reviewers for 1996

Each manuscript submitted to *British Journal of Anaesthesia* is reviewed by members of the editorial staff, and also by individuals with particular expertise in the area of study under consideration. All reviewers are asked to consider the scientific merit of each communication and its relevance to the clinical practice of anaesthesia. Consequently, acceptance for publication is based on the views of two or more individuals as to originality, validity and clinical relevance of the information presented.

The Editor would like to acknowledge the significant contribution made by the undernoted individuals who, in addition to the editorial team, reviewed manuscripts during 1996.

CORRESPONDENCE

Unexpected high spinal block in obstetrics

Sir,—Elliott, Voyvodic and Brownridge recently reported an unexpected subarachnoid block in a parturient, despite careful aspiration testing and prior administration of local anaesthetic via a catheter, presumably located in the lumbar extradural space.[1] We recently described five similar cases of high spinal block produced by the initial test dose alone after negative aspiration testing.[2] We have had three additional cases since our report, two in labouring parturients and one in an elderly woman undergoing ankle surgery. In common with our previously reported cases, patients were seated during insertion and testing of the catheter, and 18-gauge Tuohy needles with 20-gauge open-tip, single-orifice polyamide catheters were used (B. Braun Medical, Inc., Bethlehem PA, USA). After uneventful catheter insertions, careful negative pressure aspiration produced no fluid. The test dose administered (3 ml of glucose-free 1.5% lignocaine with adrenaline 1:200000) produced abrupt high sensory block and complete lower extremity motor block consistent with subarachnoid injection in each patient. High spinal block was accompanied by profound hypotension in both parturients. One developed a high motor block resulting in ventilatory failure requiring tracheal intubation, followed by emergency Caesarean delivery for persistent fetal bradycardia. In each case, CSF was aspirated easily through the catheter with subsequent negative pressure aspiration testing. As in our previous cases, none of the patients developed postdural puncture headache (PDPH), despite dural and arachnoid punctures.

Several authors have suggested that "a subdural catheter can perforate the arachnoid mater...at any time"[1] and, "the test dose given through a catheter placed in the subdural space causes the arachnoid to tear".[3] We agree, and provide the accompanying figure (fig. 1) as a unified explanation of the mechanisms underlying arachnoid rupture and the associated low incidence of PDPH. Although initial placement of the catheter is subdural, subsequent arachnoid rupture occurs because of sudden positive pressure generated in the low-compliance subdural space by injection of a small volume of fluid. This is consistent with findings common to all our cases, namely absence of CSF during placement of the catheter, inability to aspirate fluid before catheter injection, and free flow of CSF after injection and onset of spinal block. Elliott, Voyvodic and Brownridge did not state if CSF was aspirated after the onset of subarachnoid block, however, computed tomography demonstrated clearly subarachnoid catheter placement in their patient.

Also, consistent with this mechanism is the absence of PDPH in all cases described by us (seven of whom were labouring parturients) and the single parturient described by Palkar, Boudreaux and Mankad.[4] Such a low incidence of PDPH in parturients experiencing arachnoid puncture with an 18-gauge Tuohy needle or 20-gauge extradural catheter is unlikely. However, absence of PDPH might be expected if the dural puncture site and site of arachnoid tear do not overlap, as we propose (fig. 1). After removal of the catheter, positive hydrostatic pressure in the subarachnoid space generated in the upright position should effectively seal the dural hole with underlying arachnoid mater. This contrasts with the more common occurrence of inadvertent dural puncture recognized by immediate CSF flow through the needle or catheter, in which the dural and arachnoid puncture sites directly overlap each other. Such cases have a high risk of PDPH.

Because of the high blocks and hazardous associated effects observed, we have altered our testing of extradural catheters. To help detect a subdural catheter that becomes subarachnoid on injection, we perform a negative pressure aspiration test before and after injection of 3 ml of saline, as suggested by some authors.[5] Injection of 3 ml of saline should be as effective as, and safer than, a local anaesthetic test dose in detecting arachnoid rupture. Furthermore, we have abandoned the lignocaine test dose. Abraham and colleagues proposed hyperbaric 1.5% lignocaine (Xylocaine, Astra, Westboro, MA, USA) as a safe alternative intrathecal marker,[6] however, this incurs significant added expense ($6.65 per 2 ml vial in the USA). Instead, we combine adrenaline 15 μg with 2 ml of glucose-free 0.25% bupivacaine to produce a combined i.v. and intrathecal test solution. Bupivacaine 0.25% (2 ml) has been shown to safely provide rapid onset of labour analgesia and sensory block, with little risk of hypotension or high motor block when administered intrathecally.[7] We find the inclusion of adrenaline useful because of the 5% incidence of i.v. cannulation associated with this catheter in our institution. These changes in both aspiration technique and test dose should minimize the occurrence of unexpected high spinal block without increasing expense or time.

Is Doppler monitoring mandatory in laparoscopic surgery?

Sir,—In the article published recently by Nyarwaya and colleagues[1] on carbon dioxide embolism in piglets, the authors observed some disturbances in $P\text{E}'_{CO_2}$ and Sp_{O_2}, with few changes in haemodynamic variables, and they concluded that "The presence of Doppler monitoring should be mandatory" in laparoscopic surgery because of the risk of carbon dioxide embolism which may not be detected with usual monitoring (ECG, AP, Sp_{O_2}, $P\text{E}'_{CO_2}$).

Although it is true that carbon dioxide embolism is infrequent during laparoscopic surgery,[2] most occur without any clinical disturbances and are detected only by transoesophageal echocardiography or precordial Doppler,[3] without the need for therapy. For these reasons, in common with other authors,[4] we believe that monitoring of patients without previous pathology should include ECG, AP, $P\text{E}'_{CO_2}$ and Sp_{O_2}. Doppler monitoring, pulmonary catheter, or both, is recommended in patients at risk, although the indications for laparoscopic surgery should be assessed carefully and attention paid to the important haemodynamic changes that occur with pneumoperitoneum.[5 6]

Finally, although carbon dioxide embolism occurs infrequently in laparoscopic surgery, the presence of a patent foramen ovale must be excluded because of the danger of paradoxical embolism.[7 8]

Sir,—The letter of Ferrando and colleagues emphasizes at least two important points concerning the risk of gas embolism in anaesthetized patients undergoing laparoscopic surgery. First, they suggest assessing, before operation, in any patient undergoing laparoscopic surgery, whether or not a patent foramen ovale exists. We agree totally with this proposal because of the potential occurrence of venous gas embolism, and subsequent risk of "paradoxical" systemic embolism. Nevertheless, the value of such a preoperative testing procedure will never reach a safety level of 100%.[1] Second, as reported previously[2] (and supported also more recently experimentally[3]), signs of mild carbon dioxide embolism may be difficult to detect if routine monitoring is restricted to ECG, NIBP, Sp_{O_2} and $P\text{E}'_{CO_2}$. For a fixed or even progressively increasing carbon dioxide embolism, the value of $P\text{E}'_{CO_2}$ monitoring for quantification of the magnitude of the carbon dioxide embolism is highly questionable (see fig. 5, upper trace[3]). In any circumstances, carbon dioxide as any other gas embolism is easily detected by more sensitive and specific diagnostic tools, such as pre-thoracic or oesophageal echocardiography.[2 4] For our group, it is not appropriate to expose the patient to the clearly increased risk of gas embolism of changing composition,[5] despite the fact that the nature of the injected gas is obviously carbon dioxide at the start, without having specific and sensitive monitoring for early detection of such events.

In the case of gas embolism with peritoneal carbon dioxide insufflation, the difference between a catastrophe[6 7] and an incident may be the promptness of correct diagnosis obtained with sensitive and specific monitors[4] followed by rapid adequate corrective manoeuvres. For these reasons, we believe that Doppler monitoring is mandatory in laparoscopic surgery.

Fuzzy logic control of inspired volatile anaesthetic concentrations

Sir,—The article of Curatolo and colleagues on fuzzy logic control of inspired isoflurane and oxygen concentrations is in our opinion an important contribution to automatic control of the gaseous composition in the circle system. This seems to be the method of the future to facilitate minimal flow techniques to the majority of anaesthetists. Automatic control, however, should be capable of competing with manually controlled methods.

Our concerns are about the method in which the volatile anaesthetic delivery was calculated. The formula used by the authors seems to take the volatile anaesthetic as a fraction of the fresh gas passing the flowmeters. However, the volatile anaesthetic is added to that gas flow so that total gas flow (100%) consists of the volatile anaesthetic, as set at the vaporizer (vap%), in addition to the fresh gas passing the flowmeters (100%−vap%). Thus volatile delivery has to be calculated as follows:[1]

$$\text{delivery} = \frac{\text{EGF}}{1 - \frac{\text{Vap}}{100}} - \text{FGF (ml min}^{-1}\text{)}$$

where FGF=sum of fresh gas set at the flowmeters (ml min^{-1}) and Vap=vaporizer setting (vol%).

Comparison of the results from the two formulae shows that volatile delivery calculated by the formula used in this article is underestimated to a percentage corresponding to the vaporizer setting (vap%).[2] While 1–5 % may be negligible for traditional volatile agents and when only costs are of concern, the difference becomes relevant with volatile agents used in high concentrations, such as desflurane, and in relevant studies, such as the one considered here. The article compared a "low flow" and a "minimal flow" technique. During minimal flow, the vaporizer is at higher settings than during low flow. Consequently, underestimation of volatile consumption is more pronounced in the minimal flow group than in the low flow group. Thus the data given in the article show a slightly greater difference in delivery between the two groups than is actually there.

Compared with our own experience, volatile anaesthetic consumption reported in this study with respect to only the maintenance period appears to be high. In manually controlled minimal flow techniques we calculated an average isoflurane delivery of only 12.9 ml min^{-1} in 20 entire anaesthetics for the period from intubation to extubation (thus including the wash-in periods) lasting 149±69 min maintained at an end-tidal isoflurane concentration of approximately 0.8 vol%.[3] We used an Ohmeda Modulus CD/CV with the MAS circle system, the volume of which is approximately 1.5 litre less than that of the Dräger Cicero used by Curatolo and co-workers.

The frequent sharp increases in fresh gas flow to remove foreign gas from the circle system are quoted to explain why the net difference in volatile consumption between the two flow rates is relatively small. One may consider that the higher volume of the circle system makes the excess gas during minimal flow and the high flow flush less effective in removing foreign gases from the circle system. Furthermore, the system response to changes in the vaporizer setting are slower with a larger circle system. These factors may have contributed to the lower volatile anaesthetic consumption in our work.

3. Kuhn I, Wissing H. Wirtschaftlichkeit von Desfluran im Vergleich zu Isofluran bei Niedrigflußnarkosen. *Anaesthesist* 1995; 44: S459.

Sir,—We thank Drs Wissing and Kuhn for their interest in our investigation and for their comments.

We agree that the formula to calculate isoflurane delivery suggested by Drs Wissing and Kuhn gives a more precise estimation. However, as they pointed out, underestimation resulting from our formula is quantitatively insignificant and does not therefore influence the conclusions of the investigation. We agree that a more accurate calculation should be used when performing a similar study on desflurane.

Concerning the difference in isoflurane consumption between our study and the experience of Drs Wissing and Kuhn, we believe that such a comparison cannot be made without more detailed information on patients characteristics, premedication, co-administration of other analgesics, anaesthetist involved, surgical procedures, etc. All of these factors can greatly affect isoflurane delivery. Furthermore, median fresh gas flow in our study was higher than 0.5 litre min^{-1} (table 5) because of the occasional activation of the "turbo" mode (fresh gas flow 10 litre min^{-1}) when a rapid change in the inspired isoflurane concentration was desired.

Hypotension during subarachnoid anaesthesia

Sir,—The article by Drs Critchley and Conway[1] investigating the effects of colloid or metaraminol, or both, in patients receiving subarachnoid anaesthesia to facilitate surgery for fractured neck of femur makes interesting reading. However, I should like to make two comments, particularly concerning their conclusion that "hypotension may be treated more effectively by using a vasopressor".

First, elderly patients presenting for fractured neck of femur surgery are, in my experience, almost invariably hypovolaemic, through loss of considerable blood volume into the fracture site and also through inadequate fluid intake in the orthopaedic wards. Performing subarachnoid block in hypovolaemic patients is dangerous[2] and therefore I believe that correction of hypovolaemia is of paramount importance in this group of patients before the use of any vasoconstrictor therapy. The statistically significant increases in mean cardiac index and central venous pressure reported in the colloid only group may represent adequate fluid replacement.

Second, we do not know if the use of metaraminol is without risk, particularly when used as an infusion in these elderly patients with potential widespread atherosclerosis. Is the routine use of a vasoconstrictor in the treatment of modest hypotension of any improved *long-term* benefit to the patient compared with fluid replacement therapy? While I accept that this was a physiological study examining the short-term effects of colloid and metaraminol, I do not believe that one can draw conclusions on which is the better treatment of hypotension without examining the incidences of postoperative complications.

Sir,—Thank you for the opportunity to reply to Dr Watters' letter commenting on our recent article on the use of colloids and metaraminol during spinal anaesthesia in patients with femoral neck fractures.[1]

Normovolaemia is essential before spinal anaesthesia. It is therefore standard practice in our hospital that all patients admitted with femoral neck fractures have i.v. hydration on admission to compensate for blood loss at the fracture site and fasting. Despite this practice, patients with femoral neck fractures still experience a greater decrease in arterial pressure during spinal anaesthesia compared with other groups, such as urology patients.[2] We believe that this increase in hypotension is caused by vasodilatation of blood vessels that become abnormally vasoconstricted as a result of the pain and trauma associated with the fracture site.

In our study we measured the effects of treatment with colloid and metaraminol on preload during spinal block. We found that both colloid 8 ml kg^{-1} and metaraminol by i.v. infusion were equally effective in correcting decreases in preload. However, the use of larger volumes of i.v. fluids to prevent hypotension has repeatedly been shown to be ineffective.[3–5] Thus vasopressors are commonly advocated. Although we cannot comment on the long-term effects of using metaraminol, we did limit our dose to the minimum required to maintain normal arterial pressure and by using an infusion we avoided excessive swings in arterial pressure.

Haemodilution induces a hypercoagulable state

Sir,—We read with interest the article by Ruttmann, James and Viljoen on hypercoagulability induced by 20% dilution of whole blood with isotonic saline or gelatine.[1] In this study, coagulation was measured using native thrombelastography (TEG), and a shortening of *r* and *k* times, and an increase in MA were found. We would like to report our own observations.

In a similar investigation involving 12 volunteers, 10 ml of citrated blood were obtained and native TEG was performed with undiluted blood (control) and with a 20% *in vitro* dilution using 0.9% saline. The volunteers then received 1 litre of the same saline solution i.v. (equal to a 20% dilution) and another TEG measurement was performed. Our results are shown in table 1.

These data confirm the results of Ruttmann, James and Viljoen showing a hypercoagulable state when saline was mixed *in vitro*. However, after i.v. infusion of saline, no significant changes in TEG variables were observed. Thus we suggest that the reported effect might be an *in vitro* phenomenon. Our opinion is enforced by observations using activated TEG (activation with Innovin 5 μl) which revealed no significant changes when saline was added *in vitro*.[2] This indicates that the *in vitro* effect might be a pitfall of native thrombelastography.

There are no data to explain this phenomenon. Non-activated (native) thrombelastography is a very sensitive method for evaluating factors influencing coagulation. This is seen for example in the long *r* time of the control in this study (9 min). Conclusions based on the effects seen in non-activated thrombelastographic measurements to the *in vivo* situation should be drawn with great care as the activation situation in non-activated thrombelastographic measurements does not reflect the *in vivo* situation. In the body, coagulation takes place mainly after severe extrinsic activation, for example after vascular injury.

The low contact activation of the coagulation system in native TEG measurements is not a physiological situation. With respect to the better clot formation and higher MA in the *in vitro* saline tests compared with the control, the following mechanism should be excluded: it is known that a high sedimentation rate leads to an artificially high MA.[3] Thus sedimentation processes during the relatively long measurement periods may play a role. Also, clot formation in non-activated TEG is influenced by many factors. A study with non-activated TEG measurements alone might not be sufficient to explain these complex mechanisms.

Table 1 Mean (SD) TEG values before and after *in vitro* and *in vivo* dilution with 20% saline (n=12). *P<0.05 compared with control (Wilcoxon)

	Control	*In vitro* dilution	*In vivo* dilution
r (min)	7.9 (2.3)	5.8 (1.9)*	9.0 (2.9)
k (min)	4.8 (1.9)	2.6 (1.4)	5.0 (1.5)
MA (mm)	51.9 (6.1)	56.7 (6.5)	47.5 (5.7)

2. Entholzner E, Calatzis AN, Kling M, Mielke L, Hipp R. *Anaesthesist* 1996; **45**: A171.
3. Lechner K. Blutgerinnungsstörungen In: Lechner K, ed. *Laboratoriumsdiagnose hämatologischer Erkrankungen 2.* Berlin, Heidelberg, New York: Springer, 1982; 177.

Sir,—We thank Dr Entholzner and colleagues for their comments. It is of interest that their *in vitro* studies confirmed our *in vitro* results,[1] despite the fact that they used citrated blood before performing the TEG studies. We have recently conducted some preliminary tests using immediately sampled blood and comparing it with the same blood citrated and then reconstituted with calcium in a manner identical to that recommended by the TEG manufacturers, that is 250 μl of citrated blood placed in the TEG cup to which is added 100 μl of 0.65% calcium chloride solution. Our observation was that the citrated and reconstituted blood clotted much more vigorously (shorter r and k times, steeper α angle and larger MA) than the non-treated controls. We are in the process of validating this observation at the present time. We are, therefore, sceptical that citrated blood truly represents the native state and that the results of Entholzner and colleagues may have reflected this.

The comment that the effect may be an *in vitro* phenomenon is of interest and we had already considered this possibility. A subsequent study of *in vivo* haemodilution has been performed by us and is currently under consideration for publication and we cannot, therefore, publish the data. However, in essence, this study showed a similar but slightly smaller phenomenon in the *in vivo* haemodilution compared with our *in vitro* experiments. We suspect that the difference observed by Entholzner and colleagues may be a result of their use of citrated blood.

As regards the difference between native and activated thrombelastography, we find their comments difficult to understand. First, the comment regarding the long r time of the control group in the study (9 min) makes no sense whether or not it refers to their letter or to our own data. It is true that the non-activated TEG measurement reflects only the activity of the intrinsic pathway. Whether or not the activated TEG truly reflects the activity created by the addition of tissue thromboplastins, such as occurs with tissue injury, is speculative and not supported to our knowledge by scientific evidence. While it is true that we speculated on several possible mechanisms for this phenomenon, in our subsequent *in vivo* study, we have also demonstrated a decrease in antithrombin III, thus confirming the possibility raised by Monkhouse that this may be at least part of the mechanism. Therefore, we cannot accept the suggestion of Entholzner and colleagues that our results are an *in vitro* effect. The article published by Ng and Lo[2] confirms that not only is this effect demonstrable *in vivo* but is demonstrable in the presence of major surgery where, presumably, activation of coagulation by tissue thromboplastins has taken place. We believe that our observations reflect a real clinical entity and not simply an *in vitro* aberration.

Haemodynamic and neuroendocrine responses after pneumoperitoneum during cholecystectomy

Sir,—O'Leary and colleagues[1] investigated haemodynamic and neuroendocrine responses after pneumoperitoneum and body position changes during cholecystectomy.

Direct mechanical compressive effect on the abdominal aorta is unlikely to contribute to the increases in cardiac afterload and arterial pressure observed during laparoscopic surgery. Indeed, in human studies, haemodynamic alterations associated with laparoscopic surgery persisted for more than 20 min after pneumoperitoneum had been evacuated.[2] Moreover, an acute 9 mm Hg increase in abdominal pressure reproduced in a dog model the haemodynamic changes associated with laparoscopic surgery in humans.[3] Such a low pressure applied to the aortic high pressure system is unlikely to have induced the reported cardiac output redistribution towards the upper part of the body.[3]

Hypercapnia is unlikely to contribute to the haemodynamic changes associated with laparoscopic surgery. Indeed, during prolonged intraperitoneal carbon dioxide insufflation, carbon dioxide diffusion into the body has been demonstrated to be limited.[4] It results in a slight increase in Pa_{CO_2} accounted for by the increase in respiratory dead space caused by diaphragmatic impairment induced by increasing intraperitoneal pressure.[5] In the study of O'Leary and colleagues,[1] end-tidal $P\mathrm{CO}_2$ was easily maintained at 0.5–0.7 kPa.

Hormonal responses described during laparoscopic surgery have been shown previously to reflect the degree of surgical stress in "conventional" open surgery.[6] Vasopressin release paralleled the time course of the increase in systemic vascular resistances.[7] Changes in plasma concentrations of catecholamines, renin and cortisol were correlated with circulatory changes associated with general anaesthesia and reflect the stress response to surgery.[6–8] Changes in endothelin concentrations reflect tissue injury associated with surgery.[8]

More striking are studies showing that physical stimulation of intraperitoneal receptors increased systemic vascular resistances and arterial pressure.[9] Sympathetic nerve section significantly reduced circulatory changes not only in the presence of intraperitoneal physical stimulation but also in experimental intraperitoneal pressure elevation.[9]

We speculate that there may be involvement of baroreflexes elicited by various intra-abdominal viscera stimulation underlying the pathophysiology of circulatory changes associated with laparoscopic surgery in humans.

Glycine absorption and hypocalcaemia

Sir,—I enjoyed reading the article by Dr Chassard and colleagues on the effect of glycine solution on calcium homeostasis[1] and would like to suggest an interpretation of their results. I have measured serum calcium concentrations during i.v. infusion of 1000 ml of glycine solution over 20 min in young men[2] and in prostatectomy patients.[3] A review of my original data shows that, during infusion, there was a close correlation between changes in serum sodium and albumin-corrected serum calcium concentrations. After infusion, however, serum calcium concentration was restored more rapidly than serum sodium concentration. Dr Chassard and colleagues also found a close correlation between serum sodium and free (ionized) calcium concentrations during the first 20 min of there study. Thereafter, serum calcium remained essentially unchanged, although the glycine infusion continued for another 40 min. All of these findings suggest that the mechanisms compensating for a diluted serum calcium concentration have the same strength as for serum sodium during 20–30 min of a glycine infusion, after which they become stronger for calcium.

Dilution of serum sodium during glycine infusions is governed mainly by the volume of irrigant absorbed. Correction occurs by diffusion of glycine and irrigant water from the extracellular to the intracellular fluid compartment, and marked, but delayed, cellular oedema develops.[4] Urine excretion also plays a part, but the urine contains large amounts of sodium,[2 3] particularly when a large volume of glycine solution is given.[5] The principal difference between the correction of diluted concentrations of sodium and calcium is that the latter ion can be mobilized easily from loosely bound bone stores, and equilibration has been claimed to occur with a half-time of 70 min.[6] The relatively poor perfusion of bone certainly explains some of this delay.

I believe that the time-course of this calcium mobilization can explain the absence of a further reduction of ionized calcium at 40 min and 60 min of the glycine infusions given by Chassard and colleagues. This indicates that hypocalcaemia probably does not get worse after 20–40 min of glycine absorption in the clinic either. When irrigating fluid is absorbed very rapidly, however, severe hypocalcaemia may develop within this time and then contribute to the hypokinetic circulation seen in the TURP syndrome.[7] A role for calcium in the treatment of this syndrome has also been suggested by two reports of patients in whom cardiac arrest and hyponatraemia developed during prostatectomy.[8 9] Some degree of "self-treatment" of the hypocalcaemia can be expected as the TURP syndrome is associated with metabolic acidosis, although this is usually fully compensated until circulatory disturbances occur.[10]

10. Hahn RG. Acid–base status following glycine absorption in transurethral surgery. *European Journal of Anaesthesiology* 1992; **9**: 1–5.

Sir,—We are grateful to Dr Hahn for his help in the discussion of our recent findings on the effects of glycine infusion on calcium homeostasis.[1] A readily exchangeable reservoir is responsible for 500 mmol of calcium exchange per day from bone to extracellular fluid. As he suggested, this could have contributed to the absence of further effect of glycine on ionized calcium after 20 min of i.v. infusion. However, the pH-normalized ionized calcium remained unchanged throughout the study, despite acute absorption of glycine (equivalent to 2000 ml for humans). As we concluded, changes in plasma sodium concentration rather than changes in calcium homeostasis are probably more important in the development of the TURP syndrome. As previous studies and Dr Hahn suggested,[2] we encourage further clinical studies, including monitoring calcium concentrations during acute TURP. This could help in the decision to introduce calcium therapy in the resuscitation of cardiovascular disturbances in this syndrome.

Locating an arterial foreign body by ultrasonography

Sir,—Shah, Downing and Davis described severance of a segment of catheter after arterial cannulation leading to embolization within the radial artery.[1] They reported that surgical exploration of the distal portion of the artery was unsuccessful and the fragment was finally retrieved after proximal radial artery exploration. We write to suggest that real-time ultrasound imaging might have been helpful by allowing rapid location of the fragment before surgical removal.

Lightweight, portable machines are available specifically for anaesthetic use (Site Rite, Dymax Corporation, Pittsburgh, PA, USA). These machines provide good quality images of vascular anatomy, especially in the neck, and their use as an aid to internal jugular vein cannulation represents an advance in safety and efficacy in adult[2] and paediatric patients.[3] The device can also be used to demonstrate the course and calibre of peripheral arteries. A short-focus probe (9 MHz frequency) with a focal length of 0.7 cm from the probe cap can easily identify an intra-luminal foreign body, which is displayed on the screen as a densely echogenic image. This allows rapid and non-invasive ultrasonic assessment of the radial artery "at the bedside". Sterile, acoustically transparent probe sheaths are available to allow aseptic examination.

We suggest that ultrasonic assessment in a situation such as this would permit confident localization of a wayward fragment and, if available, represents a potential advance in management.

BOOK REVIEWS

Regional Anesthesia and Analgesia. D. L. BROWN (editor). Published by WB Saunders, Philadelphia. Pp. 749; indexed; illustrated. Price £99.00.

This is an impressive reference book, with 750 pages and 59 authors, the stated aim of which is "to fill the need for a clinically focused textbook of regional anesthesia and analgesia". There is no doubt that it achieves this aim, albeit with a distinct bias towards North American practice; a more international blend of authors would add balance and avoid some of the parochialism that exists.

By dividing the book into five sections, the huge amount of information is easy to navigate. Section one could be omitted as it contains only the personal views of the editor on regional anaesthesia (better expressed as a foreword) and some history which rather emphasizes the minutiae of the early years of the American Society of Regional Anesthesia. Section two, "Basic science" is possibly the best in the book; it covers anatomy, neuroanatomy and neurophysiology in a refreshingly readable way, combining established facts with new data in a clinically relevant presentation. In rapidly changing areas such as regional anaesthesia and the stress response (chapter 7), no textbook can be totally up to date but this is a good summary of recent work. The section ends with pharmacology; chapter 8 by de Jonge ("Local anesthetic pharmacology") is a masterly climax and should be read by both examinee and examiner.

Section three "Induction of regional anesthesia" starts with a whimper—an irrelevant chapter on equipment and some repetitive pharmacology. It gets into its stride with the core detail of the book, the systematic description of central and peripheral nerve blocks from head to toe. If some techniques are described rather concisely for a beginner, it is because Dr Brown has a companion volume *Atlas of Regional Anesthesia* (very practical and lavishly illustrated) which he would wish the reader to buy.

While leaving room for disagreement with particular details of individual techniques, the chapters are well written with practical expertise and highlighted clinical notes to improve a novice's chances. The advice on managing the conduct of a block and subsequent patient care during and after surgery is eminently sensible and underlines the stated aims of the book. Chapter 19, "Neuraxial blocks", epitomizes the overall quality of this section and the ethos of the book itself.

Section four covers the expected (physiological) and unexpected (complications) effects of regional anaesthesia without too much repetition of earlier chapters, and section five discusses the use of regional anaesthesia in surgery, obstetrics and acute and chronic pain management. Inevitably, there is repetition, with some blocks being described several times in different parts of the book but minor criticisms aside, this section will repay time spent reading it. Of necessity, the chapters on pain are not comprehensive reviews of this major topic but more an attempt to put the use of regional anaesthesia into the correct perspective. Chapters 39 ("Outcome after extradural anaesthesia") and chapter 40 ("Pharmacology of pain control") are particularly good reviews of these very topical subjects.

There are some excellent books on regional anaesthesia and pain management currently available and a large, expensive textbook must be special if it is to succeed. The editor and publishers have done everything possible to ensure that this book will succeed. It is beautifully produced, with clear and informative illustrations which enhance the text.

H. B. J. Fischer

Key Topics in Anaesthesia. T. M. CRAFT AND P. M. UPTON. Published by Bios Scientific Ltd, Oxford. Pp. 341; indexed. Price £21.95.

This is the second edition of a book which has become one of the standard revision aids for trainee anaesthetists before postgraduate examinations. One either likes or hates this method of study for examinations. A quick flick through the book will readily indicate to which group one belongs. It is 341 pages of concentrated fact. If it had been around when I took my examinations I would certainly have purchased it.

There are 111 broad headings which could be considered as chapter titles from a larger textbook. These have then been arranged in alphabetical format. This does not necessarily make looking up individual topics easier. The book also has an index. However, *Key Topics* is not meant to be used in this way. It aims to provide a framework of information on key areas commonly appearing as topics in postgraduate examinations. In this it succeeds and should form a useful revision aid. In addition, at the end of each "chapter" there are very helpful lists of related topics of interest and suggestions for further reading. The references given are topical and in the main up to date.

The authors accept that the text is not comprehensive and some subspecialties such as intensive care, pain management and regional blocks are not well covered. (Perhaps these are areas for future inclusion in the *Key Topics* series.) However, there were also one or two omissions elsewhere. For instance, NCEPOD was covered but another favourite examination question on the Report on Confidential Enquiries into Maternal Deaths in the United Kingdom was not included. Also, treatment of pre-eclampsia and the diagnosis and treatment of TURP syndrome were not well covered. These points apart, the book is an excellent aid to both the examination candidate and examiner. I would expect well used copies to be present in all trainees' brief cases.

N. R. Webster

The Pocket Companion to the Textbook of Critical Care Medicine. W. C. SHOEMAKER, A. GRENVIK, S. N. AYRES AND P. R. HOLBROOK. Published by WB Saunders, Philadelphia. Pp. 844; indexed; illustrated. Price £29.50.

Management of the critically ill is a difficult and often intimidating task for doctors in training. Combined with the recent increase in intensive care training requirements and the emphasis on a multidisciplinary approach to patient management, the publication of *The Pocket Companion to the Textbook of Critical Care Medicine* is well timed.

This text is intended to be a pocket book for the trainee doctor on intensive care assignment and aims to provide a step-by-step approach to the management of most clinical problems. Each chapter covers essential relevant physiology, patient work-up, monitoring and management. The range of topics covered is comprehensive and up to date, with particularly good chapters on paediatric and obstetric emergencies.

Although the text is generally readable, clarity is sometimes obscured by a long-winded prose style. The cook book approach used in the chapter on resuscitation is confusing and likely to prove difficult to follow in the "heat of battle". The algorithms included are detailed but lack impact because of the small print size. The absence of any references is disappointing and a little surprising. The book is, perhaps, more successful as a summary of the original *Textbook of Critical Care Medicine* than it is a convenient practical handbook for clinical use.

Although based on North American practice, this does not detract from the value of the book for a physician working in intensive care anywhere in the world. It can be recommended more as a useful addition to the ICU library than an essential purchase.

C. Hickey

Current Topics in Intensive Care, 3rd Edn. R. P. DELLINGER, H. BURCHARDI, G. J. DOBB AND J. BION (editors). Published by WB Saunders, London. Pp. 282; indexed; illustrated. Price £30.00.

This is the third in a series of pocket-sized texts which are published annually. It consists of 13 chapters, each with an extensive list of up-to-date references, written by 21 international contributors, nine of whom work in the USA. It has been written for both clinicians practising intensive care and trainees preparing for postgraduate examinations. Six of the chapters discuss clinical topics. These are balanced by four chapters of basic scientific information, pertinent to clinical practice, on: nitric oxide in circulatory shock; animal models for research; adhesion molecules; and formation and resolution of pulmonary oedema. There are also three reviews on modern radiographic imaging techniques, featuring Doppler echocardiography and transcranial Doppler ultrasonography.

The chapters covering clinical topics have been well written and provide a valuable review of their subjects. Therapeutic monitoring of commonly used drugs such as antibiotics, anticonvulsants, digoxin and cyclosporin is considered in depth; the economics of monitoring drug concentrations is also examined. The fundamentals of mechanical ventilation, which are essential knowledge for any intensivist, are considered over three chapters and the clinical problems associated with managing the acute asthmatic patient are also discussed. The hazards of a ventilator strategy based on preset volume goals are detailed: such practice may now seem outdated to many British anaesthetists. Dr Nicholas Hill has reviewed the role of non-invasive positive pressure ventilation, concluding that carefully selected patients with chronic obstructive airways disease are most likely to benefit from this new development. Clearly, non-invasive ventilation is an attractive alternative to tracheal intubation, but we have not yet found a role for it in acutely deteriorating postoperative patients. Mervyn Singer's review of early enteral feeding in the acutely ill patient reminds us of how much better this nutritional route is, not only for our patients, but also for our budgets. This will be preaching to the converted for most intensivists, but I fear that not all of our surgical colleagues are fully convinced!

Professor Eric Milne's chapter on imaging techniques in the critically ill patient considers the value of such modern technologies as computer tomography (CT), magnetic resonance imaging, ultrasound, angiography and nuclear imaging. His discourse on the plain chest x-ray will prompt me to look afresh at such films. However, considering the number of CT scans of head, thorax and abdomen performed on critically ill patients, I would prefer to have had the value of these investigations demonstrated by more illustrations. The chapter on echocardiography presents the background to Doppler imaging and shows how mathematical manipulation allows cardiac output, intracardiac pressures and pressure gradients across the heart valves to be measured non-invasively. Several clinical studies are reviewed, and the potential which echocardiography has to complement the invasive cardiovascular monitoring, now so commonplace in intensive care practice, is acknowledged.

The essay on adhesion molecules and tissue injury provides an insight into an important but complex area and suggests therapeutic approaches which may be developed. Professor Thiemermann explores the potential role for inhibitors of nitric oxide synthase in circulatory shock; these drugs are at present undergoing clinical trials in such patients.

In summary, I enjoyed reading this book, with its useful reviews of many scientific and clinical topics relevant to present day intensive care practice. At £30, the price is typical of books of this size, but is good value.

G. T. Taylor

The Anaesthesia Viva: vol.1. J. URQUHART AND M. BLUNT. Published by Greenwich Medical Media, London. Pp 161; indexed; illustrated. Price £12.50.

This book is yet another of those which aim to guide fellowship examination candidates to success. It comprises over 200 questions on the basic sciences section of the new primary FRCA examination. However, it makes no attempt to cover the entire syllabus, but we are promised volume 2 later this year.

The book is composed of 14 sections and three somewhat superfluous appendices. The subjects of the sections, 50% physiology and 50% pharmacology and statistics, reflect more or less the content of viva 1 of the examination. Cardiorespiratory topics make up the bulk of the first half and the remainder is reasonably well balanced. Pharmacology comprises 30% pharmacokinetics, pharmacodynamics and anaesthetic drugs, with the remainder divided fairly evenly, although statistics occupies only three pages. The format is that of question and explanatory answer, but the quality of the explanation is variable, for example "Can you draw the oxyhaemoglobin dissociation curve" is followed by the statement "If you cannot you will fail". This is unfortunate as the diagram then contains an error on the label of the x axis! Oversimplification in the explanation sometimes leads to confusion, for example a line missed in the derivation of the shunt equation fails to supply a logical sequence—not useful in a teaching book.

The sequence of questions is somewhat random in places; isolated facts without relating a concept to an overall systematic review leads to inconsistency, for example different values given for ECF volume in different discussions of fluid distribution. Many of the questions are examiners' favourites but may not appear in future "new exam" vivas! Similarly, there are old chestnuts (e.g. antibiotic interference with neuromuscular block) which are no longer relevant. There are sections on therapeutic regimens in a book purporting to be on basic physiology and pharmacology, but there is inconsistency in the absence of management guidelines in some subjects with a more fundamental physiological rationale.

The typeface is very clear and the pages are presented in a clean format, but there are several typographical errors in equations and diagrams, surely unforgivable in these subjects.

On the credit side, the book contains an enormous amount of factual material concentrated in an affordable volume. Some may enjoy this as a form of learning, where disjointed questions are supplied with explanations. A more organized approach could be gained by reading standard texts. As a means of self-assessment this format may have more to commend it. The preface, written by a member of the council of the College, gives important advice on using this book only as a supplement to standard texts, and this advice is reiterated at the end of the authors' introduction. It is perhaps premature to assess the value of a book on postgraduate examinations in anaesthesia at a time when the system itself is undergoing change. However, the book is a timely and commendable attempt to provide worthwhile assistance for the new generation of trainees in anaesthesia.

D. Fell

Perioperative Management for House Surgeons. P. R. HAMBLY AND M. C. SAINSBURY. Published by Bios Scientific Ltd, Oxford. Pp. 280; indexed; illustrated. Price £17.95.

This is an excellent book. The authors, two senior registrars in anaesthesia, state in the preface that they hope the book will provide help with those questions to which, at 03:00, no one seems to have the answers; the book certainly achieves this objective. The text is divided into two sections, the first dealing with preoperative issues and the second with postoperative problems. The final part of the book consists of short, sharp, succinct "action plans". The book covers all of the important areas involved in the perioperative management of patients. The style of writing is clear, to the point and often witty. The chapter on communicating with patients and colleagues is particularly well written and contains very useful advice for a new house surgeon. Indeed, the book is full of good, sound, practical tips and when I gave it to my own house surgeon to peruse I only got it back after a lot of pestering! The book can easily be read from start to finish as an educational exercise but, importantly, it is very well indexed and therefore easy to find information quickly. The action pages are particularly good. One minor quibble is that it would be nice to see an action page on postoperative chest pain.

In summary, the authors have achieved their intended aim admirably and the book provides a wealth of important practical management tips and pathways for the perioperative patient. I have written to my Trust Risk Management Committee to suggest that every surgical houseman is given a copy of this book—it will be money well invested!

N. J. M. London

Diagnostic Testing in Emergency Medicine. A. B. WOLFSON AND P. M. PARIS (editors). Published by WB Saunders, Philadelphia. Pp. 626; indexed. Price £30.00.

This is an easy to read reference guide to tests available to clinicians in the emergency situation, not only in accident and emergency, but also in hospital.

Broadly, it is divided into three sections: a general section with emphasis on tests used for paediatrics, pregnancy and the elderly; a second section on clinical syndromes, that is which test to do in a particular clinical situation (e.g. DVT); and a final section on diagnostic tests, taking each group of tests and discussing the value in specific situations based on the current clinical literature (e.g. CT scanning, neurological, with a sub-section on intracerebral haemorrhage).

The book has been published by American physicians and obviously, therefore, has a clear American bias with considerably more emphasis on tests in diagnosis, compared with the British more clinically based diagnostic process. However, our own clinical practice is gradually changing. Therefore, this represents a well discussed and thoroughly referenced manual, which makes it easy to understand with supporting further reading.

As we move into a more evidence-based system of medicine, any extra tests which we wish to perform have to be heavily justified to management. This, therefore, is a useful tool.

Provided one interprets this book with a British clinical point of view, it is a useful reference book for those involved in emergency care, destined, more reasonably perhaps, to the hospital or departmental library rather than one's back pocket.

D. N. Quinton

Handbook of Clinical Anaesthesia. J. C. GOLDSTONE AND B. J. POLLARD (editors). Published By Churchill Livingstone, Edinburgh. Pp. 722; indexed; Illustrated. Price: £50.00

This paperback is in a somewhat new format. The editors have persuaded a large number of contributors to produce sets of guidance notes for anaesthetic problems. The approach is problem-orientated within three sections: patient problems, surgical procedures and anaesthetic factors. Thus the order is as we might approach a patient—what are the general problems, what are the surgeons likely to do and what sort of anaesthetic problems may be encountered. This can lead to some duplication. For example, hyperthyroidism is discussed as a medical problem with advice as to perioperative management and later, by a different author, under the management of thyroidectomy. The thyroid operation also gets a mention under the difficult airway in the anaesthetic problem section. Such duplication is inevitable in this format but may well be a helpful reminder for anyone checking on a topic using the contents list rather than the index. But the list of topics is impressive: it covers virtually all the commoner medical problems and the types of surgery.

Each small review uses lists and a standard format. There are cross references to other chapters and usually a bibliography of recent articles. The general effect is of a helpful set of notes for those of us who meet the occasional unusual problem and a very helpful set for those taking examinations. There are the occasional infelicitous comments. For patients to undergo abdominal aortic surgery we are advised to "reassure the patient and maintain a calm environment" in the anaesthetic room. Don't all patients deserve this? Should we keep up the calm environment in the operating room and also afterwards? But this is a minor quibble; the book will be of practical help to most.

SUBJECT INDEX

A Practical Approach to Pain Management, Lefkowitz, M., *et al.*, (editors), (*R*) 702–703

ABC of Brainstem Death, 2nd Edn, Pallis, C., *et al.*, (*R*) 303

Acetylcholine, Differential effects of ketamine and pentobarbitone on acetylcholine release from the rat hippocampus and striatum, Sato, K., *et al.* 381–384

Acid–base equilibrium, buffers, An oral sodium citrate–citric acid non-particulate buffer in humans, Hauptfleisch, J. J., *et al.* 642–644

Acid–base equilibrium, metabolic acidosis, Normovolaemic haemodilution attenuates cardiac depression induced by sodium bicarbonate in canine metabolic acidosis, Tanaka, M., *et al.* 408–412

Acid–base equilibrium, pH, Acid–base state of cerebrospinal fluid during pregnancy and its effect on spread of spinal anaesthesia, Hirabayashi, Y., *et al.* 352–355

——, An oral sodium citrate–citric acid non-particulate buffer in humans, Hauptfleisch, J. J., *et al.* 642–644

Acid–base equilibrium, respiratory acidosis, Normovolaemic haemodilution attenuates cardiac depression induced by sodium bicarbonate in canine metabolic acidosis, Tanaka, M., *et al.* 408–412

Age factors, Dose–response relationships for neostigmine antagonism of rocuronium-induced neuromuscular block in children and adults, Abdulatif, M., *et al.* 710–715

——, Is it always necessary to antagonize residual neuromuscular block? Do children differ from adults? Hunter, J. M., (*E*) 707–709

——, Patient-controlled sedation for cataract surgery using peribulbar block, Pac-Soo, C. K., *et al.* 370–374

——, Spinal anaesthesia with 0.5% hyperbaric bupivacaine in elderly patients: effect of site of injection on spread of analgesia, Veering, B. Th., *et al.* 343–346

Airway, mucosa, Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation, Mallick, A., *et al.* 731–734

Airway, obstruction, Respiratory mechanics after abdominal surgery measured with continuous analysis of pressure, flow and volume signals, Nimmo, A. F., *et al.* 317–326

Airway, pressure, New approaches to acute lung injury, Bigatello, L. M., *et al.* 99–109

Airway, reflexes, Effect of an upper respiratory tract infection on upper airway reactivity, Nandwani, N., *et al.*, (*ARS*) 288P

Anaesthesia, audit, Cost of volatile anaesthetic agents, Daniel, M., (*C*) 437

——, Cusum: a statistical method to evaluate competence in practical procedures, Hammond, E. J., *et al.*, (*C*) 562

——, Cusum: a statistical method to evaluate competence in practical procedures, Kestin, I. G., (*C*) 562

——, Randomization is important in studies with pain outcomes: systematic review of transcutaneous electrical nerve stimulation in acute postoperative pain, Carroll, D., *et al.* 798–803

——, The care of patients and transport by air, Morley, A. P., (*C*) 435

——, The care of patients and transport by air, Shirley, P. J., (*C*) 435

Anaesthesia, day-case, Comparison of propofol and a propofol–methohexitone mixture for induction of day-case anaesthesia, Thompson, N., *et al.* 213–216

Anaesthesia, depth, Effect of remifentanil on the auditory evoked response and haemodynamic changes after intubation and surgical incision, McGregor, R. R., *et al.*, (*ARS*) 688P

——, Midlatency auditory evoked potentials as indicators of perceptual processing during general anaesthesia, de Beer, N. A. M., *et al.* 617–624

——, Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology, Thomsen, C. E., *et al.* 172–178

——, Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol, Schwender, D., *et al.* 179–184

——, Topographic distribution of the bispectral index, Hall, J. D., *et al.*, (*ARS*) 689–690P

Anaesthesia, emergency service, The care of patients and transport by air, Morley, A. P., (*C*) 435

——, The care of patients and transport by air, Shirley, P. J., (*C*) 435

Anaesthesia, general, Does anaesthesia have long-term consequences? Masterson, G. R., *et al.*, (*E*) 569–571

——, Isoflurane waste gas exposure during general anaesthesia: the laryngeal mask compared with tracheal intubation, Hoerauf, K. H., *et al.* 189–193

——, Volumetric analysis of aeration in the lungs during general anaesthesia, Drummond, G. B., (*C*) 697–698

——, Volumetric analysis of aeration in the lungs during general anaesthesia, Reber, A., *et al.*, (*C*) 698

Anaesthesia, obstetric, Acid–base state of cerebrospinal fluid during pregnancy and its effect on spread of spinal anaesthesia, Hirabayashi, Y., *et al.* 352–355

——, Ambulatory extradural analgesia in labour reduces risk of Caesarean section, May, A. E., *et al.*, (*ARS*) 692–693P

——, Caesarean section; efficacy of morphine patient-controlled anaesthesia *vs* ketorolac infusion, Bewlay, M. A., *et al.*, (*ARS*) 687P

——, Cardiac arrest after Caesarean section under subarachnoid block, Scull, T. J., *et al.* 274–276

——, CSF progesterone and spread of subarachnoid anaesthesia in pregnancy, Chan, M. T. V., *et al.*, (*C*) 293

——, CSF progesterone and spread of subarachnoid anaesthesia in pregnancy, Hirabayashi, Y., (*C*) 293–294

——, Difficult tracheal intubation, Broomhead, C. J., *et al.*, (*C*) 436

——, Difficult tracheal intubation, Jonas, M., *et al.*, (*C*) 436–437

——, Extradural anaesthesia for Caesarean section in a patient with moyamoya disease, Ngan Kee, W. D., *et al.* 550–552

——, Extradural clonidine combined with sufantanil and 0.0625% bupivacaine for analgesia in labour, Chassard, D., *et al.* 458–462

——, Failed intubation during obstetric anaesthesia, Jenkins, J. G., (*C*) 698

——, Failed tracheal intubation, Hawthorne, L., *et al.*, (*C*) 559

——, Failed tracheal intubation, Hawthorne, L., *et al.*, (*C*) 559–560

——, Failed tracheal intubation, Hawthorne, L., *et al.*, (*C*) 560

——, Failed tracheal intubation, Kessell, G., (*C*) 560

——, Failed tracheal intubation, McBrien, M. E., (*C*) 559

——, Failed tracheal intubation, Norman, B., (*C*) 559

——, General anaesthesia for Caesarean section in a parturient with Noonan's syndrome, McLure, H. A., *et al.* 665–668

——, Influence of patient position on withdrawal forces during removal of lumbar extradural catheters, Morris, G. N., *et al.* 419–420

——, Single bolus compared with a fractionated dose injection technique of bupivacaine for extradural Caesarean section: effect on uteroplacental and fetal haemodynamic state, Karinen, J., *et al.* 140–144

——, Soft tissue anatomy within the vertebral canal in pregnant women, Hirabayashi, Y., *et al.* 153–156

——, Spinal anaesthesia for Caesarean section, Foster, R. N., *et al.*, (*C*) 301

——, Spinal anaesthesia for Caesarean section, Stoneham, M., *et al.*, (*C*) 301–302

——, Spinal anaesthesia for Caesarean section, Vickers, R., *et al.*, (*C*) 301

——, Spinal anaesthesia for Caesarean section: effect of Sprotte needle orientation, James, K. S., *et al.* 150–152

——, Spinal anaesthesia with 0.25% hyperbaric bupivacaine for Caesarean section: effects of volume, Chung, C. J., *et al.* 145–149

——, Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia, Ramadhani, S. A. L., *et al.* 312–316

——, Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia, Ramadhani, S. A. L., *et al.*, (*e*) 701

——, Unexpected high spinal block in obstetrics, Richardson, M. G., *et al.*, (*C*) 806–807
——, Unrecognized "crack" cocaine abuse in pregnancy, Campbell, D., *et al.* 553–555
Anaesthesia, paediatric, Dose–response relationships for neostigmine antagonism of rocuronium-induced neuromuscular block in children and adults, Abdulatif, M., *et al.* 710–715
——, Effect of anaesthesia on lung function in children with asthma, May, H. A., *et al.* 200–202
——, Intubating conditions and time course of rocuronium-induced neuromuscular block in children, Fuchs-Buder, T., *et al.* 335–338
——, Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children, Malinovsky, J.-M., *et al.* 203–207
——, Perioperative changes in α_1-acid glycoprotein concentrations, Tucker, G. T., (*C*) 130
——, Pharmacokinetics of atracurium after paediatric orthotopic liver transplantation, Chow, B. F. M., *et al.*, (*ARS*) 687–688P
——, Preoxygenation in children using expired oxygraphy, Butler, P. J., *et al.* 333–334
——, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, Habre, W., *et al.* 739–743
Anaesthesia Review 12, Kaufman, L., *et al.*, (editors), (*R*) 564
Anaesthetic techniques, extradural, Ambulatory extradural analgesia in labour reduces risk of Caesarean section, May, A. E., *et al.*, (*ARS*) 692–693P
——, Distinguishing cerebrospinal fluid from saline used to identify the extradural space, El-Behesy, B. A. Z., *et al.* 784–785
——, Extradural anaesthesia for Caesarean section in a patient with moyamoya disease, Ngan Kee, W. D., *et al.* 550–552
——, Extradural clonidine combined with sufantanil and 0.0625% bupivacaine for analgesia in labour, Chassard, D., *et al.* 458–462
——, Inflammatory changes after extradural anaesthesia may affect the spread of local anaesthetic within the extradural space, Igarashi, T., *et al.* 347–351
——, Normal saline i.v. fluid load decreases uterine activity in active labour, Cheek, T. G., *et al.* 632–635
——, Pre-emptive analgesia with NSAID—what does it achieve? Hudspith, M. J., *et al.*, (*C*) 128–129
——, Pre-emptive analgesia with NSAID—what does it achieve? Morrison, L. M. M., *et al.*, (*C*) 129
——, Single bolus compared with a fractionated dose injection technique of bupivacaine for extradural Caesarean section: effect on uteroplacental and fetal haemodynamic state, Karinen, J., *et al.* 140–144
——, Spinal anaesthesia for Caesarean section, Foster, R. N., *et al.*, (*C*) 301
——, Spinal anaesthesia for Caesarean section, Stoneham, M., *et al.*, (*C*) 301–302
——, Spinal anaesthesia for Caesarean section, Vickers, R., *et al.*, (*C*) 301
——, Time course of increased haemodilution in hypotension induced by extradural anaesthesia, Drobin, D., *et al.* 223–226
——, Unexpected high spinal block in obstetrics, Richardson, M. G., *et al.*, (*C*) 806–807
Anaesthetic techniques, hypotensive, Atrioventricular conduction during adenosine-induced hypotension in dogs anaesthetized with sevoflurane, Ishii, R., *et al.* 393–398
Anaesthetic techniques, hypothermia, Efficacy of intraoperative heat administration by ventilation with warm humidified gases and an oesophageal warming system, Beck, E., *et al.* 530–533
Anaesthetic techniques, induction, Comparison of propofol and a propofol–methohexitone mixture for induction of day-case anaesthesia, Thompson, N., *et al.* 213–216
——, Influence of induction technique on intubating conditions after rocuronium in adults: comparison with rapid-sequence induction using thiopentone and suxamethonium, Sparr, H. J., *et al.* 339–342
——, Intubating conditions and time course of rocuronium-induced neuromuscular block in children, Fuchs-Buder, T., *et al.* 335–338
Anaesthetic techniques, i.v., Computer-controlled infusion of propofol for long neurosurgical procedures, Lim, T. A., *et al.*, (*ARS*) 289–290P
——, Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children, Malinovsky, J.-M., *et al.* 203–207
Anaesthetic techniques, laryngoscopy, Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia, Ramadhani, S. A. L., *et al.* 312–316
——, Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia, Ramadhani, S. A. L., *et al.*, (*e*) 701
——, What future is there for predicting difficult intubation? Charters, P., (*E*) 309–311
Anaesthetic techniques, low flow, Fuzzy logic control of inspired volatile anaesthetic concentrations, Curatolo, M., *et al.*, (*C*) 808
——, Fuzzy logic control of inspired volatile anaesthetic concentrations, Wissing, H., *et al.*, (*C*) 807–808
Anaesthetic techniques, nasal, Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children, Malinovsky, J.-M., *et al.* 203–207
Anaesthetic techniques, preoxygenation, Preoxygenation in children using expired oxygraphy, Butler, P. J., *et al.* 333–334
Anaesthetic techniques, rectal, Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children, Malinovsky, J.-M., *et al.* 203–207
Anaesthetic techniques, regional, Thrombelastography changes in pre-eclampsia and eclampsia, Orlikowski, C. E. P., *et al.* 157–161
Anaesthetic techniques, regional, caudal, Comparison of caudal bupivacaine and diamorphine with caudal bupivacaine alone for repair of hypospadias, Kelleher, A. A., *et al.* 586–590
Anaesthetic techniques, regional, peribulbar, Patient-controlled sedation for cataract surgery using peribulbar block, Pac-Soo, C. K., *et al.* 370–374
Anaesthetic techniques, subarachnoid, Acid–base state of cerebrospinal fluid during pregnancy and its effect on spread of spinal anaesthesia, Hirabayashi, Y., *et al.* 352–355
——, Cardiac arrest after Caesarean section under subarachnoid block, Scull, T. J., *et al.* 274–276
——, CSF progesterone and spread of subarachnoid anaesthesia in pregnancy, Chan, M. T. V., *et al.*, (*C*) 293
——, CSF progesterone and spread of subarachnoid anaesthesia in pregnancy, Hirabayashi, Y., (*C*) 293–294
——, Evaluation of the usefulness of intrathecal bupivacaine infusion for analgesia after hip and knee arthroplasty, Niemi, L., *et al.* 544–545
——, Heparinase-guided thrombelastography in an anticoagulated parturient, Abramson, D. C., *et al.* 556–558
——, Hypotension during subarachnoid anaesthesia, Critchley, L. A. H., *et al.*, (*C*) 808–809
——, Hypotension during subarachnoid anaesthesia, Watters, M., (*C*) 808
——, Spinal anaesthesia for Caesarean section, Foster, R. N., *et al.*, (*C*) 301
——, Spinal anaesthesia for Caesarean section, Stoneham, M., *et al.*, (*C*) 301–302
——, Spinal anaesthesia for Caesarean section, Vickers, R., *et al.*, (*C*) 301
——, Spinal anaesthesia for Caesarean section: effect of Sprotte needle orientation, James, K. S., *et al.* 150–152
——, Spinal anaesthesia with 0.25% hyperbaric bupivacaine for Caesarean section: effects of volume, Chung, C. J., *et al.* 145–149
——, Spinal anaesthesia with 0.5% hyperbaric bupivacaine in elderly patients: effect of site of injection on spread of analgesia, Veering, B. Th., *et al.* 343–346
Anaesthetics gases, nitrous oxide, Adequate general anaesthesia—what are we trying to achieve? Munglani, R., *et al.*, (*C*) 300–301
——, Adequate general anaesthesia—what are we trying to achieve? O'Connor, T. C., *et al.*, (*C*) 299–300
——, Comparison of the effects of controlled ventilation with 100% oxygen, 50% oxygen in nitrogen, and 50% oxygen in nitrous oxide on responses to venous air embolism in pigs, Kyttä, J., *et al.* 658–661
——, Effect of naloxone on nitrous oxide analgesia, Gillman, M. A., *et al.*, (*C*) 435
——, Effect of naloxone on nitrous oxide analgesia, Mashimo, T., *et al.*, (*C*) 436
——, Effects of fentanyl, nitrous oxide, or both, on baroreceptor reflex regulation in the cat, Lennander, Ö., *et al.* 399–403
——, Is Doppler monitoring mandatory in laparoscopic surgery? d'Hollander, A. A., (*C*) 807
——, Is Doppler monitoring mandatory in laparoscopic surgery? Ferrando, A., *et al.*, (*C*) 807
——, Nitrous oxide produces a non-linear reduction in thiopentone requirements, Katoh, T., *et al.* 265–267
——, Visual evoked potentials and nitrous oxide-induced neuronal depression: role for benzodiazepine receptors, Dzoljic, M., *et al.* 522–525

Anaesthetics i.v., Effects of i.v. anaesthetics and lipid solutions on polymorphonuclear leucocyte chemotaxis *in vitro*, Leuweri, M., *et al.*, (*ARS*) 695P
——, I.v. anaesthetic agents do not interact with the verapamil binding site on L-type voltage-sensitive Ca^{2+} channels, Hirota, K., *et al.* 385–386
——, I.v. anaesthetic agents inhibit dihydropyridine binding to L-type voltage-sensitive Ca^{2+} channels in rat cerebrocortical membranes, Hirota, K., *et al.* 248–253
Anaesthetics i.v., alfentanil, Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation, Mallick, A., *et al.* 731–734
Anaesthetics i.v., eltanolone, Myocardial effects of eltanolone in hamsters with hypertrophic cardiomyopathy, Ruel, P., *et al.* 653–657
——, Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone, Spens, H. J., *et al.* 194–199
Anaesthetics i.v., etomidate, Different *in vitro* effects of aqueous or lipid etomidate preparations on neutrophil respiratory burst, Leuwer, M., *et al.*, (*ARS*) 282–283P
——, Effect of etomidate on the mass response of cells of cortical lamina V evoked by antidromic activation in the urethane-anaesthetized rat, Arnott, R. H., *et al.*, (*ARS*) 282P
——, Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics? Keita, H., *et al.* 254–256
Anaesthetics i.v., ketamine, Assessment of a model predicted infusion of ketamine used with propofol for total i.v. anaesthesia, Swinhoe, C. F., *et al.*, (*ARS*) 286–287P
——, Differential effects of ketamine and pentobarbitone on acetylcholine release from the rat hippocampus and striatum, Sato, K., *et al.* 381–384
——, Effect of racemic mixture and the (S+)-isomer of ketamine on temporal and spatial summation of pain, Arendt-Nielsen, L., *et al.* 625–631
——, Effect of systemic *N*-methyl-D-aspartate receptor antagonist (ketamine) on primary and secondary hyperalgesia in humans, Ilkjaer, S., *et al.*, (*e*) 567
——, Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics? Keita, H., *et al.* 254–256
——, Ketamine and norketamine plasma concentrations after i.v., nasal and rectal administration in children, Malinovsky, J.-M., *et al.* 203–207
——, Ketamine inhibits nitric oxide production in mouse-activated macrophage-like cells, Shimaoka, M., *et al.* 238–242
——, Ketamine: its mechanism(s) of action and unusual clinical uses, Hirota, K., *et al.*, (*E*) 441–444
Anaesthetics i.v., methohexitone, Comparison of patient-controlled sedation with either methohexitone or propofol, Hamid, S. K., *et al.* 727–730
——, Comparison of propofol and a propofol–methohexitone mixture for induction of day-case anaesthesia, Thompson, N., *et al.* 213–216
——, Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils, Heine, J., *et al.* 387–392
Anaesthetics i.v., propofol, Alfentanil-mediated analgesia during propofol injection: no evidence for a peripheral action, Wrench, I. J., *et al.* 162–164
——, Antiemetic effect of subhypnotic doses of propofol after thyroidectomy, Ewalenko, P., *et al.* 463–467
——, Cardiopulmonary bypass-induced changes in plasma concentrations of propofol and in auditory evoked potentials, Hammarén, E., *et al.* 360–364
——, Comparative actions of propofol and thiopentone on cell membranes of isolated guineapig ventricular myocytes, Sakai, F., *et al.* 508–516
——, Comparative effects of thiopentone and propofol on respiratory resistance after tracheal intubation, Wu, R. S. C., *et al.* 735–738
——, Comparison of patient-controlled sedation with either methohexitone or propofol, Hamid, S. K., *et al.* 727–730
——, Comparison of propofol and a propofol–methohexitone mixture for induction of day-case anaesthesia, Thompson, N., *et al.* 213–216
——, Computer-controlled infusion of propofol for long neurosurgical procedures, Lim, T. A., *et al.*, (*ARS*) 289–290P
——, Concentration-related effects of propofol on the auditory evoked response, Tooley, M. A., *et al.* 720–726
——, Effect of propofol on the electrocorticogram in patients undergoing cortical resection, Chu, D. L. K., *et al.*, (*ARS*) 688–689P
——, Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils, Heine, J., *et al.* 387–392
——, Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics? Keita, H., *et al.* 254–256
——, Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation, Mallick, A., *et al.* 731–734
——, Patient-controlled sedation for cataract surgery using peribulbar block, Pac-Soo, C. K., *et al.* 370–374
——, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, Habre, W., *et al.* 739–743
——, Propofol protects rat hepatocytes against an oxidant stress, Navapurkar, V. U., *et al.*, (*ARS*) 691P
——, Psychophysical and electrophysiological responses to experimental pain may be influenced by sedation: comparison of the effects of a hypnotic (propofol) and an analgesic (alfentanil), Petersen-Felix, S., *et al.* 165–171
——, Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol, Schwender, D., *et al.* 179–184
——, Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone, Spens, H. J., *et al.* 194–199
Anaesthetics i.v., thiamylal, Thiobarbiturates suppress depolarization-induced contraction of vascular smooth muscle without suppression of calcium influx, Kitamura, R., *et al.* 503–507
Anaesthetics i.v., thiopentone, Comparative actions of propofol and thiopentone on cell membranes of isolated guineapig ventricular myocytes, Sakai, F., *et al.* 508–516
——, Comparative effects of thiopentone and propofol on respiratory resistance after tracheal intubation, Wu, R. S. C., *et al.* 735–738
——, Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils, Heine, J., *et al.* 387–392
——, Influence of induction technique on intubating conditions after rocuronium in adults: comparison with rapid-sequence induction using thiopentone and suxamethonium, Sparr, H. J., *et al.* 339–342
——, Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics? Keita, H., *et al.* 254–256
——, Nitrous oxide produces a non-linear reduction in thiopentone requirements, Katoh, T., *et al.* 265–267
——, Thiobarbiturates suppress depolarization-induced contraction of vascular smooth muscle without suppression of calcium influx, Kitamura, R., *et al.* 503–507
——, Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone, Spens, H. J., *et al.* 194–199
Anaesthetics local, Effects of local anaesthetics on carrageenan-evoked inflammatory nociceptive processing in the rat, Buritova, J., *et al.* 645–652
——, Hyaluronidase and peribulbar block, Dempsey, G. A., *et al.*, (*ARS*) 284P
——, Is the neuronal dihydropyridine binding site on L-type calcium channels a target for local anaesthetic agents? Browne, T., *et al.*, (*ARS*) 290P
Anaesthetics local, amethocaine, Acid–base state of cerebrospinal fluid during pregnancy and its effect on spread of spinal anaesthesia, Hirabayashi, Y., *et al.* 352–355
——, CSF progesterone and spread of subarachnoid anaesthesia in pregnancy, Chan, M. T. V., *et al.*, (*C*) 293
——, CSF progesterone and spread of subarachnoid anaesthesia in pregnancy, Hirabayashi, Y., (*C*) 293–294
Anaesthetics local, bupivacaine, Comparison of caudal bupivacaine and diamorphine with caudal bupivacaine alone for repair of hypospadias, Kelleher, A. A., *et al.* 586–590
——, Comparison of the effect of intrathecal and extradural fentanyl on gastric emptying in labour, Kelly, M. C., *et al.*, (*ARS*) 686P
——, Evaluation of the usefulness of intrathecal bupivacaine infusion for analgesia after hip and knee arthroplasty, Niemi, L., *et al.* 544–545
——, Extradural clonidine combined with sufantanil and 0.0625% bupivacaine for analgesia in labour, Chassard, D., *et al.* 458–462
——, Myocardial extraction of bupivacaine in anaesthetized sheep and by hearts of sheep and rats *in vitro*, Foth, H., *et al.* 257–264
——, Single bolus compared with a fractionated dose injection technique of bupivacaine for extradural Caesarean section: effect on uteroplacental and fetal haemodynamic state, Karinen, J., *et al.* 140–144
——, Spinal anaesthesia for Caesarean section: effect of Sprotte needle orientation, James, K. S., *et al.* 150–152
——, Spinal anaesthesia with 0.25% hyperbaric bupivacaine for

Caesarean section: effects of volume, Chung, C. J., *et al.* 145–149

——, Spinal anaesthesia with 0.5% hyperbaric bupivacaine in elderly patients: effect of site of injection on spread of analgesia, Veering, B. Th., *et al.* 343–346

Anaesthetics local, lignocaine, A model of the first pass passage of drugs from i.v. injection site to the heart—parameter estimates for lignocaine in the sheep, Upton, R. N. 764–772

——, Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation, Mallick, A., *et al.* 731–734

——, Potentiation of local lignocaine-induced sensory block by calcium channel blockers in rats, Iwasaki, H., *et al.* 243–247

Anaesthetics volatile, Comparative effects of halothane, isoflurane and pentobarbitone on calcium currents in identified molluscan neurones, Morris, T. J., *et al.*, (*ARS*) 696P

——, Cost of volatile anaesthetic agents, Daniel, M., (*C*) 437

——, Volatile anaesthetics and neuromuscular block, Vanlinthout, L. E. H., *et al.*, (*C*) 561–562

——, Volatile anaesthetics and neuromuscular block, Wright, P. M. C., (*C*) 561

Anaesthetics volatile, desflurane, Effect of halothane, isoflurane and desflurane on lower oesophageal sphincter tone, Chassard, D., *et al.* 781–783

——, Measurement of desflurane partial pressure in blood, Smith, M. A., *et al.*, (*ARS*) 292P

——, Potency and time course of action of rocuronium during desflurane and isoflurane anaesthesia, Kumar, N., *et al.* 488–491

Anaesthetics volatile, ether, Ether anaesthesia comes to London. December 1846, Spence, A. A., (*E*) 705–706

Anaesthetics volatile, halothane, Adequate general anaesthesia—what are we trying to achieve? Munglani, R., *et al.*, (*C*) 300–301

——, Adequate general anaesthesia—what are we trying to achieve? O'Connor, T. C., *et al.*, (*C*) 299–300

——, Comparison of the effects of halothane and isoflurane on the electroencephalogram of the horse, Johnson, C. B., *et al.*, (*ARS*) 689P

——, Dose–response curve for anaesthetics based on the Monod–Wyman–Changeux model, Iwai, T., *et al.* 517–521

——, Effect of halothane, isoflurane and desflurane on lower oesophageal sphincter tone, Chassard, D., *et al.* 781–783

——, Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients, Tiainen, P., *et al.* 744–747

——, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, Habre, W., *et al.* 739–743

——, Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology, Thomsen, C. E., *et al.* 172–178

——, Role of prostaglandins and nitric oxide on halothane-induced arteriolar dilatation in rat diaphragm, de Larminat, V., *et al.* 232–237

Anaesthetics volatile, isoflurane, Comparison of the effects of halothane and isoflurane on the electroencephalogram of the horse, Johnson, C. B., *et al.*, (*ARS*) 689P

——, Dose–response curve for anaesthetics based on the Monod–Wyman–Changeux model, Iwai, T., *et al.* 517–521

——, Effect of halothane, isoflurane and desflurane on lower oesophageal sphincter tone, Chassard, D., *et al.* 781–783

——, Fuzzy logic control of inspired volatile anaesthetic concentrations, Curatolo, M., *et al.*, (*C*) 808

——, Fuzzy logic control of inspired volatile anaesthetic concentrations, Wissing, H., *et al.*, (*C*) 807–808

——, Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients, Tiainen, P., *et al.* 744–747

——, Isoflurane for sedation in a case of congenital myasthenia gravis, McBeth, C., *et al.* 672–674

——, Isoflurane waste gas exposure during general anaesthesia: the laryngeal mask compared with tracheal intubation, Hoerauf, K. H., *et al.* 189–193

——, Modulation of recombinant invertebrate GABA$_A$ receptors by isoflurane: effects of a point mutation in the M2 domain, Edwards, M. D., *et al.*, (*ARS*) 281P

——, Potency and time course of action of rocuronium during desflurane and isoflurane anaesthesia, Kumar, N., *et al.* 488–491

——, Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology, Thomsen, C. E., *et al.* 172–178

——, Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol, Schwender, D., *et al.* 179–184

Anaesthetics volatile, sevoflurane, Atrioventricular conduction during adenosine-induced hypotension in dogs anaesthetized with sevoflurane, Ishii, R., *et al.* 393–398

——, Effect of sevoflurane anaesthesia on plasma concentrations of glutathione S-transferase, Ray, D. C., *et al.* 404–407

——, Sevoflurane, Daniel, M., (*C*) 294–295

——, Sevoflurane, Smith, I., *et al.*, (*C*) 295

——, Sevoflurane degradation to compound A in anaesthesia breathing systems, Cunningham, D. D., *et al.* 537–543

Anaesthetist, training, Cusum: a statistical method to evaluate competence in practical procedures, Hammond, E. J., *et al.*, (*C*) 562

——, Cusum: a statistical method to evaluate competence in practical procedures, Kestin, I. G., (*C*) 562

——, Use of mechanical simulator for training in applying cricoid pressure, Ashurst, N., *et al.* 468–472

Analgesia, obstetric, Comparison of the effect of intrathecal and extradural fentanyl on gastric emptying in labour, Kelly, M. C., *et al.*, (*ARS*) 686P

Analgesia, patient-controlled, Caesarean section; efficacy of morphine patient-controlled anaesthesia *vs* ketorolac infusion, Bewlay, M. A., *et al.*, (*ARS*) 687P

——, Respiratory depression following morphine and alfentanil in combination, Ramirez, J. A., *et al.*, (*ARS*) 690P

Analgesia, postoperative, Respiratory mechanics after abdominal surgery measured with continuous analysis of pressure, flow and volume signals, Nimmo, A. F., *et al.* 317–326

——, Surgical pain is followed not only by spinal sensitization but also by supraspinal antinociception, Wilder-Smith, O. H. G., *et al.*, (*e*) 566–567

Analgesia, pre-emptive, Adequate general anaesthesia—what are we trying to achieve? Munglani, R., *et al.*, (*C*) 300–301

——, Adequate general anaesthesia—what are we trying to achieve? O'Connor, T. C., *et al.*, (*C*) 299–300

——, Analgesia: dose-effect or pre-emptive effect? Mallick, A., *et al.*, (*C*) 297–298

——, Analgesia: dose-effect or pre-emptive effect? Mansfield, M. D., *et al.*, (*C*) 298

——, Effects of local anaesthetics on carrageenan-evoked inflammatory nociceptive processing in the rat, Buritova, J., *et al.* 645–652

——, Pre-emptive analgesia with NSAID—what does it achieve? Hudspith, M. J., *et al.*, (*C*) 128–129

——, Pre-emptive analgesia with NSAID—what does it achieve? Morrison, L. M. M., *et al.*, (*C*) 129

——, Surgical pain is followed not only by spinal sensitization but also by supraspinal antinociception, Wilder-Smith, O. H. G., *et al.*, (*e*) 566–567

Analgesic techniques, extradural, Thoracic extradural infusions for pain after thoracotomy: are fentanyl–bupivacaine mixtures better than fentanyl alone? Mahon, S. V., *et al.*, (*ARS*) 691P

Analgesic techniques, regional, intrathecal, Antinociception by intrathecal midazolam involves endogenous neurotransmitters acting at spinal cord delta opioid receptors, Goodchild, C. S., *et al.* 758–763

Analgesics non-opioid, aspirin, Aspirin and the bleeding time, Sonksen, J. R., *et al.*, (*ARS*) 687P

Analgesics non-opioid, diclofenac, Morphine consumption in patients receiving rectal paracetamol and diclofenac alone and in combination, Montgomery, J. E., *et al.* 445–447

Analgesics non-opioid, ketorolac, Caesarean section; efficacy of morphine patient-controlled anaesthesia *vs* ketorolac infusion, Bewlay, M. A., *et al.*, (*ARS*) 687P

Analgesics non-opioid, paracetamol, Morphine consumption in patients receiving rectal paracetamol and diclofenac alone and in combination, Montgomery, J. E., *et al.* 445–447

Analgesics non-opioid, piroxicam, Effect of combining tramadol with piroxicam for analgesia after total hip replacement, Eckersall, S., *et al.*, (*ARS*) 692P

Analgesics opioid, Antinociception by intrathecal midazolam involves endogenous neurotransmitters acting at spinal cord delta opioid receptors, Goodchild, C. S., *et al.* 758–763

——, Is glutamate release from rat cerebrocortical slices opioid receptor subtype selective? Nicol, B., *et al.*, (*ARS*) 282P

——, Molecular mechanisms of drug metabolism in the critically ill, Park, G. R. 32–49

Analgesics opioid, alfentanil, Alfentanil-mediated analgesia during propofol injection: no evidence for a peripheral action, Wrench, I. J., *et al.* 162–164

——, Influence of induction technique on intubating conditions after rocuronium in adults: comparison with rapid-sequence induction using thiopentone and suxamethonium, Sparr, H. J., *et al.* 339–342

——, Psychophysical and electrophysiological responses to experimental pain may be influenced by sedation: comparison of the effects of a hypnotic (propofol) and an analgesic (alfentanil), Petersen-Felix, S., *et al.* 165–171
——, Respiratory depression following morphine and alfentanil in combination, Ramirez, J. A., *et al.*, (*ARS*) 690P
——, Synergistic interactions between midazolam and alfentanil in isolated neonatal rat spinal cord, Feng, J., *et al.* 375–380
Analgesics opioid, diamorphine, Comparison of caudal bupivacaine and diamorphine with caudal bupivacaine alone for repair of hypospadias, Kelleher, A. A., *et al.* 586–590
Analgesics opioid, fentanyl, Adequate general anaesthesia—what are we trying to achieve? Munglani, R., *et al.*, (*C*) 300–301
——, Adequate general anaesthesia—what are we trying to achieve? O'Connor, T. C., *et al.*, (*C*) 299–300
——, Comparison of the effect of intrathecal and extradural fentanyl on gastric emptying in labour, Kelly, M. C., *et al.*, (*ARS*) 686P
——, Effects of fentanyl, nitrous oxide, or both, on baroreceptor reflex regulation in the cat, Lennander, Ö., *et al.* 399–403
——, Perioperative pharmacokinetics of transdermal fentanyl in young and elderly patients, Thompson, J. P., *et al.*, (*ARS*) 290–291P
——, Thoracic extradural infusions for pain after thoracotomy: are fentanyl–bupivacaine mixtures better than fentanyl alone? Mahon, S. V., *et al.*, (*ARS*) 691P
Analgesics opioid, morphine, Analgesia: dose-effect or pre-emptive effect? Mallick, A., *et al.*, (*C*) 297–298
——, Analgesia: dose-effect or pre-emptive effect? Mansfield, M. D., *et al.*, (*C*) 298
——, Caesarean section; efficacy of morphine patient-controlled anaesthesia *vs* ketorolac infusion, Bewlay, M. A., *et al.*, (*ARS*) 687P
——, Morphine consumption in patients receiving rectal paracetamol and diclofenac alone and in combination, Montgomery, J. E., *et al.* 445–447
Analgesics opioid, remifentanil, Effect of remifentanil on the auditory evoked response and haemodynamic changes after intubation and surgical incision, McGregor, R. R., *et al.*, (*ARS*) 688P
Analgesics opioid, sufentanil, Extradural clonidine combined with sufantanil and 0.0625% bupivacaine for analgesia in labour, Chassard, D., *et al.* 458–462
Analgesics opioid, tramadol, Effect of combining tramadol with piroxicam for analgesia after total hip replacement, Eckersall, S., *et al.*, (*ARS*) 692P
Anatomy, extradural space, Soft tissue anatomy within the vertebral canal in pregnant women, Hirabayashi, Y., *et al.* 153–156
Antagonists, enzyme, plasma cholinesterase, Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block, Naguib, M., *et al.* 424–426
Antagonists neuromuscular block, edrophonium, Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block, Naguib, M., *et al.* 424–426
——, Neuromuscular blocking action of suxamethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine, Fleming, N. W., *et al.* 492–495
Antagonists neuromuscular block, neostigmine, Dose–response relationships for neostigmine antagonism of rocuronium-induced neuromuscular block in children and adults, Abdulatif, M., *et al.* 710–715
——, Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? Baurain, M. J., *et al.* 496–499
——, Neuromuscular blocking action of suxamethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine, Fleming, N. W., *et al.* 492–495
Antagonists neuromuscular block, pyridostigmine, Neuromuscular blocking action of suxamethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine, Fleming, N. W., *et al.* 492–495
Antagonists opioid, naloxone, Effect of naloxone on nitrous oxide analgesia, Gillman, M. A., *et al.*, (*C*) 435
——, Effect of naloxone on nitrous oxide analgesia, Mashimo, T., *et al.*, (*C*) 436
Anticonvulsants, Chronic carbamazepine therapy does not influence mivacurium-induced neuromuscular block, Spacek, A., *et al.* 500–502
Arterial pressure, drug effects, Effects of rocuronium and vecuronium on intracranial pressure, mean arterial pressure and heart rate in neurosurgical patients, Schramm, W. M., *et al.* 607–611
Arterial pressure, hypotension, Time course of increased haemodilution in hypotension induced by extradural anaesthesia, Drobin, D., *et al.* 223–226
Arteries, Determinants of splanchnic blood flow, Takala, J. 50–58
Arteries, aorta, Haemodynamic and metabolic response to endovascular repair of infra-renal aortic aneurysms, Baxendale, B. R., *et al.* 581–585
Arteries, cannulation, An iatrogenic arterial foreign body, Shah, U. S., *et al.* 430–431
——, Locating an arterial foreign body by ultrasonography, Ball, D. R., *et al.*, (*C*) 811
Assessment, ASA classification, ASA classification and perioperative variables as predictors of postoperative outcome, Wolters, U., *et al.* 217–222
Asthma, Effect of anaesthesia on lung function in children with asthma, May, H. A., *et al.* 200–202
——, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, Habre, W., *et al.* 739–743
Autonomic nervous system, autoregulation, Effect of carbon dioxide on cerebral autoregulation as assessed by the transient hyperaemic response test, Cavill, G., *et al.*, (*ARS*) 685–686P

Baillière's Clinical Anaesthesiology: International Practice and Research, vol. 10, No. 1. The Lung in Anaesthesia and Intensive Care, Pearl, R. G., (*R*) 439
Blood, anticoagulants, Aspirin and the bleeding time, Sonksen, J. R., *et al.*, (*ARS*) 687P
Blood, anticoagulants, heparin, Heparinase-guided thrombelastography in an anticoagulated parturient, Abramson, D. C., *et al.* 556–558
Blood, chemotaxis, Effects of i.v. anaesthetics and lipid solutions on polymorphonuclear leucocyte chemotaxis *in vitro*, Leuwerı, M., *et al.*, (*ARS*) 695P
Blood, coagulation, Haemodilution induces a hypercoagulable state, Entholzner, E. K., *et al.*, (*C*) 809
——, Haemodilution induces a hypercoagulable state, Mardel, S. N., *et al.*, (*C*) 700–701
——, Haemodilution induces a hypercoagulable state, Ruttman, T. G., *et al.*, (*C*) 701
——, Haemodilution induces a hypercoagulable state, Ruttmann, T. G., *et al.*, (*C*) 809
——, Hypercoagulability induced by crystalloids, Farmery, A. D., *et al.*, (*C*) 132
——, Hypercoagulability induced by crystalloids, Ruttmann, T. G., *et al.*, (*C*) 132
——, Thrombelastography changes in pre-eclampsia and eclampsia, Orlikowski, C. E. P., *et al.* 157–161
Blood, flow, Determinants of splanchnic blood flow, Takala, J. 50–58
——, Disturbance of leucocyte circulation and adhesion to the endothelium as factors in circulatory pathology, Adams, D. H., *et al.* 17–31
——, Effects of dopamine on oxygen consumption and gastric mucosal blood flow during cardiopulmonary bypass in humans, Karzai, W., *et al.* 603–606
Blood, flow, feto-uteroplacental, Single bolus compared with a fractionated dose injection technique of bupivacaine for extradural Caesarean section: effect on uteroplacental and fetal haemodynamic state, Karinen, J., *et al.* 140–144
Blood, haemodilution, Time course of increased haemodilution in hypotension induced by extradural anaesthesia, Drobin, D., *et al.* 223–226
Blood, leucocytes, Disturbance of leucocyte circulation and adhesion to the endothelium as factors in circulatory pathology, Adams, D. H., *et al.* 17–31
——, Effects of i.v. anaesthetics and lipid solutions on polymorphonuclear leucocyte chemotaxis *in vitro*, Leuweri, M., *et al.*, (*ARS*) 695P
Blood, neurophils, Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils, Heine, J., *et al.* 387–392
Blood, volume, Time course of increased haemodilution in hypotension induced by extradural anaesthesia, Drobin, D., *et al.* 223–226

Children, Effect of anaesthesia on lung function in children with asthma, May, H. A., *et al.* 200–202

——, Intubating conditions and time course of rocuronium-induced neuromuscular block in children, Fuchs-Buder, T., *et al.* 335–338

——, Is it always necessary to antagonize residual neuromuscular block? Do children differ from adults? Hunter, J. M., (*E*) 707–709

——, Preoxygenation in children using expired oxygraphy, Butler, P. J., *et al.* 333–334

Clinical Anaesthesia, Aitkenhead, A. R., *et al.*, (editors), (*R*) 702

Clinical Anaesthesiology—International Practice and Research—Obstetric Anaesthesia, Bogod, D. G., (editor), (*R*) 134

Clinical Anesthesiology, Morgan, G. E. Jr, *et al.*, (*R*) 438–439

Clinical Intensive Care, Hillman, K., *et al.*, (*R*) 702

Clinical Orthopedic Anesthesia, Tetzlass, J. E., (*R*) 438

Clinical Risk Management, Vincent, C., (editor), (*R*) 564–565

Clinical Scenarios in Anaesthesia, Chambers, W. A., *et al.*, (*R*) 133

Complications, acute respiratory distress syndrome, New approaches to acute lung injury, Bigatello, L. M., *et al.* 99–109

Complications, airway obstruction, The reinforced laryngeal mask airway for dento-alveolar surgery, Quinn, A. C., *et al.* 185–188

Complications, ASA classification, ASA classification and perioperative variables as predictors of postoperative outcome, Wolters, U., *et al.* 217–222

Complications, barotrauma, New approaches to acute lung injury, Bigatello, L. M., *et al.* 99–109

Complications, bronchospasm, Comparative effects of thiopentone and propofol on respiratory resistance after tracheal intubation, Wu, R. S. C., *et al.* 735–738

Complications, cardiac arrest, Cardiac arrest after Caesarean section under subarachnoid block, Scull, T. J., *et al.* 274–276

Complications, cardiomyopathy, General anaesthesia for Caesarean section in a parturient with Noonan's syndrome, McLure, H. A., *et al.* 665–668

Complications, cerebral oedema, Fulminant and late onset hepatic failure, Gimson, A. E. S. 90–98

Complications, cholesterol crystal embolization, Severe systemic cholesterol embolization after open heart surgery, Piriou, V., *et al.* 277–280

Complications, cocaine abuse, Unrecognized "crack" cocaine abuse in pregnancy, Campbell, D., *et al.* 553–555

Complications, compartment syndrome, Bilateral compartment syndrome complicating prolonged lithotomy position, Tuckey, J. 546–549

Complications, disseminated intravascular coagulation, Hepatic rupture complicating eclampsia in pregnancy, Karadia, S., *et al.* 792–794

Complications, eclampsia, Hepatic rupture complicating eclampsia in pregnancy, Karadia, S., *et al.* 792–794

Complications, endotoxaemia, Endotoxaemia and postoperative hypermetabolism in coronary artery bypass surgery: the role of ketanserin, Oudemans-van Straaten, H. M., *et al.* 473–479

Complications, epilepsy, Effect of propofol on the electrocorticogram in patients undergoing cortical resection, Chu, D. L. K., *et al.*, (*ARS*) 688–689P

Complications, eye injury, Use of rocuronium in a pregnant patient with an open eye injury, receiving magnesium medication, for preterm labour, Gaiser, R. R., *et al.* 669–671

Complications, foreign body, An iatrogenic arterial foreign body, Shah, U. S., *et al.* 430–431

——, Locating an arterial foreign body by ultrasonography, Ball, D. R., *et al.*, (*C*) 811

Complications, hepatic, Hepatic rupture complicating eclampsia in pregnancy, Karadia, S., *et al.* 792–794

Complications, hynonatraemia, Glycine absorption and hypocalcaemia, Chassard, D., *et al.*, (*C*) 811

——, Glycine absorption and hypocalcaemia, Hahn, R. G., (*C*) 810–811

Complications, hypercapnia, Normovolaemic haemodilution attenuates cardiac depression induced by sodium bicarbonate in canine metabolic acidosis, Tanaka, M., *et al.* 408–412

Complications, hypertension, Prevention of cardiovascular response to tracheal intubation, Mallick, A., *et al.*, (*C*) 296–297

Complications, hypertrophic obstructive cardiomyopathy, Orthotopic liver transplantation in two patients with hypertrophic obstructive cardiomyopathy, Harley, I. D., *et al.* 675–677

Complications, hypocalcaemia, Calcium homeostasis during i.v. infusion of 1.5% glycine in anaesthetized pigs, Chassard, D., *et al.* 271–273

——, Glycine absorption and hypocalcaemia, Chassard, D., *et al.*, (*C*) 811

——, Glycine absorption and hypocalcaemia, Hahn, R. G., (*C*) 810–811

Complications, hyponatraemia, Calcium homeostasis during i.v. infusion of 1.5% glycine in anaesthetized pigs, Chassard, D., *et al.* 271–273

Complications, hypotension, Decreased arterial oxygenation during deliberate hypotension: a comparison of trimetaphan camsylate, sodium nitroprusside and glyceryl trinitrate, van Oldenbeek, C., *et al.*, (*ARS*) 286P

——, Hypotension during subarachnoid anaesthesia, Critchley, L. A. H., *et al.*, (*C*) 808–809

——, Hypotension during subarachnoid anaesthesia, Watters, M., (*C*) 808

Complications, infections, Determinants of intestinal barrier failure in critical illness, Aranow, J. S., *et al.* 71–81

——, The immuno-inflammatory cascade, Galley, H. F., *et al.* 11–16

——, Sepsis and cytokines: current status, Blackwell, T. S., *et al.* 110–117

Complications, jaundice, Fulminant and late onset hepatic failure, Gimson, A. E. S. 90–98

Complications, liver disease, Fulminant and late onset hepatic failure, Gimson, A. E. S. 90–98

Complications, malignant hyperthermia, Contractures of malignant hyperthermia muscle: where do halothane and caffeine act? Smith, P. D., *et al.*, (*ARS*) 283–284P

Complications, maxillofacial injuries, A modification of sub-mental intubation, Green, J. D., *et al.* 789–791

Complications, menorrhagia, Complications of hysteroscopic treatments of menorrhagia, Williamson, K. M., *et al.*, (*E*) 305–308

Complications, morbidity, Aortic stent surgery, Baranowski, A. P., *et al.*, (*C*) 699

——, Aortic stent surgery, Wildsmith, J. A. W., *et al.*, (*C*) 699

Complications, moyamoya disease, Extradural anaesthesia for Caesarean section in a patient with moyamoya disease, Ngan Kee, W. D., *et al.* 550–552

Complications, mucosal pressure, Optimal intracuff pressures with the laryngeal mask, Brimacombe, J., *et al.*, (*C*) 295–296

——, Optimal intracuff pressures with the laryngeal mask, Marjot, R. M., *et al.*, (*C*) 296

Complications, multiple organ failure, Multiple organ failure: from basic science to prevention, Bion, J., *et al.*, (*E*) 1–2

——, Splanchnic ischaemia/reperfusion and multiple organ failure, Biffl, W. L., *et al.* 59–70

——, The intensive care unit cost of surviving and dying, Bion, J., *et al.*, (*C*) 698–699

——, The intensive care unit cost of surviving and dying, Thompson, H., *et al.*, (*C*) 698

Complications, myasthenia gravis, Isoflurane for sedation in a case of congenital myasthenia gravis, McBeth, C., *et al.* 672–674

Complications, Noonan's syndrome, General anaesthesia for Caesarean section in a parturient with Noonan's syndrome, McLure, H. A., *et al.* 665–668

Complications, phaeochromocytoma, Tolerance of laparoscopy for resection of phaeochromocytoma, Mann, C., *et al.* 795–797

Complications, pneumoperitoneum, Gasless laparoscopic cholecystectomy: comparison of postoperative recovery with conventional technique, Koivusalo, A.-M., *et al.* 576–580

Complications, postoperative, ASA classification and perioperative variables as predictors of postoperative outcome, Wolters, U., *et al.* 217–222

Complications, pre-eclampsia, Thrombelastography changes in pre-eclampsia and eclampsia, Orlikowski, C. E. P., *et al.* 157–161

Complications, pulmonary hypertension, Combination of inhaled nitric oxide with i.v. nitroglycerin or with a prostacyclin analogue in the treatment of experimental pulmonary hypertension, Van Obbergh, L. J., *et al.* 227–231

Complications, regurgitation, Laryngeal mask airway is associated with reflux in the lithotomy position, McCrory, C., *et al.*, (*ARS*) 693P
——, Use of mechanical simulator for training in applying cricoid pressure, Ashurst, N., *et al.* 468–472
Complications, respiratory, Effect of an upper respiratory tract infection on upper airway reactivity, Nandwani, N., *et al.*, (*ARS*) 288P
——, Postoperative pulmonary function after laparoscopic and open cholecystectomy, Karayiannakis, A. J., *et al.* 448–452
——, Respiratory mechanics after abdominal surgery measured with continuous analysis of pressure, flow and volume signals, Nimmo, A. F., *et al.* 317–326
Complications, sepsis, Mechanisms of cell injury and death, Cobb, J. P., *et al.* 3–10
Complications, subarachnoid block, Unexpected high spinal block in obstetrics, Richardson, M. G., *et al.*, (*C*) 806–807
Complications, subclavian occlusion, A complication of intra-arterial shunting during carotid endarterectomy, Dyer, M. W., *et al.*, (*C*) 699
Complications, trauma, The care of patients and transport by air, Morley, A. P., (*C*) 435
——, The care of patients and transport by air, Shirley, P. J., (*C*) 435
Comprehensive Human Physiology from Cellular Mechanisms to Integrations, vols 1 and 2, Greger, G., *et al.*, (editors), (*R*) 563–564
Computers, Fuzzy logic control of inspired volatile anaesthetic concentrations, Curatolo, M., *et al.*, (*C*) 808
——, Fuzzy logic control of inspired volatile anaesthetic concentrations, Wissing, H., *et al.*, (*C*) 807–808
——, Fuzzy logic control of mechanical ventilation during anaesthesia, Schäublin, J., *et al.* 636–641
Computers, APACHE II, Preliminary study of prediction of ICU mortality by artificial neural network, Beatty, P. C. W., *et al.*, (*ARS*) 287–288P
Computers, neural networks, Preliminary study of prediction of ICU mortality by artificial neural network, Beatty, P. C. W., *et al.*, (*ARS*) 287–288P
Core Curriculum for Professional Education in Pain, 2nd Edn, Fields, H. L., (editor), (*R*) 703
Cough, Assessment of vocal cord function using tussometry, Caranza, R., *et al.*, (*ARS*) 290P
Critical Care of Infants and Children, Todres, I. D., *et al.*, (editors), (*R*) 564
Critical Care: Standards, Audit and Ethics, Tinker, J., *et al.*, (editors), (*R*) 563
Current Topics in Intensive Care, 3rd Edn, Dellinger, R. P., *et al.*, (editors), (*R*) 812–813

Diagnostic Testing in Emergency Medicine, Wolfson, A. B., *et al.*, (editors), (*R*) 813–814
Dog, Atrioventricular conduction during adenosine-induced hypotension in dogs anaesthetized with sevoflurane, Ishii, R., *et al.* 393–398
——, Beneficial effects of dexmedetomidine on ischaemic myocardium of anaesthetized dogs, Roekaerts, P. M. H. J., *et al.* 427–429
——, Normovolaemic haemodilution attenuates cardiac depression induced by sodium bicarbonate in canine metabolic acidosis, Tanaka, M., *et al.* 408–412
——, Pancuronium increases pulmonary arterial pressure in lung injury, Du, H., *et al.* 526–529
Drug delivery, computerized, Assessment of a model predicted infusion of ketamine used with propofol for total i.v. anaesthesia, Swinhoe, C. F., *et al.*, (*ARS*) 286–287P
——, Computer-controlled infusion of propofol for long neurosurgical procedures, Lim, T. A., *et al.*, (*ARS*) 289–290P
Drug delivery, transdermal, Perioperative pharmacokinetics of transdermal fentanyl in young and elderly patients, Thompson, J. P., *et al.*, (*ARS*) 290–291P

Embolism, air, Comparison of the effects of controlled ventilation with 100% oxygen, 50% oxygen in nitrogen, and 50% oxygen in nitrous oxide on responses to venous air embolism in pigs, Kyttä, J., *et al.* 658–661
Embolism, carbon dioxide, Is Doppler monitoring mandatory in laparoscopic surgery? d'Hollander, A. A., (*C*) 807
——, Is Doppler monitoring mandatory in laparoscopic surgery? Ferrando, A., *et al.*, (*C*) 807
Enzymes, cholinesterase, Neuromuscular blocking action of suxamethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine, Fleming, N. W., *et al.* 492–495
Enzymes, cytochrome P450, Molecular mechanisms of drug metabolism in the critically ill, Park, G. R. 32–49
Enzymes, glutathione S-transferase, Effect of sevoflurane anaesthesia on plasma concentrations of glutathione S-transferase, Ray, D. C., *et al.* 404–407
Enzymes, glutathione transferase, Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients, Tiainen, P., *et al.* 744–747
Enzymes, hyaluronidase, Hyaluronidase and peribulbar block, Dempsey, G. A., *et al.*, (*ARS*) 284P
Equipment, blankets, Convective warming after CABG, Deakin, C. D., (*C*) 298–299
——, Convective warming after CABG, Ponte, J., *et al.*, (*C*) 299
Equipment, breathing systems, Performance of vaporizers in circle systems [III], Brosnan, S., *et al.*, (*ARS*) 684P
——, Sevoflurane degradation to compound A in anaesthesia breathing systems, Cunningham, D. D., *et al.* 537–543
Equipment, catheters extradural, Influence of patient position on withdrawal forces during removal of lumbar extradural catheters, Morris, G. N., *et al.* 419–420
——, Removal of extradural catheters, Trikha, A., (*C*) 295
Equipment, exchange bougie, A fibreoptically guided exchange bougie, Atherton, D. P. L., *et al.*, (*ARS*) 288–289P
Equipment, extradural space indicators, Inflammatory changes after extradural anaesthesia may affect the spread of local anaesthetic within the extradural space, Igarashi, T., *et al.* 347–351
Equipment, fibrescopes, Use of the fibrescope–video camera system for difficult trachael intubation, Aoyama, K., *et al.* 662–664
Equipment, filters, An effective method of scavenging nitric oxide, Squire, S., *et al.* 432–434
Equipment, masks anaesthesia, Isoflurane waste gas exposure during general anaesthesia: the laryngeal mask compared with tracheal intubation, Hoerauf, K. H., *et al.* 189–193
——, Laryngeal mask airway is associated with reflux in the lithotomy position, McCrory, C., *et al.*, (*ARS*) 693P
——, Optimal intracuff pressures with the laryngeal mask, Brimacombe, J., *et al.*, (*C*) 295–296

——, Thiobarbiturates suppress depolarization-induced contraction of vascular smooth muscle without suppression of calcium influx, Kitamura, R., *et al.* 503–507

Ions, ion channels, Comparative actions of propofol and thiopentone on cell membranes of isolated guineapig ventricular myocytes, Sakai, F., *et al.* 508–516

——, Comparative effects of halothane, isoflurane and pentobarbitone on calcium currents in identified molluscan neurones, Morris, T. J., *et al.*, (*ARS*) 696P

——, I.v. anaesthetic agents inhibit dihydropyridine binding to L-type voltage-sensitive Ca^{2+} channels in rat cerebrocortical membranes, Hirota, K., *et al.* 248–253

Ions, ion channels, kinetics, I.v. anaesthetic agents do not interact with the verapamil binding site on L-type voltage-sensitive Ca^{2+} channels, Hirota, K., *et al.* 385–386

Ions, magnesium, Use of rocuronium in a pregnant patient with an open eye injury, receiving magnesium medication, for preterm labour, Gaiser, R. R., *et al.* 669–671

Ions, potassium, Comparative actions of propofol and thiopentone on cell membranes of isolated guineapig ventricular myocytes, Sakai, F., *et al.* 508–516

Key Topics in Anaesthesia, Craft, T. M., *et al.*, (*R*) 812

Kidney, blood flow, Lack of specific renal haemodynamic effects of different doses of dopamine after infrarenal aortic surgery, Girbes, A. R. J., *et al.* 753–757

——, Mechanisms of acute renal failure, Lote, C. J., *et al.* 82–89

Kidney, failure, Mechanisms of acute renal failure, Lote, C. J., *et al.* 82–89

Kidney, function, Lack of specific renal haemodynamic effects of different doses of dopamine after infrarenal aortic surgery, Girbes, A. R. J., *et al.* 753–757

Kidney, metabolism, Mechanisms of acute renal failure, Lote, C. J., *et al.* 82–89

Larynx, cricoid pressure, Use of mechanical simulator for training in applying cricoid pressure, Ashurst, N., *et al.* 468–472

Larynx, laryngoscopy, Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia, Ramadhani, S. A. L., *et al.* 312–316

——, Sternomental distance as the sole predictor of difficult laryngoscopy in obstetric anaesthesia, Ramadhani, S. A. L., *et al.*, (*e*) 701

Liver, function, Fulminant and late onset hepatic failure, Gimson, A. E. S. 90–98

——, Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients, Tiainen, P., *et al.* 744–747

Liver, hepatotoxicity, Hepatocellular integrity during and after isoflurane and halothane anaesthesia in surgical patients, Tiainen, P., *et al.* 744–747

Liver, metabolism, A model of the first pass passage of drugs from i.v. injection site to the heart—parameter estimates for lignocaine in the sheep, Upton, R. N. 764–772

——, Myocardial extraction of bupivacaine in anaesthetized sheep and by hearts of sheep and rats *in vitro*, Foth, H., *et al.* 257–264

Liver, transplantation, Hepatic rupture complicating eclampsia in pregnancy, Karadia, S., *et al.* 792–794

——, Orthotopic liver transplantation in two patients with hypertrophic obstructive cardiomyopathy, Harley, I. D., *et al.* 675–677

——, Perioperative mucosal pH$_i$ in orthotropic liver transplantation, Camprubi, I., *et al.*, (*C*) 560–561

——, Perioperative mucosal pH$_i$ in orthotropic liver transplantation, Welte, M., (*C*) 561

——, Pharmacokinetics of atracurium after paediatric orthotopic liver transplantation, Chow, B. F. M., *et al.*, (*ARS*) 687–688P

Low Flow Anaesthesia, Baum, J. A., *et al.*, (*R*) 134–135

Lung, Myocardial extraction of bupivacaine in anaesthetized sheep and by hearts of sheep and rats *in vitro*, Foth, H., *et al.* 257–264

Lung, atelectasis, Postoperative pulmonary function after laparoscopic and open cholecystectomy, Karayiannakis, A. J., *et al.* 448–452

——, Volumetric analysis of aeration in the lungs during general anaesthesia, Drummond, G. B., (*C*) 697–698

——, Volumetric analysis of aeration in the lungs during general anaesthesia, Reber, A., *et al.*, (*C*) 698

Lung, blood flow, Inhalation of a nitric oxide synthase inhibitor to a hypoxic or collapsed lung lobe in anaesthetized pigs: effects on pulmonary blood flow distribution, Fredén, F., *et al.* 413–418

Lung, cilia, Effect of theophylline and forskolin on human respiratory cilia beat frequency *in vitro*, Alexander-Williams, M., *et al.*, (*ARS*) 685P

Lung, damage, New approaches to acute lung injury, Bigatello, L. M., *et al.* 99–109

——, Pancuronium increases pulmonary arterial pressure in lung injury, Du, H., *et al.* 526–529

Lung, function, Effect of anaesthesia on lung function in children with asthma, May, H. A., *et al.* 200–202

——, Postoperative pulmonary function after laparoscopic and open cholecystectomy, Karayiannakis, A. J., *et al.* 448–452

——, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, Habre, W., *et al.* 739–743

Lung, gas exchange, Decreased arterial oxygenation during deliberate hypotension: a comparison of trimetaphan camsylate, sodium nitroprusside and glyceryl trinitrate, van Oldenbeek, C., *et al.*, (*ARS*) 286P

Lung, intravascular pressures, Pancuronium increases pulmonary arterial pressure in lung injury, Du, H., *et al.* 526–529

Lung, mechanics, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, Habre, W., *et al.* 739–743

Lung, shunting, Permissive hypercapnia and gas exchange in lungs with high $\dot{Q}s/\dot{Q}t$: a mathematical model, Joyce, C. J., *et al.* 678–683

Measurement techniques, acoustic quantification, On-line estimation of left ventricular stroke volume using transoesophageal echocardiography and acoustic quantification, Greim, C.-A., *et al.* 365–369

Measurement techniques, cardiac output, Measurement of cardiac output by transoesophageal Doppler echocardiography in anaesthetized horses: comparison with thermodilution, Young, L. E., *et al.* 773–780

Measurement techniques, electromyography, Intubating conditions and time course of rocuronium-induced neuromuscular block in children, Fuchs-Buder, T., *et al.* 335–338

Measurement techniques, flow cytometry, Flow cytometry evaluation of the *in vitro* influence of four i.v. anaesthetics on respiratory burst of neutrophils, Heine, J., *et al.* 387–392

Measurement techniques, flowmetry, Effect of hypothermia on rectal mucosal perfusion in infants undergoing cardiopulmonary bypass, Booker, P. D., *et al.* 591–596

——, Gut mucosal perfusion in neonates undergoing cardiopulmonary bypass, Booker, P. D., *et al.* 597–602

Measurement techniques, gas exchange, Measurement of desflurane partial pressure in blood, Smith, M. A., *et al.*, (*ARS*) 292P

Measurement techniques, impedance cardiography, Standardization of non-invasive impedance cardiography for assessment of stroke volume: comparison with thermodilution, Woltjer, H. H., *et al.* 748–752

Measurement techniques, magnetic resonance imaging, Soft tissue anatomy within the vertebral canal in pregnant women, Hirabayashi, Y., *et al.* 153–156

Measurement techniques, near infrared spectroscopy, CBF in adults using near infrared spectroscopy (NIRS): potential for bedside measurement? Hopton, P., *et al.*, (*C*) 131

——, CBF in adults using near infrared spectroscopy (NIRS): potential for bedside measurement? Owen-Reece, H., *et al.*, (*C*) 131

Measurement techniques, neuromuscular block, Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? Baurain, M. J., *et al.* 496–499

Measurement techniques, thermodilution, Measurement of cardiac output by transoesophageal Doppler echocardiography in anaesthetized horses: comparison with thermodilution, Young, L. E., *et al.* 773–780

——, Standardization of non-invasive impedance cardiography for assessment of stroke volume: comparison with thermodilution, Woltjer, H. H., *et al.* 748–752

Measurement techniques, thoracic impedance, Thoracic impedance used for measuring chest wall movement in postoperative patients, Drummond, G. B., *et al.* 327–332

Measurement techniques, thrombelastography, Haemodilution induces a hypercoagulable state, Entholzner, E. K., *et al.*, (*C*) 809

——, Haemodilution induces a hypercoagulable state, Mardel, S. N., *et al.*, (*C*) 700–701

——, Haemodilution induces a hypercoagulable state, Ruttman, T. G., *et al.*, (*C*) 701

——, Haemodilution induces a hypercoagulable state, Ruttmann, T. G., *et al.*, (*C*) 809
——, Heparinase-guided thrombelastography in an anticoagulated parturient, Abramson, D. C., *et al.* 556–558
——, Hypercoagulability induced by crystalloids, Farmery, A. D., *et al.*, (*C*) 132
——, Hypercoagulability induced by crystalloids, Ruttmann, T. G., *et al.*, (*C*) 132
——, Thrombelastography changes in pre-eclampsia and eclampsia, Orlikowski, C. E. P., *et al.* 157–161
Measurement techniques, tomography, Volumetric analysis of aeration in the lungs during general anaesthesia, Drummond, G. B., (*C*) 697–698
——, Volumetric analysis of aeration in the lungs during general anaesthesia, Reber, A., *et al.*, (*C*) 698
Measurement techniques, tonometry, Gut mucosal perfusion in neonates undergoing cardiopulmonary bypass, Booker, P. D., *et al.* 597–602
Measurement techniques, transoesophageal echocardiography, Measurement of cardiac output by transoesophageal Doppler echocardiography in anaesthetized horses: comparison with thermodilution, Young, L. E., *et al.* 773–780
——, Transoesophageal echocardiography in anaesthesia and intensive care, Townend, J. N., *et al.*, (*E*) 137–139
Measurement techniques, tussometry, Assessment of vocal cord function using tussometry, Caranza, R., *et al.*, (*ARS*) 290P
Memory, Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology, Thomsen, C. E., *et al.* 172–178
——, Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol, Schwender, D., *et al.* 179–184
Metabolism, drug, Molecular mechanisms of drug metabolism in the critically ill, Park, G. R. 32–49
Metabolism, lactate, Haemodynamic and metabolic response to endovascular repair of infra-renal aortic aneurysms, Baxendale, B. R., *et al.* 581–585
Metabolism, lipid, Effects of i.v. anaesthetics and lipid solutions on polymorphonuclear leucocyte chemotaxis *in vitro*, Leuweri, M., *et al.*, (*ARS*) 695P
Metabolism, oxygen consumption, Endotoxaemia and postoperative hypermetabolism in coronary artery bypass surgery: the role of ketanserin, Oudemans-van Straaten, H. M., *et al.* 473–479
Model, cat, Effects of fentanyl, nitrous oxide, or both, on baroreceptor reflex regulation in the cat, Lennander, Ö., *et al.* 399–403
Model, cell culture, Interaction of vecuronium with recombinant human m2 muscarinic receptors, Cembala, T. M., *et al.*, (*ARS*) 291–292P
Model, computer simulation, Fuzzy logic control of inspired volatile anaesthetic concentrations, Curatolo, M., *et al.*, (*C*) 808
——, Fuzzy logic control of inspired volatile anaesthetic concentrations, Wissing, H., *et al.*, (*C*) 807–808
——, Fuzzy logic control of mechanical ventilation during anaesthesia, Schäublin, J., *et al.* 636–641
Model, lung, Effect of theophylline and forskolin on human respiratory cilia beat frequency *in vitro*, Alexander-Williams, M., *et al.*, (*ARS*) 685P
Model, mathematical, Dose–response curve for anaesthetics based on the Monod–Wyman–Changeux model, Iwai, T., *et al.* 517–521
——, Permissive hypercapnia and gas exchange in lungs with high $\dot{Q}s/\dot{Q}t$: a mathematical model, Joyce, C. J., *et al.* 678–683
——, Standardization of non-invasive impedance cardiography for assessment of stroke volume: comparison with thermodilution, Woltjer, H. H., *et al.* 748–752
Model, mollusc, Comparative effects of halothane, isoflurane and pentobarbitone on calcium currents in identified molluscan neurones, Morris, T. J., *et al.*, (*ARS*) 696P
Model, mouse, Ketamine inhibits nitric oxide production in mouse-activated macrophage-like cells, Shimaoka, M., *et al.* 238–242
Model, rat, I.v. anaesthetic agents do not interact with the verapamil binding site on L-type voltage-sensitive Ca^{2+} channels, Hirota, K., *et al.* 385–386
——, I.v. anaesthetic agents inhibit dihydropyridine binding to L-type voltage-sensitive Ca^{2+} channels in rat cerebrocortical membranes, Hirota, K., *et al.* 248–253
——, Myocardial extraction of bupivacaine in anaesthetized sheep and by hearts of sheep and rats *in vitro*, Foth, H., *et al.* 257–264
Model, simulation, Use of mechanical simulator for training in applying cricoid pressure, Ashurst, N., *et al.* 468–472
Model, ventilatory mechanics, Fuzzy logic control of mechanical ventilation during anaesthesia, Schäublin, J., *et al.* 636–641
Monitoring, arterial pressure, An iatrogenic arterial foreign body, Shah, U. S., *et al.* 430–431
——, Locating an arterial foreign body by ultrasonography, Ball, D. R., *et al.*, (*C*) 811
Monitoring, echocardiography, On-line estimation of left ventricular stroke volume using transoesophageal echocardiography and acoustic quantification, Greim, C.-A., *et al.* 365–369
——, Orthotopic liver transplantation in two patients with hypertrophic obstructive cardiomyopathy, Harley, I. D., *et al.* 675–677
——, Transoesophageal echocardiography in anaesthesia and intensive care, George, S. J., (*C*) 700
Monitoring, electrocardiography, Atrioventricular conduction during adenosine-induced hypotension in dogs anaesthetized with sevoflurane, Ishii, R., *et al.* 393–398
Monitoring, electroencephalography, Comparison of the effects of halothane and isoflurane on the electroencephalogram of the horse, Johnson, C. B., *et al.*, (*ARS*) 689P
——, Concentration-related effects of propofol on the auditory evoked response, Tooley, M. A., *et al.* 720–726
——, Quantitative EEG in assessment of anaesthetic depth: comparative study of methodology, Thomsen, C. E., *et al.* 172–178
——, Spectral edge frequency of the electroencephalogram to monitor "depth" of anaesthesia with isoflurane or propofol, Schwender, D., *et al.* 179–184
——, Topographic distribution of the bispectral index, Hall, J. D., *et al.*, (*ARS*) 689–690P
Monitoring, evoked potentials, Concentration-related effects of propofol on the auditory evoked response, Tooley, M. A., *et al.* 720–726
——, Midlatency auditory evoked potentials as indicators of perceptual processing during general anaesthesia, de Beer, N. A. M., *et al.* 617–624
——, Visual evoked potentials and nitrous oxide-induced neuronal depression: role for benzodiazepine receptors, Dzoljic, M., *et al.* 522–525
Monitoring, neuromuscular function, Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block, Naguib, M., *et al.* 424–426
Monitoring, oxygen, Influence of motivation of care providers on the incidence of postoperative hypoxaemia in the recovery room, Rheineck-Leyssius, A. T., *et al.* 453–457
——, Preoxygenation in children using expired oxygraphy, Butler, P. J., *et al.* 333–334
Monitoring, pH oesophageal, Perioperative mucosal pH_i in orthotropic liver transplantation, Camprubi, I., *et al.*, (*C*) 560–561
——, Perioperative mucosal pH_i in orthotropic liver transplantation, Welte, M., (*C*) 561
Monitoring, spirometry, Effect of anaesthesia on lung function in children with asthma, May, H. A., *et al.* 200–202
Monitoring, stroke volume, Standardization of non-invasive impedance cardiography for assessment of stroke volume: comparison with thermodilution, Woltjer, H. H., *et al.* 748–752
Monitoring, temperature, Convective warming after CABG, Deakin, C. D., (*C*) 298–299
——, Convective warming after CABG, Ponte, J., *et al.*, (*C*) 299
——, Evaluation of two warming systems after cardiopulmonary bypass, Janke, E. L., *et al.* 268–270
Mouse, Ketamine inhibits nitric oxide production in mouse-activated macrophage-like cells, Shimaoka, M., *et al.* 238–242
Muscle respiratory, Respiratory mechanics after abdominal surgery measured with continuous analysis of pressure, flow and volume signals, Nimmo, A. F., *et al.* 317–326
——, Role of prostaglandins and nitric oxide on halothane-induced arteriolar dilatation in rat diaphragm, de Larminat, V., *et al.* 232–237
Muscle skeletal, Contractures of malignant hyperthermia muscle: where do halothane and caffeine act? Smith, P. D., *et al.*, (*ARS*) 283–284P
Muscle skeletal, diaphragm, Comparison of the effects of mivacurium on the diaphragm and geniohyoid muscles, d'Honneur, G., *et al.* 716–719
——, Effects of 5-hydroxytryptamine on the partially curarized rat phrenic nerve diaphragm preparation, Hindle, A. T., *et al.*, (*ARS*) 694P
Muscle skeletal, geniohyoid, Comparison of the effects of

mivacurium on the diaphragm and geniohyoid muscles, d'Honneur, G., *et al.* 716–719

Muscle skeletal, wasting, Nutrition and immunonutrition, O'Leary, M. J., *et al.* 118–127

Muscle vascular, responses, Thiobarbiturates suppress depolarization-induced contraction of vascular smooth muscle without suppression of calcium influx, Kitamura, R., *et al.* 503–507

Nausea, postoperative, An explanatory model for postoperative vomiting after gynaecological surgery, Sabrine, A., *et al.*, (*ARS*) 693P

Neonate, Gut mucosal perfusion in neonates undergoing cardiopulmonary bypass, Booker, P. D., *et al.* 597–602

Nerve, neurotransmitters, Is inhibition of dopamine uptake relevant to the hypnotic action of i.v. anaesthetics? Keita, H., *et al.* 254–256

Nerve, stimulation, Randomization is important in studies with pain outcomes: systematic review of transcutaneous electrical nerve stimulation in acute postoperative pain, Carroll, D., *et al.* 798–803

Nerve, tissue, S-100 concentrations during hypothermic and normothermic cardiopulmonary bypass, Harris, D., *et al.*, (*ARS*) 695–696P

Neuromuscular block, antagonism, Is it always necessary to antagonize residual neuromuscular block? Do children differ from adults? Hunter, J. M., (*E*) 707–709

Neuromuscular block, atracurium, Interactions between suxamethonium and mivacurium or atracurium, Kim, K. S., *et al.* 612–616

——, Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? Baurain, M. J., *et al.* 496–499

——, Pharmacokinetics of atracurium after paediatric orthotopic liver transplantation, Chow, B. F. M., *et al.*, (*ARS*) 687–688P

Neuromuscular block, measurement of response, Chronic carbamazepine therapy does not influence mivacurium-induced neuromuscular block, Spacek, A., *et al.* 500–502

——, Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block, Naguib, M., *et al.* 424–426

——, Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? Baurain, M. J., *et al.* 496–499

——, Onset of neuromuscular block at the larynx using video imaging, Girling, K. J., *et al.*, (*ARS*) 283P

——, Potency and time course of action of rocuronium during desflurane and isoflurane anaesthesia, Kumar, N., *et al.* 488–491

Neuromuscular block, mivacurium, Chronic carbamazepine therapy does not influence mivacurium-induced neuromuscular block, Spacek, A., *et al.* 500–502

——, Comparison of the effects of mivacurium on the diaphragm and geniohyoid muscles, d'Honneur, G., *et al.* 716–719

——, Edrophonium and human plasma cholinesterase combination for antagonism of mivacurium-induced neuromuscular block, Naguib, M., *et al.* 424–426

——, Effects of oral antihistamine premedication on mivacurium-induced histamine release and side effects, Doenicke, A., *et al.* 421–423

——, Interactions between suxamethonium and mivacurium or atracurium, Kim, K. S., *et al.* 612–616

Neuromuscular block, Org 9487, Pharmacodynamics of Org 9487: onset and recovery characteristics of single and three incremental bolus doses, Mills, K. G., *et al.*, (*ARS*) 684–685P

Neuromuscular block, pancuronium, Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? Baurain, M. J., *et al.* 496–499

——, Pancuronium increases pulmonary arterial pressure in lung injury, Du, H., *et al.* 526–529

Neuromuscular block, rocuronium, Dose–response relationships for neostigmine antagonism of rocuronium-induced neuromuscular block in children and adults, Abdulatif, M., *et al.* 710–715

——, Effects of rocuronium and vecuronium on intracranial pressure, mean arterial pressure and heart rate in neurosurgical patients, Schramm, W. M., *et al.* 607–611

——, Influence of induction technique on intubating conditions after rocuronium in adults: comparison with rapid-sequence induction using thiopentone and suxamethonium, Sparr, H. J., *et al.* 339–342

——, Intubating conditions and time course of rocuronium-induced neuromuscular block in children, Fuchs-Buder, T., *et al.* 335–338

——, Effects of alpha$_2$-adrenoceptor agonists on gastric emptying and gastrointestinal transit in the rat, Asai, T., *et al.*, (*ARS*) 686P
Sympathetic nervous system, catecholamines, Influence of different volume therapy regimens on regulators of the circulation in the critically ill, Boldt, J., *et al.* 480–487
Sympathetic nervous system, dexmedetomidine, Beneficial effects of dexmedetomidine on ischaemic myocardium of anaesthetized dogs, Roekaerts, P. M. H. J., *et al.* 427–429
Sympathetic nervous system, metaraminol, Hypotension during subarachnoid anaesthesia, Critchley, L. A. H., *et al.*, (*C*) 808–809
——, Hypotension during subarachnoid anaesthesia, Watters, M., (*C*) 808

Teetotal, Tea-total, Manners, J. M., (*C*) 297
Temperature, body, Convective warming after CABG, Deakin, C. D., (*C*) 298–299
——, Convective warming after CABG, Ponte, J., *et al.*, (*C*) 299
——, Efficacy of intraoperative heat administration by ventilation with warm humidified gases and an oesophageal warming system, Beck, E., *et al.* 530–533
Temperature, effects, Efficacy of intraoperative heat administration by ventilation with warm humidified gases and an oesophageal warming system, Beck, E., *et al.* 530–533
Temperature, monitoring, Convective warming after CABG, Deakin, C. D., (*C*) 298–299
——, Convective warming after CABG, Ponte, J., *et al.*, (*C*) 299
——, Efficacy of intraoperative heat administration by ventilation with warm humidified gases and an oesophageal warming system, Beck, E., *et al.* 530–533
——, Evaluation of two warming systems after cardiopulmonary bypass, Janke, E. L., *et al.* 268–270
——, Use of a pneumatic tourniquet induces changes in central temperature, Estebe, J.-P., *et al.* 786–788
The Anaesthesia Viva: vol. 1, Urquhart, J., *et al.*, (*R*) 813
The Cambridge Dictionary of Statistics in the Medical Sciences, Everitt, B. S., (*R*) 133–134
The Massachusetts General Hospital Hand Book of Pain Management, Borsook, D., *et al.*, (editors), (*R*) 134
The Pocket Companion to the Textbook of Critical Care Medicine, Shoemaker, W. C., *et al.*, (*R*) 812
Total Burn Care, Herndon, D. N., (editor), (*R*) 135
Toxicity, hepatic, Effect of sevoflurane anaesthesia on plasma concentrations of glutathione S-transferase, Ray, D. C., *et al.* 404–407

Uterus, activity, Normal saline i.v. fluid load decreases uterine activity in active labour, Cheek, T. G., *et al.* 632–635

Ventilation, apnoea, Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone, Spens, H. J., *et al.* 194–199
Ventilation, artificial, Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation, Mallick, A., *et al.* 731–734

Ventilation, effects, Ventilatory effects of eltanolone during induction of anaesthesia: comparison with propofol and thiopentone, SPENS, H. J., *et al.* 194–199

Ventilation, hypoventilation, Permissive hypercapnia and gas exchange in lungs with high $\dot{Q}s/\dot{Q}t$: a mathematical model, JOYCE, C. J., *et al.* 678–683

Ventilation, mechanical, Comparison of the effects of controlled ventilation with 100% oxygen, 50% oxygen in nitrogen, and 50% oxygen in nitrous oxide on responses to venous air embolism in pigs, KYTTÄ, J., *et al.* 658–661

——, Fuzzy logic control of mechanical ventilation during anaesthesia, SCHÄUBLIN, J., *et al.* 636–641

——, Volumetric analysis of aeration in the lungs during general anaesthesia, DRUMMOND, G. B., (*C*) 697–698

——, Volumetric analysis of aeration in the lungs during general anaesthesia, REBER, A., *et al.*, (*C*) 698

Ventilation, mechanics, Propofol or halothane anaesthesia for children with asthma: effects on respiratory mechanics, HABRE, W., *et al.* 739–743

Ventilation, one-lung, Inhalation of a nitric oxide synthase inhibitor to a hypoxic or collapsed lung lobe in anaesthetized pigs: effects on pulmonary blood flow distribution, FREDÉN, F., *et al.* 413–418

Ventilation, postoperative, Thoracic impedance used for measuring chest wall movement in postoperative patients, DRUMMOND, G. B., *et al.* 327–332

Ventilation, rib cage, Thoracic impedance used for measuring chest wall movement in postoperative patients, DRUMMOND, G. B., *et al.* 327–332

Vomiting, An explanatory model for postoperative vomiting after gynaecological surgery, SABRINE, A., *et al.*, (*ARS*) 693P

Vomiting, incidence, Nausea and vomiting after cardiac surgery, GREBENIK, C. R., *et al.* 356–359

Vomiting, nausea, Antiemetic effect of subhypnotic doses of propofol after thyroidectomy, EWALENKO, P., *et al.* 463–467

——, Nausea and vomiting after cardiac surgery, GREBENIK, C. R., *et al.* 356–359

Vomiting, nausea, anaesthetic factors, Antiemetic effect of subhypnotic doses of propofol after thyroidectomy, EWALENKO, P., *et al.* 463–467

Vomiting, nausea, surgical factors, Nausea and vomiting after cardiac surgery, GREBENIK, C. R., *et al.* 356–359
